THE PERIODS OF THE CHEMICAL ELEMENTS	xvii
PERIODIC SYSTEM OF THE ELEMENTS IN GROUPS AND SERIES	xviii
INTRODUCTION.	1

The province of chemistry—The study of nature—Chemical transformations—The indestructibility of matter—Examples illustrating the indestructibility of matter—The most usual chemical apparatus—The limits of chemical transformation—The hypothesis of phlogiston—Lavoisier's experiments and deductions—Simple bodies—Metals and non-metals—The elements—Chemical affinity—The conservation of energy—Chemical equilibria—The conditions of reaction—Dissociation—Contact phenomena.

CHAPTER

I.	ON WATER AND ITS COMPOUNDS	40
----	--------------------------------------	----

Occurrence of water—Moisture of air and other gases—The law of vapour pressure—Atmospheric and river water—Bacteriological research—Spring water—Sea water—The hardness of water—Distilled water—The properties of water—The metric system of weights and measures—The vapour pressure of steam—Hygroscopic water—Solutions—Diffusion of solutions—Crystalloids and colloids—Dialysis—Osmotic pressure—Coefficient of solubility—Bunsen's absorptiometer—Heat of solution—Freezing mixtures—Solubility of gases—The law of Henry—Dalton—Kinetic theory of gases—Law of partial pressures—Solubility of solids—Separation of ice from solutions—

Depression—Separation of crystals of bodies dissolved—Water of crystallisation — Supersaturated solutions — Emulsions—Cryohydrates—Definite solutions—Fuming acids—Crystallohydrates—Hydrates.

II. THE COMPOSITION OF WATER; HYDROGEN 110

Synthesis of water—Analysis of water—Dissociation of water—Preparation of hydrogen—The law of maximum work—Collection of gases—Properties of Hydrogen—Laws of Boyle-Mariotte and Gay-Lussac—Discrepancies in them—Permanent gases—Absolute boiling-point—Critical state—Liquefaction of gases—Liquefaction of hydrogen—Equation of state—Occlusion—Reactions of hydrogen—Hydrogen flame—Reduction—Composition of water.

III. OXYGEN AND THE CHIEF ASPECTS OF ITS SALINE COMBINATIONS 150

The occurrence of hydrogen—Respiration—Preparation of hydrogen—Atmolysis—Properties of oxygen—Combustion—Eudiometer—Temperature of combustion of detonating gas—The velocity of propagation of explosions—Calorimeters—Thermochemistry—Combustion of detonating gas—The flame—Oxidation—Oxides—Acids—Reaction with litmus—Indicators—Alkalies—Neutralisation—Salts—Electrolysis of salts—Double decomposition—Forms of salts—Equivalents—Dualism—The electrochemical doctrine—The hydrogen theory of acids—The unitary theory—Salts in nature.

IV. OZONE AND HYDROGEN PEROXIDE—DALTON'S LAW 197

Formation of ozone—The silent discharge—Ozonisers—Properties of ozone—Ozonometric test paper—Isomerism—Liquefaction of ozone—Ozone in nature—Peroxide of hydrogen—Its action on chromic acid—Properties of peroxide of hydrogen—Hydroxyl—Law of multiple proportions—The atomic theory—The doctrines of Democritus and Boscovitch—The particle or molecule—The vortex hypothesis—The lunar atmosphere in its bearing on the atomic theory—The law of combining weights.

V. NITROGEN AND AIR 224

Occurrence of nitrogen—Preparation of nitrogen—Properties of nitrogen—Combustion of nitrogen—Ammonia—Assimilated nitrogen—Atmospheric air—Analysis of air—Composition of air—Weight of cubic measure of air—Gravity—Conception of weight and mass—Liquefaction of air—Linde's apparatus—

CHAPTER

PAGE

Properties of liquid air and its uses—Argon—Its preparation and properties—The analogues of argon—Helium, neon, krypton, and xenon—Other components of air—Atmospheric dust—The part played by the different components of air—Variations in the air's composition—Ventilation—Disinfection.

VI. THE COMPOUNDS OF NITROGEN WITH HYDROGEN AND OXYGEN 262

Ammonia—Nessler's reagent—Preparation of ammonia—Sal-ammoniac—Properties of ammonia and its liquefaction—Carré's ice machine—Combustion of ammonia—Spirits of hartshorn—Alkaline property of ammonia and its salts—Ammonium—Sodium ammonium—Ammonium amalgam—Its compounds with salts—Law of substitution—Uses of ammonia—Hydroxylamine—Hydrazine—Pernitric acid—Transformation of nitric acid into ammonia and conversely—Hydrazoic acid—Oxides of nitrogen—Nitric acid—Displacement of acids by acids—Nitrates—Ammonium nitrate—Nitro-compounds—Oxidation by nitric acid—Nitric anhydride—Nitrogen peroxide and nitrogen dioxide—Nitrous anhydride and acid—Nitric oxide—Action of nitric oxide on sulphurous anhydride—Manufacture of sulphuric acid in lead chambers—Nitrous oxide—Hyponitrous acid—Natterer's apparatus.

VII. MOLECULES AND ATOMS. THE LAWS OF GAY-LUSSAC AND AVOGADRO-GERHARDT 319

Volumes of gases in reaction—Methods of determining the vapour density—First law of Gay-Lussac—Second law of Gay-Lussac—Reactions of combination, decomposition, and substitution—Law of Avogadro-Gerhardt—Normal vapour densities—Abnormal vapour densities and their cause—Molecules and atoms—General formula for gases—*Vis viva* of the molecules of gases and vapours—Velocity of sound in gases—Latent heat of evaporation of molecular quantities—The influence of the molecular weight on the properties of solutions—Osmotic pressure—The cryoscopic method (Raoult) for determining the molecular weight—The dependence of the boiling-point of solutions on the molecular weight—The weight of the molecule in a liquid state—The hypothesis of electrolytic dissociation—The coefficient of refraction and the molecular weight.

VIII. CARBON AND THE HYDROCARBONS 362

Occurrence of carbon—Wood—Dry distillation—Smoke—Charcoal—Humus, peat, brown coal—Coal—Anthracite—Coke—Soot—Properties of charcoal—Absorption by charcoal—Carbides

—Graphite and the diamond—The electric furnace—Hydrocarbons—The viscosity of liquids—The law of even numbers and the law of limits—The heat of combustion of various substances—Marsh gas—Illuminating gas—The blowpipe—Davy's lamp—The application of the law of substitutions to express the composition of the hydrocarbons—Isomerism of the hydrocarbons—Ethylene—Acetylene—Naphtha—Its formation.

IX. COMPOUNDS OF CARBON WITH OXYGEN AND NITROGEN . . . 404

Carbonic anhydride—The respiration of animals—The preparation of carbonic acid gas—Liquid and solid carbonic anhydride—Acidity—The basicity of acids—Measure of affinity between acids and bases—Carbonates—Dissociation of carbonic anhydride—Percarbonic acid—Organic acids—Carboxyl—Carbon monoxide—Generator gas—Water gas—Properties of carbon monoxide—Cyanides and nitriles—Cyanogen—Acid and neutral ammonium carbonates—Carbonic acid—Urea—Cyanic acid—Hydrocyanic acid and its salts—Paracyanogen.

X. SODIUM CHLORIDE — BERTHOLLET'S LAWS — HYDROCHLORIC ACID 440

Organogens—The atomicity of the elements—Forms of combination—Sodium chloride—Its extraction from sea water—Rock salt—Precipitated salt—Graduators—Crystals of salt—Solutions of salt—Double decompositions of salt—Action of sulphuric acid on salt—Berthollet's doctrine—The influence of mass—The limit of double decomposition—Reactions of acids and bases—Gustavson's researches—Hydrochloric acid—Manufacture and absorption of hydrochloric acid—Properties of hydrochloric acid—Its solutions—The chlorides—Sal-ammoniac.

XI. THE HALOGENS : CHLORINE, BROMINE, IODINE, AND FLUORINE 480

The preparation of chlorine—Properties of chlorine—Photochemistry—Aqua regia—Chloranhydrides—Bleaching—Metalepsis—Chloroform—Chloride of carbon—Chloride of nitrogen—Bleaching powder—Oxide of chlorine—Chlorous acid—Hypochlorous acid and potassium chlorate—Dioxide of chlorine—Chloric acid—The general properties of the halogens—Fluorine—Fluoride of carbon—Hydrofluoric acid—Engraving on glass—Bromine—Iodine—Dissociation of hydriodic acid—Hydrobromic and hydriodic acids—Nitrogen iodide—Hypoiodic acid—Iodoso-compounds—Hypobromous acid—Iodic acid—Mono- and tri-chlorides of iodine.

CHAPTER

PAGE

XII. SODIUM 531

Sodium sulphate—Its solutions—The acid sulphate and pyrosulphate of sodium—Soda—Lixiviation—Leblanc's process—The ammonia process—Bicarbonate of sodium—Caustic soda—Soap—Reactions of caustic soda—Metallic sodium—Sodium amalgams—Sodium carbide—Sodium hydride—Sodium amide—Suboxide and peroxide of sodium—Sodium ethyl.

XIII. POTASSIUM, RUBIDIUM, CÆSIUM, AND LITHIUM. SPECTRUM ANALYSIS 561

Occurrence of potassium—The absorptive power of soils—Potash—Sulphate of potassium—Potassium bromide and iodide—Caustic potash—Cyanide of potassium—Nitre—Chili nitre—Gunpowder—Metallic potassium—Alloys of $K + Na$ —The coloration of flame—Spectrum analysis—Absorption spectra—Wave-lengths of spectra of the elements—Kirchhoff's law—Star spectra—Spectra of compounds—The spectrum is determined by the molecules—Lithium—Rubidium and cæsium—The metals of the alkalies.

XIV. THE VALENCY AND SPECIFIC HEAT OF THE METALS. MAGNESIUM, CALCIUM, STRONTIUM, BARIUM, AND BERYLLIUM 598

The equivalents of the metals—Law of Dulong and Petit—The variation of the specific heat with the temperature—The specific heats of gases, liquids, and solids—The relation of the two specific heats of gases—Magnesium and calcium—Their occurrence—Metallic magnesium—Magnesia—Double salts of ammonia and magnesium—Diffusion of the double salts—Magnesium sulphate—Basic salts of magnesium—Magnesium chloride—Metallic calcium—Lime—Cement—Peroxide of calcium—Dissociation of calcium carbonate—Gypsum—Calcium chloride—Barium and strontium and their salts—Oxide of barium and caustic baryta—Peroxide of barium—Metallic barium and strontium—Beryllium—Metallic beryllium—The nitrides and hydrides of the metals of the alkaline earths—Their carbides.

CONTENTS

OF

THE SECOND VOLUME

CHAPTER		PAGE
XV.	THE GROUPING OF THE ELEMENTS AND THE PERIODIC LAW	1
	Isomorphism—Solid solutions—Isomorphous mixtures—The relation between the compositions of isomorphous bodies—Haüy's law—Homeomorphism—Hemimorphism, paramorphism—Morphotropy—The small number of simple forms of combination—The forms or compositions of the saline oxides—Suboxides—Peroxides—Limiting forms—The periodic dependence of the compositions or forms of combination of the elements on their atomic weights—Large and small periods—The zero group—Various modes of expressing periodic dependence—The correspondence between the elements and complex carbon radicles—The periodicity of the oxygen, hydrogen, and metallo-organic compounds of the elements—The positions of the elements in groups and series—The prediction of the properties of unknown elements—Its confirmation by the discovery of gallium and germanium—The employment of the periodic law to determine the atomic weights of the elements—The atomic weights do not merge into each other—The properties of the elements are functions of their mass—Chemical properties—The distribution of the elements in nature—The melting-point—Thermochemical properties—Alloys—Atomic volumes—Specific volumes—Apparent digressions from the periodic law—Tables expressing the periodic law.	
XVI.	ZINC, CADMIUM, AND MERCURY	48
	Zinc sulphates, oxide of zinc—Chloride of zinc—Oxychloride of zinc—Metallic zinc—Action of acids on zinc—Zinc dust—Cadmium—Its salts—Mercury—Ores of mercury—Purification of mercury—Compounds of mercury—Oxides of mercury—Calomel—Corrosive sublimate—Basic salts of mercury—Diiodide and cyanide of mercury—Nitride of mercury—Amalgams—Eka-cadmium.	
XVII.	BORON, ALUMINIUM, AND THE ANALOGOUS METALS OF THE THIRD GROUP	70
	Boron—Boric anhydride—Borax—The sublimation of boric anhydride with water—Boric acid and its salts—Boron in a free state—Nitride of boron—Fluoride of boron—Hydrofluoboric acid—Phosphide of boron—Chloride of boron—Aluminium—Clay—Kaolin—Levigation—Soils—Alumina—Hydrogel and	

hydrosol of alumina—Alumina glazes—Vapour density of chloride of aluminium—Aluminium sulphate and alums—Aluminium chloride—Aluminium fluoride—Ultramarine—Metallic aluminium—Aluminium bronze—Carbide of aluminium—Magnalium—Gallium—Indium—Thallium—The elements of the rare earths (by Professor Brauner)—The discovery of the rare earths—Their occurrence in nature—The atomic composition of the rare earths—Characteristic properties and reactions—Methods for distinguishing the rare earths from each other: 1. The method of determining the atomic weights; 2. Emission spectra; 3. Absorption spectra; 4. Lecoq de Boisbaudran's spectroscopic method; 5. Phosphorescent and cathodic spectra; 6. Emission spectra of the incandescent earths—The treatment of the minerals for obtaining the rare earths—Modes of separating the rare earths—The separation of cerium—The separation of the other rare earths of the type RX_3 from each other—Scandium—Yttrium—Lanthanum—Cerium—Praseodymium—Neodymium—Samarium—Europium—Gadolinium—Terbium—Erbium—Holmium—Thulium—Dysprosium and ytterbium—The technical uses of the rare earths and their position in the periodic system of the elements.

XVIII. SILICON AND THE OTHER ELEMENTS OF THE FOURTH GROUP 125

The polymerism of silica—Free silicon—Silicates—Silicon hydride—Silicon chloroform—Silicon chloride—Silico-oxalic acid—Silicon ether—Silicon bromide and iodide—Silicon fluoride—Hydrofluosilicic acid—Carborundum—Hydrates of silica—Silica—Soluble glass—Soluble silica—Graham's researches—Silicates—Orthoclase—Zeolites—Portland cement—Glass—Germanium—Tin—Tin alloys—Compounds of tin—Oxides of tin—Stannic and metastannic acids—Chloride of tin—Fluoride and bisulphide of tin—Alkaline compounds of oxide of tin—Perstannic oxide—Lead—Sugar of lead—Oxide of lead—Salts of lead—White lead—Massicot—Potassium plumbate—Dioxide of lead—Tetrachloride of lead—Titanium and its compounds—Zirconium—Thorium.

XIX. PHOSPHORUS AND OTHER ELEMENTS OF THE FIFTH GROUP . 175

Occurrence of phosphorus—Manufacture of phosphorus—Yellow phosphorus—Red phosphorus—Thermochemical data—Matches—Metallic phosphorus—Phosphides—Compounds of phosphorus and hydrogen—Phosphoric anhydride—Phosphorous anhydride—Hypophosphorous acid—Orthophosphoric acid and its salts—Suboxides of phosphorus—Pyrophosphoric and metaphosphoric acids—Phosphorous acid—The halogen anhydrides of phosphorus—Phosgene—Method of preparing acid chloranhydrides—Amide and nitrile compounds of phosphorus—Arsenic—Oxychloride of arsenic—The halogen compounds of arsenic—Arsenious acid—Arsenic anhydride—Arseniuretted hydrogen—Marsh's apparatus—Arsenious anhydride and its compounds—Antimony—Oxide of antimony—

CHAPTER

PAGE

Metantimonic acid—Antimoniuretted hydrogen and the halogen compounds of antimony—Bismuth—Pentoxide of bismuth and pyrobismuthic acid—Oxide of bismuth and its salts—Alloys—Vanadium—Niobium—Tantalum—Oxychloride of vanadium—Vanadic anhydride—Niobium and tantalum and their compounds.

XX. SULPHUR, SELENIUM, AND TELLURIUM 227

Occurrence of sulphur—Flowers of sulphur and bar sulphur—Varieties of sulphur—The molecule of sulphur—Sulphuretted hydrogen—Properties of sulphuretted hydrogen—Sulphides—Sulphides of phosphorus—Polysulphides of hydrogen—Sulphurous oxide—Sulphites—Hydrosulphurous acid—Nitrosulphates—Sulphonitrites—Chamber crystals—Nitrosulphuric acid—Hyposulphurous acid and hyposulphites—Sulphuric anhydride—Fuming sulphuric acid and pyrosulphuric acid—Pyrosulphuryl chloride—Sulphuric acid—Contact method of manufacturing sulphuric acid—Hydrates of sulphuric acid—Freezing-points of solutions of sulphuric acid—Specific gravities of solutions of sulphuric acid—Sulphates—Sulphoacids—Peroxide of sulphur and persulphuric acid—Thionic acids—Carbon bisulphide—Thionates—Thiophosgene—Thionic acid and its salts—Oxysulphide of carbon—Chlorides of sulphur—Thionyl chloride—Chloranhydrides of sulphuric acid—Phosphorus fluosulphide—Sulphur hexafluoride—Amides and nitriles of sulphur—Nitride of sulphur and pentasulphide of nitrogen—Selenium and tellurium and their compounds.

XXI. CHROMIUM, MOLYBDENUM, TUNGSTEN, URANIUM, AND MANGANESE 302

Occurrence of chromium—Bichromate of potassium—Ammonium salts of chromic acid—Yellow chromate of potassium and chromic anhydride—Pentafluoride of chromium—Chromyl chloride—Peligot's salt—Perchromic acid—Chrome alums—Green and violet varieties of salts of chromic oxide—Chromic oxide—Chloride of chromium—Salts of chromous oxide—Metallic chromium—Molybdenum and tungsten and their compounds—Complex acids—Tungsten bronze—Silico-tungstic acid—Hydrosols of tungstic acid—Permolybdic and pertungstic acids—Uranium and its compounds—Radio-active substances—Manganese—Salts of manganous oxide—Manganous oxide—Manganic oxide—Metallic manganese—Ferromanganese—Potassium permanganate—Nitride of manganese—Potassium manganate—Manganic anhydride—Trioxide of manganese and manganic acid—Velocity of chemical reaction.

XXII. IRON, COBALT, AND NICKEL 342

Occurrence of iron—Treatment of ores—Blast furnace—Cast iron—Puddled iron—Properties of iron and steel—Bloomery process—Cementation—Bessemer process—Gilchrist process—

Martin's process—Chemically pure iron—Rust—Behaviour of iron with acids—Iron amalgams—Iron vitriol—Chloride of iron—Suboxide of iron—Magnetic oxide—Oxide of iron and its hydrates—Chlorate and nitrate of iron—Orthophosphate of iron—Iron alums—Ferric acid—Compounds of iron and carbon monoxide—Cyanides of iron—Nitride of iron—Nitroprussides and nitrosulphides—Nickel and cobalt—Salts of nickel and cobalt—Oxide of nickel—Dioxide of cobalt—Alloys of nickel—Compounds of nickel with carbon monoxide.

XXIII. THE PLATINUM METALS 392

Characteristics—Osmium-iridium—Platinum—Ammonio-compounds of platinum—Metallic platinum—Platinum black—Soluble platinum—Chloride of platinum—Double salts—Dichloride of platinum—Oxide of platinum and its hydrate—Chloride and iodide of palladium—Metallic palladium—Its hydride—Rhodium—Sesquioxide of iridium—Ruthenic and osmic anhydrides—Ruthenium and osmium—Platino-cyanides—Rutheno-cyanides—Double thionates and chlorides of platinum—Double sulphites—Compounds with carbon monoxide—Double nitrites—Platino-ammonium compounds.

XXIV. COPPER, SILVER, AND GOLD 419

Occurrence of copper: extraction from its ores—Metallic copper—Allotropic copper—Oxides of copper—Subchloride—Iodide—Fluoride and cyanide of copper—Hydride of copper—Oxide of copper—Ammonium compounds of oxide of copper—Nitride and phosphide of copper—Basic salts of copper—Law of phases—Nitrate of copper—Copper vitriol—Carbonate of copper—Crystalline forms of the salts $R_2M(SO_4)_2 \cdot 6H_2O$ —Alloys of Copper—Silver assay by wet and dry methods—Chemically pure silver—Amalgamation—Colloidal solutions of silver—Absorption of oxygen by silver—Oxides of silver—Fulminating silver—Nitrate of silver—Displacement of metals by metals—Haloid salts of silver—Subchloride of silver—Photo-salts—Cyanide of silver—Plating—Stas's rescarches—Prout's hypothesis—Occurrence of gold—Separation of gold from silver—Pure gold—Chloride of gold—Purple of Cassius—Aurate of potassium—Cyanides of gold and potassium—Fordos and Gelis' salt.

APPENDIX I. AN ATTEMPT TO APPLY TO CHEMISTRY ONE OF THE PRINCIPLES OF NEWTON'S NATURAL PHILOSOPHY . 471

APPENDIX II. THE PERIODIC LAW OF THE CHEMICAL ELEMENTS . 489

APPENDIX III. AN ATTEMPT TOWARDS A CHEMICAL CONCEPTION OF THE ETHER 509

INDEX OF AUTHORITIES 531

INDEX OF SUBJECTS 542

TRANSLATOR'S PREFACE

As in the previous English editions of these 'Principles,' so also in the present translation, it has been the aim of the Translator to give, as nearly as possible, a literal rendering of the Russian work.

All the more important of the new figures in the original have been reproduced, the only omissions, which are few in number, being either portraits or illustrations of well-known apparatus.

Of the Appendices issued with the first English edition, two have been retained; for permission to print the first of these we have to thank the Managers of the Royal Institution, while, for allowing the Faraday Lecture to appear, we are indebted to the Council of the Chemical Society of London. The matter of Appendix III. of the former English edition has now been incorporated into the text of the book, so that this appendix has been omitted. Its place is taken by an article, recently written by Professor Mendeléeff, on 'A Chemical Conception of the Ether.'

November, 1904.

AUTHOR'S PREFACE

TO

THE SEVENTH RUSSIAN EDITION

THIS work was written during the years 1868–1870, its object being to acquaint the student not only with the experimental facts and laws of chemistry, but also with the insight given by this science into the unchangeable substratum underlying the varying forms of matter.

If statements of fact themselves depend upon the person who observes them, how much more distinct is the reflection of the personality of him who gives an account of methods and philosophical speculations forming the essence of a science! For this reason there will inevitably be much that is subjective—bearing the stamp of time and locality—in every objective exposition of science. And as an individual production is only significant in virtue of that which has preceded and that which is contemporary with it, it resembles a mirror, which in reflecting exaggerates the size and clearness of neighbouring objects, and causes a person near it to see reflected most plainly those objects which are on the side to which it is directed, and sometimes even the person holding the mirror. Although I have endeavoured to make my book a true mirror directed towards the whole domain of chemical changes and of the elements taking part in them, yet involuntarily those influences near to me being the most clearly reflected and the most brightly illuminated have tinted the entire work with their colouring. In this way the chief peculiarity of the book has

been determined. Experimental and practical data and their application in life and industry occupy their place, but the philosophical principles of our science form the chief theme of the work. In former times sciences, like bridges, could only be built up by supporting them on a few broad buttresses and long girders. In addition to the exposition of the principles of chemistry, it has been my desire to show how this science has now been built up like a suspension bridge, supported by the united strength of a number of slender, but firmly fixed, chains—individually of little strength—and has thus been carried over difficulties which before appeared insuperable. In comparing the science of the past, the present, and the future, in placing the particulars of its restricted experiments side by side with its aspirations after unbounded and infinite truth, and in restraining myself from yielding to a bias towards the most attractive path, I have endeavoured to incite in the reader a spirit of inquiry which, dissatisfied with speculative reasonings alone, should subject every idea to experiment, to encourage the habit of stubborn work, and to excite a search for fresh chains of evidence to complete the bridge over the bottomless unknown. History proves that it is possible by this means to avoid three equally pernicious extremes: the Utopian—a visionary contemplation which strives to create all from an impulse of thought alone—the stagnant realism which is content with bare facts, and presumptuous scepticism, irresolute about everything. Sciences like chemistry, which deal with ideas as well as with material substances, and create a possibility of immediately verifying that which has been or may be discovered or assumed, demonstrate at every step that the work of the past has availed much, and that, without it, it would be impossible to advance into the ocean of the unknown. They also show the possibility of becoming acquainted with fresh portions of this unknown, and compel us, while duly respecting the teachings of history, to cast aside classical illusions, and to engage in the work of tranquil and systematic investigation,

which is not only the sole means of attaining mental satisfaction, but is also practically useful to ourselves and all our fellow-creatures.¹

¹ Chemistry, like every other science, is at once a means and an end. It is a means of attaining certain practical results. Thus, by its assistance, the obtaining of matter in its various forms is facilitated; it shows new possibilities of availing ourselves of the forces of nature, indicates the methods of preparing many substances, points out their properties, &c. In this sense chemistry is closely connected with the work of the manufacturer and the artisan, it plays a useful part, and is a means of promoting the general welfare. Besides this honourable vocation, chemistry has another. With it, as with every other elaborated science, there are many lofty aspirations, the contemplation of which serves to inspire its workers and adherents. This contemplation comprises not only the principal data of the science, but also the generally accepted deductions, together with hypotheses which refer to phenomena as yet but imperfectly known. In this latter sense scientific contemplation varies much with times and persons, it bears the stamp of creative power, and embraces the highest forms of scientific progress. In that pure enjoyment experienced on approaching to the ideal, in the eagerness to draw aside the veil from the hidden truth, and even in that discord which exists between the various workers, we ought to see the surest pledges of further scientific progress. Science thus advances, discovering new truths, and at the same time obtaining practical results. The edifice of science not only requires material, but also a plan, and necessitates the work of preparing the materials, putting them together, working out the plans and the symmetrical proportions of the various parts. To conceive, understand, and grasp the whole symmetry of the scientific edifice, including its unfinished portions, is equivalent to tasting that enjoyment only conveyed by the highest forms of beauty and truth. Without the material, the plan alone is but a castle in the air, a mere possibility; whilst the material without a plan is but useless matter. All depends on the concordance of the materials with the plan and execution, and the general harmony thereby attained. In the work of science the artisan, architect, and creator are very often one and the same individual; but sometimes, as in other walks of life, there is a difference between them; sometimes the plan is preconceived, sometimes it follows the preparation and accumulation of the raw material. Free access to the edifice of science is not only allowed to those who devised the plan, worked out the detailed drawings, prepared the materials, or piled up the brickwork, but also to all those who are desirous of making a close acquaintance with the plan, and wish to avoid dwelling in the vaults or in the garrets where the useless lumber is stored.

Knowing how contented, free, and joyous is life in the realm of science, one fervently wishes that many would enter its portals. On this account many pages of this treatise are unwittingly stamped with the earnest desire that the habits of chemical contemplation which I have endeavoured to instil into the minds of my readers will incite them to the further study of science. Science will then flourish in them and by them, on a fuller acquaintance not only with that little which is enclosed within the narrow limits of my work, but with the further learning which they must imbibe in order to make themselves masters of our science and partakers in its further advancement.

Those who enlist in the cause of science have no reason to fear when they remember the urgent need for practical workers in the spheres of agriculture, arts,

Thus the desire to direct those thirsting for truth to the pure source of the science of the forces acting throughout nature forms the first and most important aim of this book. The time has arrived when a knowledge of physics and chemistry forms as important a part of education as that of the classics did two centuries ago. In those days the nations which excelled in classical learning stood foremost, just as now the most advanced are those which are superior in the knowledge of the natural sciences, for they represent the strength as well as the signs of our times. If the universe clearly exhibits a unity of purpose, the cause of this is surely first seen in the unity of the principles of science, which inevitably become more and more uniform and progressive, and, although individually untrammelled, are bound to submit to the yoke of laws conceived and revealed. And chemistry, as the youngest branch of natural science, promises in the future a richer harvest than it has already given. One of the chief aims of this book is to attract and retain fresh, unshackled forces for this youthful science by pointing out what has been achieved, what remains to be achieved, and in what directions advances may be made. Only by gradually extending the conquests already made can the coming generation of chemists benefit mankind and disperse the shades of ignorance and superstition. The seeds sown by science are reaped by mankind. In contemplating the infinite, science has no limits.

Although I feel confident that 'good will' will be awakened by our science, I know that time is long, and that many efforts, conditions, and circumstances are needed for the fruits to ripen.

While following the above and chief aim, I set myself also a second object: to furnish a text-book giving an elementary knowledge of chemistry, and so satisfy a want which undoubtedly exists among students and those who have recourse

and manufacture. By summoning adherents to the work of theoretical chemistry, I am confident that I call them to a most useful labour, to the habit of dealing correctly with nature and its laws, and to the possibility of becoming truly practical men.

to chemistry either as a source of truth or as a means of living.² Hence, although the fundamental object of this work was to express and embrace the general chemical teaching of the present day from a personal point of view, I have nevertheless striven throughout to maintain such a level as would render the 'Principles of Chemistry' accessible to the beginner.

² I recommend those who are commencing the study of chemistry with my book *to first read only what is printed in large type*, because in that part I have endeavoured to concentrate all the fundamental, indispensable knowledge required for that study. In the footnotes, printed in small type (which should be read only after the large text has been mastered), certain details are discussed; they are either further examples, or debatable questions on existing ideas which I thought useful to lay before those entering into the sphere of science, or certain historical and technical details which might be withdrawn from the fundamental portion of the book. Without intending to attain in my treatise to the completeness of a work of reference, I have still endeavoured to express the principal developments of science as they concern the chemical elements viewed in that aspect in which they appeared to me after long-continued study of the subject and participation in the contemporary advance of knowledge.

I have also placed my personal views, suppositions, and arguments in the footnotes, which are chiefly designed for details and references. But I have endeavoured to avoid here, as in the text, not only all that I consider doubtful, but also those details which belong either to special branches of chemistry (for instance, to analytical, organic, physical, theoretical, physiological, agricultural, or technical chemistry) or to different branches of natural science which are gradually coming into closer and closer contact with chemistry. Chemistry, I am convinced, must occupy a place among the natural sciences side by side with mechanics; for mechanics treats of matter as a system of ponderable points having scarcely any individuality and only standing in a certain state of mobile equilibrium. For chemistry, matter is an entire world of life, with an infinite variety of individuality both in the elements and in their combinations. In studying the general uniformity from a mechanical point of view, I think that the highest point in the knowledge of nature cannot be attained without taking into account the individuality of things in which chemistry is set to seek for general higher laws. Mechanics forms the classical basis of natural philosophy, while chemistry, as a comparatively new and still young science, already strives to—and will, in the future—introduce a new, living aspect into the philosophy of nature; all the more is this so, as chemistry alone is never at rest or anywhere dead—its vital action has universal sway, and inevitably determines the general aspect of the universe. Just as the microscope and telescope enlarge the scope of vision, and discover life in seeming immobility, so chemistry, in discovering and striving to discern the life of the invisible world of atoms and molecules and their ultimate limit of divisibility, will clearly introduce new and important problems into our conception of nature. And I think that its *rôle*, which is now considerable, will increase more and more in the future; that is, I think that, in its further development, it will occupy a place side by side with mechanics for the comprehension of the secrets of nature. But here we require some second Newton; and I have no doubt but that he will soon appear.

Many aspects of this work are determined by this combination of requirements, which frequently differ widely. In the preparation of such a book it is necessary not to be carried away by what appears to be a plausible theory in explaining individual facts and to always endeavour to transmit the simple truth of a given fact, extracting it from the vast store of the literature of the subject and from tried personal experience. In publishing a new edition of this work I have striven to add any facts of importance recently discovered and to revise the former edition in the above spirit. With this object I have gone entirely over this edition, and a comparison of it with the former one will show that the additions and alterations have, in many instances, cost as much labour as their original compilation. I also wished to show in an elementary treatise on chemistry the striking advantages gained by the application of the periodic law, which I first saw in its entirety in the year 1869, when I was engaged in writing the first edition of this book, in which, indeed, the law was first enunciated. At that time, however, this law was not established so firmly as now, when so many of its consequences have been verified by the researches of numerous chemists. The, to me, unexpectedly rapid success with which the teaching of the periodicity of the elements has spread in our science, and perhaps, also, the perseverance with which I collected in this work, and upon a new plan, the most important data respecting the elements and their mutual relations, explained sufficiently the fact that the former editions of my work have been translated into English³ and German.⁴ Deeply touched by the favourable opinions expressed by English and American men of science upon my book, I ascribe them chiefly to the periodic law placed at the basis of my treatise, and especially of the second part of the book, which contains a large amount of data having a special, and sometimes unex-

³ The English translation was made by G. Kamensky, and edited by A. J. Greenaway; published by Longmans, Green & Co.

⁴ The German translation was made by L. Jawein and A. Thillot; published by Ricker (St. Petersburg).

pected, bearing from the point of view of this law. As the entire scheme of this work is subordinated to the law of periodicity, which may be illustrated in a tabular form by placing the elements in series, groups, and periods, such tables are given at the end of this Preface.

But the thought that this book might fall not only into the hands of the beginner for whom it is intended, but also of authorities who might wish to know the views held by an old disciple of science on the current problems of chemistry, greatly complicated the preparation of a new edition, for it necessitated making a selection of the most essential of the vast number of new researches published year by year, and explaining my views on them without greatly enlarging the bulk of the work.⁵ After having closely followed all the chief conquests of chemical science since the days of Berzelius, Liebig, Dumas, and Gerhardt, and having seen the triumph of much that lay neglected and the fall of much that was exalted, I involuntarily acquired a tendency to analyse new facts and a desire to transmit to my readers the results of such analysis, if it could, in my opinion, help towards a proper explanation and generalisation of the chemical elements. In carefully preparing this

⁵ A mere dry and impersonal statement of facts and of the opinions of others, although new and important, would in no way correspond with the spirit of this book, which is mainly designed for the beginner, and for the expression of my personal views on the chemical elements. In my opinion, only a connection of ideas with facts, and of observations with a line of thought, can act in the right direction; otherwise reality slips away and fiction easily supersedes it, as has been, is, and will be frequently the case, and this I strenuously wish to avoid in this book. My chief desire is to inspire a spirit of inquiry, and if I often express my personal opinions, I do not wish to hide either the reasons which guide others in another direction or views which are contrary to my own. Of these views I may mention those which recognise an 'electrolytic dissociation' in saline solutions, the formation of the chemical elements from a single primary matter, &c. In shortly, but as far as possible exactly and objectively, stating observed facts, I endeavour, as well as I am able, to elucidate their sense and to group them in a precise and real manner, revealing further horizons for future scientific research. I have tried to exclude nothing which I knew and considered reliable and instructive, although it might have contradicted my views. Notwithstanding the care I have taken in collecting the difficult data cited in this book, I am far from thinking that it contains a complete review of all that is instructive in the doctrine of the chemical elements.

edition, I have not lost sight of the fact that I am hardly likely to publish another, and I have therefore, in many cases, spoken more definitely than formerly. After having been an insignificant but zealous worker in chemistry for almost half a century, I wished that my book should retain some traces of how a confirmed disciple of Gerhardt regards the fundamental problems of the theory of the chemical elements at the beginning of the twentieth century. As an example, I may mention that the more I have thought on the nature of the chemical elements, the more decidedly have I turned away from the classical notion of a primary matter, and from the hope of attaining the desired end by a study of electrical and optical phenomena, and the more clearly have I recognised that first and foremost are needed truer conceptions of 'mass' and 'ether' than those in vogue at the present time.⁶ The return to electro-chemism

⁶ When I consider the undoubtedly real and all-permeating 'ether,' and involuntarily ask myself of what it consists, I cannot admit the idea that its atoms or matter are only composed of a 'primary matter' of which all atoms are built up, for if that were so one might expect not only cases of the appearance and disappearance of the 'mass' of a substance, but also of the transformation of one element into another, and all we know forces us to deny that this is possible, although thousands—from the spiritualists to Emmens (the conversion of silver into gold, 1897) and Fittica (the conversion of phosphorus into arsenic, 1900)—have tried and are trying to prove the contrary. And, of course, no one except a metaphysician would permit himself, and will hardly ever consent, to deny the presence of matter, 'atoms,' and mass in 'ether.' And if we recognise the materiality and mass of 'ether,' it seems to me first of all necessary to admit that it is a substance without power of chemical reaction on other substances. Not so long ago such an idea might have appeared most unreal; but now, when instances of substances incapable of reacting have been discovered in argon and its analogues, this view is quite possible. Besides being admissible, a light substance deprived of all chemical force should apparently certainly exist and is to be foreseen. Moreover, the distribution of the elements according to groups and series (Preface, tables I. and II.) in the periodic system, and the fact that a zero group must be recognised besides groups I.–VIII., give reason for thinking that there is also a zero series of elements lighter than hydrogen, and even an element in the hydrogen series of the zero group (is not this coronium or one of the volcanic gases, the spectra of which were observed by Nasini, Anderlini, and Salvadori in 1898?), and an element of the zero series and zero group should be many times lighter than hydrogen in its atomic weight. Let us call this weight x . It should be an unliquefiable gas, and its density with respect to hydrogen under like conditions should be $x/2$, i.e. its molecule should contain one atom like that of helium, argon, &c. The extremely small density of the gas, i.e. the extremely rapid motion proper to its molecules, their very small weight, and also the position in the zero

which is so evident in the supporters of the hypothesis of 'electrolytic dissociation,' and the notion of a splitting up of atoms into 'electrons,' in my opinion only complicate and in no way explain so real a matter (since the days of Lavoisier) as the chemical changes of substances, which led to the recognition of the invariable and ponderable atoms of simple bodies. The definition of mass gave a means for analysing and grasping chemical transformations of substances, and for arriving at the atom, while the mass of the atom was shown by the periodic law to influence all its chief chemical properties. Thus chemistry in its principles stood on the firm foundations laid by Galileo, Newton, and Lavoisier, and in order to gain further insight and knowledge of the atoms themselves, the fundamental conceptions of mass, gravity, and ether will have to be explained by a method of experiment alone, otherwise the realism of science will again open its doors to such metaphysical and 'metachemical' conceptions as phlogiston and other mystical dreams. For my part, I endeavour to remain true to the testament of realism left by Newton and Lavoisier, and it is my wish to instil this sentiment into my young readers.

In this seventh edition I have not found it necessary to alter any of the essential features of previous editions, and have only completed them by the addition of many new details. In this respect invaluable assistance has been rendered me by my dear friend, Professor Brauner, of the University of Prague, by his complete and concise contribution on the 'Elements of the Rare Earths,' which he wrote at my request. Many data have been added thereto in recent years, and it needs such an authority on the 'rare earths' as Professor Brauner to interpret this complex, difficult, and yet unfinished subject, where the obtaining

group, should contribute to the fact that this gas should permeate and penetrate everywhere; that it should occupy space, but not attach itself stably to anything with the harmonious motion of chemical combination, so that it cannot accumulate anywhere. And these imaginary properties should also be those of the substance 'ether.' In endeavouring to clothe the conception of 'ether' with a chemical dress, and so render it an actual, real possibility in harmony with the purely realistic periodic law, I think I am serving the cause of unity in natural philosophy.

of reliable data is complicated not only by the peculiarities and analogies of many facts, but also by the rareness of the earths themselves. Professor Brauner has himself contributed largely to the history of these metals, and his description of them contains much of his individual work. I offer him my most grateful thanks for his contribution. I am also greatly indebted to Mr. V. D. Saposhnikoff for revising the sheets for the press and for compiling the Index, which will be found of great help to those seeking for any special subject in this book.

¹ The atomic weights of helium, argon, and the analogous gases, judging from their densities (pp. 247-253), are greater than those of the halogens and less than those of the metals of the alkalies, but no compounds of these elements are known.

² The density of argon indicates an atomic weight 39.9; but, judging from the preceding note, it is probably greater than that of Cl but less than that of K, i.e. about 38.

³ The atomic weight of Ni is given as 58.7; but as this metal, judging from its properties, should follow after Co = 59, its atomic weight should not be less but greater than that of Co. Therefore it is probable that further research will prove these atomic weights to be slightly different from the above.

⁴ The discovery of a metal resembling Mn (ekamanganese) with an atomic weight 99 may be expected.

⁵ Judging by its properties and the periodic law, tellurium should have an atomic weight less than that of iodine, but so far experiment proves the contrary—the values obtained for Te varying from 126.4 (Steiner) to 127.9 (Metzner) with an average of 127.7, that of iodine being slightly less—126.96 (Stas), and 126.98 (Ladenburg). Both these latter figures are near 127, and it is therefore likely that further research will prove that the atomic weight of iodine is greater than 127 (which is possible because the iodine was dried with CaCl₂, which might introduce chlorine), or else a figure smaller than 127 may be afterwards found for tellurium.

⁶ A whole large period is wanting between Ce = 140 and Ta = 183, but the series of rare elements (they have not been fully investigated)—for instance, Pr = 140.5, Nd = 143.6, Gd = 156, Er = 166, Yb = 173, &c.—have, as far as is now known, atomic weights which exactly fill this interval, and therefore this portion of the periodic system is, in a way, broken and requires fresh researches.

⁷ According to Madame Curie (1902), *radium* (Vol. II., p. 328) (one of the radio-active elements) resembles barium and has an atomic weight lying between 223 and 225.

INTRODUCTION

THE rapid development of the study ¹ of the external universe, dating from the days of Galileo (†1642) and Newton (†1727), led to the

¹ The investigation of a substance or a natural phenomenon consists: (*a*) in determining the relation of the object under examination to that which is already known, either from previous researches, or from experiment, or from the knowledge of the common surroundings of life—that is, in determining and expressing the quality of the unknown by the aid of that which is known; (*b*) in measuring all that which can be subjected to measurement, and thereby indicating the quantitative relation of that under investigation to that already known—to time and space, temperature, mass, &c.; (*c*) in determining the position held by the object under investigation in the system of known objects, taking into account both qualitative and quantitative data; (*d*) in determining, from the quantities which have been measured, the empirical (visible) dependence (function, or ‘law,’ as it is sometimes termed) of variable factors—for instance, the dependence of the composition of a substance on its properties, of temperature on time, of properties on mass (weight), &c.; (*e*) in framing hypotheses or suppositions as to the actual cause and nature of the relation of that studied to that which is known or to the categories of time, space, &c.; (*f*) in experimentally verifying the logical consequences of such hypotheses; and (*g*) in advancing a theory which shall account for the nature of the properties of that studied in its relations with things already known and with the conditions under which it exists. It is manifest that it is only possible to carry out these investigations when we have taken as a basis something which is incontestable and self-evident to our understanding; such, for instance, as number, time, space, matter, form, motion, or mass. Hence it follows that in the investigation of anything, there always remains something which is accepted without investigation, or admitted as a known and recognised factor; the axioms of geometry may be taken as an example. Thus in the science of biology it is necessary to admit the faculty of organisms for multiplying themselves, as a conception whose meaning is as yet unknown. In the study of chemistry, too, the notion of elements must be accepted almost without any further analysis. However, by investigating and describing what is visible and open to direct observation by the organs of the senses, we may hope to arrive, first at hypotheses, and afterwards at theories, of what has now to be taken as the basis of our investigations. The minds of the ancients strove to seize at once the very fundamental categories of investigation, whilst all the successes of recent knowledge are based on the above-cited method of investigation, without the determination of ‘the beginning of all beginnings.’ By following this inductive method, the *exact sciences* have already succeeded in becoming accurately acquainted with much of the invisible world, not directly perceptible to the organs of sense (for example, the molecular motion of all bodies, the composition of the heavenly luminaries, and the paths of their motion, the necessity for the existence

separation of Chemistry as a special branch of natural philosophy. Not only was this owing to the increasing store of observations and experiments relating to the transformations of substances, but more especially because, in addition to gravity, cohesion, heat, light, and electricity, it became necessary to recognise the existence of peculiar internal forces in the ultimate parts of all substances, forces which make themselves manifest in the transformations of substances into one another, but remain hidden (latent) under ordinary circumstances, and whose existence cannot therefore be directly apprehended, and so for a long time remained unrecognised. The primary object of chemistry is the study of the homogeneous substances ² of which all the objects of the universe

of substances as yet unknown to experiment, &c.), and have verified the knowledge thus obtained, and employed it for increasing the interests of humanity. It may therefore be safely said that *the inductive method of investigation* is a more perfect mode of acquiring knowledge than the deductive method alone (which from a little of the unknown accepted as incontestable arrives at much which is visible and observable) by which the ancients strove to embrace the universe. By investigating the universe by an inductive method (endeavouring from the much which is observable to arrive at a little which may be verified and is indubitable), the new science refuses to recognise dogma as *truth*, but through *reason*, by a slow and laborious method of investigation, strives for and attains to true deductions.

² Substance or matter is that which occupies space and has weight; that is, which presents a mass attracted by the earth and by other masses of matter, and of which the *objects* of nature are composed, and by means of which the motions and *phenomena* of nature are accomplished. It is easy to discover, by examining and investigating in various ways the objects met with in nature and in the arts, that some of these are homogeneous, whilst others are composed of a mixture of several homogeneous substances. This is most clearly apparent in solid substances. The metals used in the arts (for example, gold, iron, copper) must be homogeneous, otherwise they are brittle and unfit for many purposes. Homogeneous matter exhibits similar properties in all its parts. By breaking up a homogeneous substance we obtain parts which, although different in form, resemble each other in their properties. Glass, pure sugar, marble, salt, &c., are examples of homogeneous substances. Examples of non-homogeneous substances are, however, much more frequent in nature and the arts. Thus the majority of the rocks are not homogeneous. In porphyries bright pieces of a mineral called 'orthoclase' are often seen interspersed amongst the dark mass of the rock. In ordinary red granite it is easy to distinguish large pieces of orthoclase mixed with dark semi-transparent quartz and flexible laminæ of mica. Similarly, plants and animals are non-homogeneous. Thus, leaves are composed of skin, fibre, pulp, sap, a green colouring matter, &c. As an example of non-homogeneous substances artificially produced, gunpowder may be cited, which is prepared by mixing together sulphur, nitre, and charcoal. Many liquids, also, are not homogeneous, as may be observed by the aid of the microscope, when drops of blood are seen to consist of a colourless liquid in which red corpuscles, invisible to the naked eye owing to their small size, are floating about. It is these corpuscles which give blood its peculiar colour. Milk is also a transparent liquid, containing microscopic drops of fat, which rise to the top and form cream when the milk is left at rest. It is possible to extract from every non-homogeneous substance those homogeneous substances of which it is made up. Thus orthoclase may be separated from porphyry by breaking it off. So also gold is extracted from auriferous sand by washing away the mixture of clay and sand. Chemistry deals only with the homogeneous substances met with in nature, or extracted from natural or artificial non-homogeneous substances. The various mixtures found in

are made up, of the transformations of these substances ³ into each other, and of the phenomena ⁴ which accompany such transformations. Every chemical change, or reaction,⁵ as it is called, can only take place under a condition of most intimate and close contact of the reacting substances,⁶ and is determined by forces peculiar to the smallest invisible

nature form the subjects of other natural sciences—such as geology, botany, zoology, anatomy, &c. Substances can only be investigated by their *properties* or by their relations to our organs of sense and to other substances and bodies, but of itself matter is beyond the grasp of our understanding; for there is something in its nature which is self-existent and foreign to our understanding and spirit. If at the present day matter is represented as composed of individual mobile atoms, this is, in my opinion, only a scheme (a method or expedient for facilitating study) based originally on the structure of the visible (sidereal, solar) universe, which is actually composed of separate stars, like the sun, of planets and their satellites, of meteorites, and of the special ether which has the faculty of transmitting light and other forms of energy and motion, all of these being united in one harmonious whole. There is a great charm in the idea that the most minute parts of nature should be constructed on the same plan as the most gigantic, but it is far from proved that such is actually the case. It does not follow, however, because matter in itself is incomprehensible to us, that the study of matter is beyond our faculties if we follow the path of inductive reasoning (inaugurated by Bacon). This is evident from the fact that, by gradually investigating matter, man gains a greater and greater mastery over it, makes more and more accurate predictions concerning it, and finds wider and more frequent applications of it for satisfying his needs. In fact, there is no reason to anticipate any limit to our knowledge of, and dominion over, matter.

³ The name 'body' is given to a substance bounded by a surface or possessing shape. The earth, as a part of the solar system, is a body. A crystal, a plant, a house, are all bodies. It is evident that, in general, knowledge concerning matter is knowledge concerning bodies. Chemistry does not deal with bodies but with substances. However in ordinary usage the words 'body' and 'substance' are very often confused. Thus we speak of chemically simple and compound 'bodies' when we should, of course, use the word 'substances.'

⁴ All those events which are accomplished by substances in time are termed 'phenomena.' Phenomena in themselves form the fundamental subject of the study of physics. Motion is the primary and most easily understood form of phenomenon, and therefore we endeavour to reason about other phenomena as clearly as when dealing with motion. For this reason mechanics, which treats of motion, forms the fundamental science of natural philosophy, and in all other sciences endeavour is made to reduce the phenomena with which they are concerned to mechanical principles. Astronomy was the first to take to this path of reasoning, and succeeded in many cases in resolving astronomical into purely mechanical phenomena. And so, under the present state of knowledge, it is inevitably necessary to recognise the separate categories, motion and matter; and as chemistry is more closely concerned with the various forms of the latter, it should, together with mechanics, or the study of motion, lie at the basis of natural science.

⁵ The verb 'to react' means to act or change chemically.

⁶ If a phenomenon proceeds at visible or measurable distances (as, for instance, magnetic attraction or gravity), it cannot be described as chemical, since these phenomena only take place at distances immeasurably small and undistinguishable to the eye or the microscope; that is to say, they are purely molecular. Even Newton recognised, however, that it was impossible to comprehend the influence of bodies on each other (for instance attraction) without the agency of some medium situated between them. And this still holds good. Therefore a 'vacuum' is not admitted in modern science, but all so-called vacua, or spaces void of air, are considered to be filled with 'ether,' which was first regarded as the medium transmitting light waves, and afterwards as a means of

particles (molecules) of matter. We must distinguish three chief classes of chemical transformations.

1. *Combination* is a reaction in which the union of two substances yields a new one, or generally, from a given number of substances, a lesser number is obtained. Thus, by heating a mixture of iron and sulphur⁷ a single new substance is produced, iron sulphide, in which the constituent substances cannot be distinguished even under the highest magnification. Before the reaction the iron could be separated from the mixture by a magnet, and the sulphur by dissolving it in certain oily liquids;⁸ in general, before combination they might be mechanically separated from each other, but after combination the two substances penetrate into each other, and are then neither mechanically separable nor individually distinguishable. As a rule, reactions of direct combination are accompanied by an evolution of heat, and the common case of combustion, evolving heat, consists in the combination of the combustible substance with a portion (the oxygen) of the atmosphere, the gases and vapours contained in the flame and smoke representing the products of the combination.

explaining the action of attractions at a distance as well as magnetic and electrical phenomena. Without entering into these conceptions, which are more or less hypothetical (like that of the chemical elements), it may not be superfluous to mention that chemical theories lie beyond the hypothesis of ether, and that, judging from our present knowledge, chemical reactions do not proceed through the medium of ether, as they only take place by actual contact. It appears to me, therefore, that the chemism of substances possesses a certain simplicity and elementary character, and I foresee that chemistry may some day lead to an explanation of our conception regarding matter. In this sense chemical phenomena are more real to the understanding than physical or mechanical phenomena. Taking into consideration the comparative youth of this branch of natural science and the speciality of the phenomena it treats of, it seems to me that the province of chemical generalisations will rapidly extend, just as the applications of chemistry to the industries are extending at the present day. This forms the peculiar charm of chemistry, and especially of physico-chemical research. If the astronomer grasps the infinitely great in its highest reality, the chemist embraces the infinitely small, and science strives to attain the infinite and everlasting, unfettered by the finite and temporal.

⁷ For this purpose a piece of iron may be made red-hot in a forge, and then placed in contact with a lump of sulphur, when iron sulphide will be obtained as a molten liquid, the combination being accompanied by an appreciable increase in the glow of the iron. Or else iron filings are mixed with powdered sulphur in the proportion of 5 parts of iron to 3 of sulphur, and the mixture placed in a glass tube, which is then heated at one part. Combination does not commence without the aid of external heat, but when once started in any portion of the mixture it extends throughout the entire mass, because the portion first heated, in forming iron sulphide, evolves sufficient heat to raise the adjacent parts of the mixture to the temperature required for starting the reaction. The rise in temperature thus produced is so high as to soften the glass tube.

⁸ Sulphur dissolves slightly in many thin oils, and to a greater extent in carbon bisulphide and some other liquids. Iron is insoluble in carbon bisulphide, and the sulphur can therefore be dissolved away from the iron, so long as the two are not chemically combined.

2. Reactions of *decomposition* are the reverse of those of combination, that is, one substance gives two, or, in general, a given number of substances yields a greater number. Thus, by heating wood (and also coal and many animal or vegetable substances) without access to air, a combustible gas, a watery liquid, resin or tar, and carbon are obtained. It is in this way that tar, illuminating gas, and charcoal are prepared on a large scale.⁹ All limestones, for example, flagstones, chalk, or marble, when heated to redness are decomposed into lime and a peculiar gas called carbonic anhydride. A similar decomposition, taking place, however, at a much lower temperature, proceeds with the green copper carbonate which is contained in natural malachite. This example will be studied more in detail presently. Whilst heat is evolved in the ordinary reactions of combination, it is, on the contrary, generally absorbed in reactions of decomposition.

3. The third class of chemical reactions—where the number of reacting substances is equal to the number of substances formed—may be considered as a simultaneous decomposition and combination. If, for instance, two compounds A and B are taken and they react on each other, forming the substances C and D; then supposing that A is decomposed into D and E, and that E combines with B to form C, we have a reaction in which two substances A (or D E) and B were taken and two others C (or E B) and D were produced. Such reactions ought to be classed under the general term of reactions of '*rearrangement*,' and the particular case where two substances give two fresh ones, reactions of '*substitution*' or '*double decomposition*.'¹⁰ Thus, if a piece of iron be immersed in a solution of blue vitriol (copper sulphate), copper is formed—or, rather, separated out, and green vitriol (iron sulphate), which only differs from the blue vitriol in that the iron has replaced the copper, is obtained in solution. In this manner iron may be coated with copper, or copper with silver; such reactions are frequently made use of in practice.

⁹ Decomposition of this kind is termed '*dry distillation*,' because, just as in distillation, the substance is heated and vapours are given off which, on cooling, condense into liquids. In general, decomposition, in absorbing heat, presents much in common with a physical change of state—such, for example, as that of a liquid into a gas. Deville likened complete decomposition to boiling, and compared partial decomposition, in which a portion of a substance is not decomposed in the presence of its products of decomposition (or dissociation), with evaporation.

¹⁰ A reaction of rearrangement may in certain cases take place with one substance only; that is to say, a substance may by itself change into a new *isomeric* form. Thus, for example, if hard yellow sulphur be heated to a temperature of 250° and then poured into cold water, it gives, on cooling, a soft brown variety. Cases of isomerism indicate the possibility of an internal rearrangement in a substance, and are the result of an alteration in the grouping of the same elements, just as a certain number of balls may be grouped in figures and forms of different shapes.

The majority of the chemical changes which occur in nature and are made use of technically are very complicated, as they consist of an association of many separate and simultaneous combinations, decompositions, and replacements. It is chiefly due to this natural complexity of chemical phenomena that for so many centuries chemistry did not exist as an exact science; that is to say, that although many chemical changes were known and made use of,¹¹ yet their real nature was unknown, and they could not be predicted or directed at will. Another reason for the tardy progress of chemical knowledge is the participation of gaseous substances, especially air, in many reactions. The true comprehension of air as a ponderable substance, and of gases in general as peculiar elastic and dispersive forms of matter, was only arrived at in the sixteenth and seventeenth centuries, and it was only after this that the transformations of substances could form a science. Up to that time, without understanding the invisible, but ponderable, gaseous and vaporous forms of matter, it was impossible to obtain any fundamental chemical knowledge, because the gases formed or used up in any reaction escaped notice. It is easy, from the impression conveyed to us by the phenomena we observe, to form the opinion that matter is created and destroyed; a whole mass of trees burn, and there only remains a little charcoal and ash, whilst from one small seed there grows little by little a majestic tree. In one case matter seems to be destroyed, and in the other to be created. This conclusion is arrived at because the formation or consumption of gases, being under the circumstances invisible to the eye, is not observed. When wood burns, it undergoes a chemical change into gaseous products, which escape as smoke. The substance of the wood is not lost; it is only converted into gaseous form by a chemical process. A very simple experiment will prove this. By collecting the smoke it may be observed that it contains gases which differ entirely from air, being incapable of supporting either combustion or respiration. These gases may be weighed, and it will then be seen that their weight exceeds that of the wood taken. This increase in weight arises from the fact that, in burning, the component parts of the wood combine with a portion of the air; in like manner iron increases in weight by rusting. When gunpowder is burnt its substance is not destroyed, but only converted into gases and smoke. So also in the growth of a tree: the seed does not increase in mass of itself and from itself, but grows because it absorbs gases from

¹¹ For example, the conversion of the juice of grapes, containing a saccharine principle (glucose), into wine or vinegar, and the extraction of metals from the ores found in the earth's crust.

the atmosphere and sucks water and substances dissolved therein from the earth through its roots. The sap and solid substances which give plants their form are produced from these absorbed gases and liquids by complicated chemical processes directed by forces acting in the living organism. Plants not only do not increase in size, but die, in a gas which does not contain the nutrient constituents of air. When moist substances dry they decrease in weight; when water evaporates we know that it does not disappear, but will return from the atmosphere as rain, dew, and snow. When water is absorbed by the earth, it does not disappear there for ever, but accumulates somewhere underground, whence it afterwards flows forth as a spring. Thus matter does not disappear and is not created, but only undergoes various physical and chemical transformations—that is to say, changes its locality and form. Matter remains in the same quantity as before; in a word it is, so far as we are concerned, everlasting. It was difficult to submit this simple and primary chemical principle to investigation, but when once made clear it rapidly spread, and now seems as natural and simple as many truths which have been acknowledged for ages. The philosophers of ancient Greece, and also Mariotte and other savants of the seventeenth century, suspected the indestructibility or conservation of matter, but they made no efforts to express it, or to make use of it for scientific purposes. The experiments by means of which this simple law was arrived at were made during the latter half of the eighteenth century by the founder of modern chemistry, LAVOISIER, the French Academician and tax farmer.^{11a} The numerous experiments of this savant were conducted with the aid of the balance, which is the only means of directly and accurately determining the quantity of matter.

By weighing all the substances, and also the apparatus, used in every experiment, and then weighing the substances obtained after the chemical change, Lavoisier found that the sum of the weights of the substances formed was always equal to the sum of the weights of the substances taken; or, in other words: **Matter is not created and does not disappear**—i.e., *matter is everlasting*—so that the mass (weight) of matter in nature remains unchanged or constant. This

^{11a} The portrait of Lavoisier is placed at the beginning of this work because he established the fundamental law of our science on an indestructible basis, and should be regarded as the founder of modern scientific chemistry. Lavoisier was born on August 26, 1743, soon after the death of Newton, and his name must rank with those of Galileo and Newton. The closing days of his life were passed during the Reign of Terror, and he was beheaded at Paris, together with 27 other tax-farmers, on May 8, 1794; but his works and ideas have rendered him immortal. A monument, the cost of which was defrayed by international subscription, was erected in his honour in Paris in the year 1900.

expression naturally includes a hypothesis, but it serves to express concisely the following lengthy period: That in all experiments, and in all the investigated phenomena of nature, it has never been observed that the weight of the substances formed was less or greater (as far as accuracy of weighing permits ¹²) than the weight of the substances originally taken, and as weight is proportional to mass ^{12a} or quantity of matter, it follows that no one has ever succeeded in observing a disappearance of matter or its appearance in fresh quantities. The law of the indestructibility of matter endows all chemical investigations with exactitude, as on its basis an equation may be formed for every chemical reaction. If in any reaction the weights of the substances taken be designated by the letters A, B, C, &c., and the weights of the substances formed by the letters M, N, O, &c., then

Therefore, should the weight of one of the reacting or resultant substances be unknown, it may be determined by solving this equation.

By applying the law of the indestructibility of matter, and by making use of the chemical balance, the chemist can never lose sight of any one of the reacting or resultant substances. Should such an oversight be made, it will at once be remarked that the sum of the weights of the substances taken is unequal to the sum of the weights of the substances formed. It is absolutely necessary, in beginning the study of chemistry, to become familiar with the simple truth which is expressed by this law, and for this purpose several examples illustrating its application will now be cited.

¹² The experiments conducted by the Belgian savant Stas (described in detail in Chap. XXIV. on Silver) form some of the most accurate of the researches which go to prove that the weight of matter is not altered in chemical reactions, as he weighed extremely accurately (introducing all the necessary corrections) the reacting and resultant substances. Landolt (1893) carried on various reactions in inverted and sealed glass U-tubes, and on weighing the tubes before reaction (when the reacting solutions were separated in each of the branches of the tubes) and afterwards (when the solutions had been well mixed by shaking) found either that the weight remained perfectly constant or that the variation was so small (for instance, 0.2 milligram) that it must be ascribed to the inevitable errors of weighing. It is now possible to weigh weights (like the Russian standard platino-iridium pound) with an accuracy of one ten-millionth part of their weight, as is done in the St. Petersburg Weights and Measures Department. Such a degree of accuracy (greater than in any other relative but direct measurement) can only be attained by observing a great many precautions, and only when dealing with such hard and invariable bodies as platino-iridium weights. In ordinary chemical works, especially when weighing glass vessels, liquids or gases, an accuracy of one millionth (that is, a milligram in a kilogram) is scarcely attainable owing to the effect of various corrections in weighing (reducing to vacuum), friction of surfaces, &c., on the ultimate result.

^{12a} The idea of the mass of matter was first given an exact form by Galileo (died 1642), and more especially by Newton (born 1643, died 1727), in the glorious epoch marking the development of the principles of inductive reasoning enunciated by Bacon and Descartes in their philosophical treatises.

1. It is well known that iron rusts in damp air,¹³ and that when heated to redness in air it becomes coated with scale (oxide) which has, like rust, the appearance of an earthy substance and resembles some of the iron ores from which metallic iron is extracted. If the iron is weighed before and after the formation of the scale or rust, it will be found that the metal has increased in weight during the operation.¹⁴ It can easily be proved that this increase in weight is accomplished at the expense of the atmosphere, and mainly, as Lavoisier proved, at the expense of that portion which is called oxygen, and which supports combustion. In fact, in a vacuum, or in gases which do not contain oxygen, for instance, in hydrogen or nitrogen, iron neither rusts nor becomes coated with scale. Had the iron not been weighed, the participation of the oxygen of the atmosphere in its transformation into an earthy substance might easily have passed unnoticed, as was the case prior to the time of Lavoisier, when phenomena like the above were, for this reason, misunderstood. It is evident from the law of the indestructibility of matter that as iron increases in weight in its conversion into scale, the latter must be a more complex substance than iron itself, and its formation is due to a reaction of combination. We might form an entirely wrong opinion about this transformation, and might consider, for instance, the scale to be a simpler substance than iron, and explain the formation of scale as due to the removal of something from the iron. Such, indeed, was the general opinion prior to Lavoisier, when it was held that iron contained a certain unknown substance called 'phlogiston,' and that scale was iron deprived of this supposed substance.

2. When copper carbonate (in the form of a powder, or as the well-known green mineral called 'malachite,' which is used both for making ornaments and as an ore for the extraction of copper) is heated to

¹³ By covering iron with enamel, varnish, an unrustable metal (such as nickel), a coating of paraffin, or some similiar substance, it may be protected from the air and moisture, and so kept from rusting.

¹⁴ Such an experiment may easily be made by taking the finest (unrusted) iron filings (ordinary filings must be first washed in ether to remove traces of grease, then dried, and passed through a very fine sieve). The filings thus obtained are capable of burning directly in air (by oxidising or forming scale), especially when they hang (attracted) from a magnet. A compact piece of iron does not burn in air, but spongy iron glows and smoulders like tinder. In making the experiment, a horseshoe magnet is fixed, with the poles downwards, on one arm of a fairly sensitive balance, and the iron filings are applied to the magnet (on a sheet of paper) so as to form a beard or fringe about the poles. The balance pan should be exactly under the filings on the magnet, in order that any filings which might fall should not alter the weight. The filings, having been weighed, are ignited by applying the flame of a candle or lamp: they easily take fire, and go on burning by themselves, forming scale. When the combustion is ended, it will be clear that the iron has increased in weight; from $5\frac{1}{2}$ parts by weight of iron filings taken, there are obtained, by complete combustion, about $7\frac{1}{2}$ parts by weight of scale.

redness it changes into a black substance called 'copper oxide.'¹⁵ This black substance is also obtained by heating copper to redness in air—that is, it is the scale or oxidation product of copper. The weight of the black oxide of copper left is less than that of the copper carbonate originally taken, and therefore we consider the reaction which occurred to have been one of decomposition, and that by it something was separated from the green copper carbonate; in fact, by closing the orifice of the vessel in which the copper carbonate is heated, with a well-fitting cork, through which passes a gas delivery tube¹⁶ the end of which is immersed under water, it will be observed that during the heating a gas is formed which bubbles through the water. This gas can be easily collected, as will presently be described, and it will be found to differ essentially from air in many respects; for instance, a burning taper is extinguished in it just as if it had been plunged into water. If weighing had not proved to us that some substance had been separated, the formation of the gas might easily have escaped our notice, as it is colourless and transparent like air. The carbonic anhydride evolved may be weighed,¹⁷ and it will be seen that the sum of the

¹⁵ For the purpose of experiment it is most convenient to take copper carbonate, which may be prepared by the experimenter himself, by adding a solution of sodium carbonate to a solution of copper sulphate. The precipitate (deposit) so formed is collected on a filter, washed, and dried. The decomposition of copper carbonate into copper oxide and carbonate anhydride is effected by so moderate a heat that it may be carried out in a glass vessel heated by a lamp. For this purpose a thin glass tube closed at one end, and called a 'test tube,' may be employed, or else a vessel called a 'retort.' The experiment is carried on, as described in example 3 on p. 11, by collecting the carbonic anhydride over water, as will be afterwards explained.

¹⁶ Gas delivery tubes are usually made of glass tubing of various diameters and thicknesses. If of small diameter and thickness, a glass tube is easily bent by heating in a gas jet or the flame of a spirit lamp, and it may also be easily divided at a given point by making a scratch with a file and then breaking the tube at this point with a sharp jerk. These properties, together with their impermeability, transparency, hardness, and regularity of bore, render glass tubes most useful in experiments with gases. A glass gas delivery tube may be hermetically fixed into a vessel by fitting it into a perforated cork, which should be soft and free from flaws, and fixing the cork into the orifice of the vessel. To protect the cork from the action of gases it is sometimes previously soaked in melted paraffin wax, or else replaced by an indiarubber stopper.

¹⁷ Gases, like all other substances, may be weighed, but, owing to their extreme lightness and the difficulty of dealing with them in large masses, they can only be weighed on very sensitive balances; that is, on such as, with a considerable load, indicate a very small change in the weight—for example, a milligram on a load of 1,000 grams. In order to weigh a gas, a glass globe furnished with a tight-fitting stop-cock is first of all exhausted of air by an air-pump (a Sprengel pump is the best), after which the stop-cock is closed, and the exhausted globe weighed. If the gas to be weighed is then let into the globe, its weight can be determined from the increase in the weight of the globe. It is necessary, however, that the temperature and pressure of the air about the balance should remain the same for both weighings, as the weight of the globe in air varies (according to the laws of hydrostatics) with the density of the latter. The volume of the air displaced, and its weight, must therefore be determined by observing

weights of the black copper oxide and the carbonic anhydride is equal to the weight of the copper carbonate ¹⁸ originally taken.

3. When red oxide of mercury (which is formed as mercury rust by heating mercury in air) is heated, it is decomposed, like copper carbonate (only by heating more slowly and at a somewhat higher temperature), with the formation of the peculiar gas, oxygen. For this purpose the oxide of mercury is placed in a glass tube or retort, ¹⁹ to

FIG. 1.—Apparatus for the decomposition of red mercury oxide.

which a gas delivery tube is attached by means of a cork. This tube is bent downwards, as shown in the drawing (fig. 1), and its open end

the temperature, density, and moisture of the atmosphere during the time of the experiment. This will be partly explained later, but may be studied more in detail by physics. Owing to the complexity of all these operations, the mass of a gas is usually determined from its volume and its density, i.e. the weight of unit volume.

¹⁸ The copper carbonate should be dried before weighing, as otherwise—besides copper oxide and carbonic anhydride—water will be obtained in the decomposition. Water enters into the composition of malachite, and has therefore to be allowed for. The water produced in the decomposition may be all collected by absorbing it in sulphuric acid or calcium chloride, as will be described further on. In order to dry a salt it must either be heated at about 100° until its weight remains constant, or be placed under an air-pump over sulphuric acid, as will also be presently described. As water is met with almost everywhere, and as it is absorbed from the air by many substances, the possibility of its presence should never be lost sight of in weighing.

¹⁹ As the decomposition of red oxide of mercury requires so high a temperature—approaching a red heat—as to soften ordinary glass, it is necessary for this experiment to take a retort (or test tube) made of hard glass, which is able to stand high temperatures without softening. For the same reason the lamp used must give a strong heat and a large flame, capable of embracing the whole of the bottom of the retort, which should be as small as possible for the convenience of the experiment.

immersed in a vessel filled with water, called a pneumatic trough.²⁰ When the gas begins to be evolved in the retort it is obliged, having no other outlet, to escape through the gas delivery tube into the water in the pneumatic trough, and its evolution will therefore be rendered visible by the bubbles coming from this tube. On heating the retort containing the mercury oxide, the air contained in the apparatus is first partly expelled, owing to its expansion by heat, and after this the peculiar gas called 'oxygen' is evolved and may be easily collected as it comes off. For this purpose a vessel (an ordinary cylinder, as in the drawing) is filled quite full with water and its mouth closed; it is next inverted and the mouth dipped under the water in the trough and then opened. The cylinder will remain full of water—that is, the water will remain

²⁰ The pneumatic trough may naturally be made of any material (china, earthenware, metal, &c.), but a glass one, as shown in the drawing, is generally used, as it allows the progress of the experiment to be better observed. For this reason, and on account of the ease with which they are kept clean, and also owing to the fact that glass is not

FIG. 2.—Apparatus for distilling, under a diminished pressure, liquids which decompose at their boiling-points under the ordinary pressure. The apparatus in which the liquid is distilled is connected with a large globe from which the air is pumped out; the liquid is heated, and the receiver cooled.

acted on by many substances which affect other materials (for instance, metals), glass vessels of all kinds are preferred to any others for chemical experiments. A glass vessel may be heated without any danger if the following precautions be observed: 1st, it should be made of thin glass, as otherwise it is liable to crack from the bad heat-conducting power of glass; 2nd, it should be surrounded by a liquid or by sand (fig. 2), or sand bath as it is called; or else it should stand in a current of hot gases without touching the fuel from which they proceed, or in the flame of a smokeless lamp. A common candle or lamp forms a deposit of soot on a cold object placed in the flame. The soot interferes with the transmission of heat, so that a glass vessel when covered with soot often cracks. And for this reason spirit lamps, which burn with a smokeless flame, or gas burners of a peculiar construction, are used. In the Bunsen burner the gas is previously mixed with air, after which it burns with a non-luminous and smokeless flame. On the other hand, if an ordinary lamp (petroleum or benzine) does not smoke it may be used without danger for heating a glass vessel, provided the glass is placed well above the flame in the current of hot gases. In all cases the heating should be begun very carefully and the temperature gradually raised.

at a higher level in it than in the surrounding vessel, owing to the atmospheric pressure. The mouth of the cylinder is placed over the end of the gas delivery tube,²¹ and the bubbles issuing from the latter will rise into the cylinder and displace the water contained in it. Gases are generally collected in this manner. When a sufficient quantity of gas has accumulated in the cylinder it can be clearly shown that it is not air, but another gas which is distinguished by its capacity for vigorously supporting combustion. In order to show this, the cylinder is closed under water, and removed from the bath; its mouth is then turned upwards, and a smouldering taper plunged into it. As is well known, a smouldering taper will be extinguished in air, but in the gas which is given off from red mercury oxide it burns clearly and vigorously, showing the property possessed by this gas for supporting combustion more energetically than air, and thus enabling it to be distinguished from the latter. It may be observed in this experiment that, besides oxygen, there is also formed metallic mercury, which, volatilising at the high temperature required for the reaction, condenses on the cooler parts of the retort in the form of a mirror or in globules. Thus two substances, mercury and oxygen, are obtained by heating red mercury oxide. In this reaction, from a single substance, two new ones are produced—that is, a decomposition has taken place. The means of collecting and investigating gases were known before Lavoisier's time, but he first showed the real part they played in the processes of many chemical changes which before his era were either wrongly understood (as will be afterwards explained) or not explained at all, but only observed in their superficial aspects. This experiment on red oxide of mercury has a special significance in the history of chemistry contemporary with Lavoisier, because the oxygen gas which is here evolved is contained in the atmosphere, and plays a most important part in nature, especially in the respiration of animals, in combustion in air, and in the formation of rusts or scorïæ (earths, as they were then called) from metals—that is, of earthy substances, like the ores from which metals are extracted.

4. In order to illustrate by experiment one more example of chemical change and the application of the law of the indestructibility of matter, we will consider the reaction between common table salt and lunar caustic, which is well known from its use in cauterising

²¹ In order to avoid the necessity of holding the cylinder, its open end is widened (and also ground so that it may be tightly closed with a ground-glass plate when necessary), and placed on a stand below the level of the water in the bath. This stand is called 'the bridge.' It has several circular openings cut through it, and the gas delivery tube is placed under one of these, and the cylinder for collecting the gas over it.

wounds. Both these substances are soluble in water. By taking clear solutions of each of these and mixing them together, it will at once be observed that a solid white substance is formed which settles to the bottom of the vessel, and is insoluble in water. This substance may be separated from the solution by filtering. This is at once evident from the fact that it does not dissolve in water. On evaporating the liquid which passes through the filter, it will be found to contain a new substance differing from both table salt and lunar caustic, but, like them, soluble in water. Thus table salt and lunar caustic, two substances soluble in water, produce, by their mutual chemical action, two new substances, one of which is insoluble in water whilst the other remains in solution. The water serves only to convert the reacting substances into a liquid and mobile state. If the lunar caustic and salt be dried ²² and weighed, and if about $58\frac{1}{2}$ grams ²³ of the latter and 170 grams of the former be taken, then $143\frac{1}{2}$ grams of insoluble silver chloride and 85 grams of soluble sodium nitrate will be obtained. The sums of the weights of the reacting and of the resultant substances are seen to be similar ($228\frac{1}{2}$ grams), which follows necessarily from the law of the indestructibility of matter.

Accepting the truth of the above law, the question naturally arises as to whether there is any limit to the various chemical transformations, or are they unrestricted in number—that is to say, is it possible from a given substance to obtain an equal quantity of any other substance? In other words, does there exist a perpetual and infinite change of one kind of material into every other kind, or is the cycle of these transformations limited? This is the second essential problem of chemistry, a question concerning the quality of matter, and one, it is evident, more complicated than the question of quantity. It cannot be solved by a mere superficial glance at the subject. Indeed, on seeing how all the varied forms and colours of plants are built up from air and the elements of the soil, and how metallic iron can be transformed into colours such as inks and Prussian blue, we might be led to think that

²² Drying is necessary in order to remove any water which may be held in the salts (see note 18).

* ²³ The exact weights of the reacting and resulting substances are determined with the greatest difficulty, not only from possible inexactitude of the balance (every weighing is only correct within the limits of sensitiveness of the balance) and weights used, not only from the difficulty in making corrections for the weight of air displaced by the vessels containing the substances weighed and by the weights themselves, but also from the hygroscopic nature of many substances (and vessels) causing absorption of moisture from the atmosphere, and from the difficulty of not losing any of the substance to be weighed in the several operations (filtering, evaporating, drying, &c) which have to be performed before arriving at a final result. All these circumstances have to be taken into consideration in exact researches.

there is no end to the qualitative changes to which matter is susceptible. But, on the other hand, everyday experience compels us to acknowledge that food cannot be made out of a stone, nor gold out of copper. Thus a definite answer can only be looked for in a close and diligent study of the subject, and the problem has been solved in different ways at different times. In ancient times the opinion most generally held was that everything visible was composed of four elements—Air, Water, Earth, and Fire. The origin of this doctrine can be traced far back into the confines of Asia, whence it was handed down to the Greeks, and very fully expounded by Empedocles, who lived before 460 B.C. This doctrine was not the result of exact research, but apparently owes its origin to the clear division of bodies into gases (like air), liquids (like water), and solids (like the earth), and to the recognition of the changes brought about in these by fire, i.e. heat. The Arabs attempted to solve the question by experimental methods, and, by way of Spain, they introduced a taste for the study of similar problems into Europe, where from that time there appear many adepts in chemistry, which was regarded as an unholy art, and called ‘alchemy.’ As the alchemists were ignorant of any exact law which could serve as a starting-point for their researches, they obtained most anomalous results. Their chief service to chemistry was that they made a number of experiments, and discovered many new chemical transformations; but it is well known how they solved the fundamental problem of chemistry. Their view may be taken as a positive acknowledgment of the infinite transmutability of matter, for they aimed at discovering the Philosopher’s Stone, capable of converting everything into gold and diamonds, and of making the old young again. This solution of the question was afterwards completely overthrown, but it must not be thought that the hopes held by the alchemists were only the fruit of their imaginations. The first chemical experiments might well lead them to such conclusions. They took, for instance, the bright metallic mineral galena, and extracted metallic lead from it. Thus they saw that from a metallic substance which is unfitted for use they could obtain another metallic substance which is ductile and valuable for many technical purposes. Furthermore, they took this lead and obtained silver, a still more valuable metal, from it. Thus they might easily conclude that it is possible to ennoble metals by means of a series of transmutations—that is to say, to obtain from them those which are more and more precious. Having got silver from lead, they assumed that it would be possible to obtain gold from silver. The imperfection of their work is to be ascribed to the fact that, as a rule, they paid little attention to quantities, and qualitative data are very often subjective

and conditional. Had they done so, they would have learnt that the weight of the lead was much less than that of the galena from which it was obtained, and the weight of the silver infinitesimal compared with that of the lead. Had they looked more closely into the process of the extraction of silver from lead (and silver at the present time is chiefly obtained from lead ores), they would have seen that the lead does not change into silver, but that it only contains a certain small quantity of the latter, and this amount having once been separated from the lead it cannot by any further operation give more. The silver which the alchemists extracted from the lead was in the lead, and was not obtained by a chemical change of the lead itself. This is now well known from experiment, but the first view of the nature of the process was very likely to be an erroneous one.²⁴ The methods of research adopted by the alchemists could give but little success, for they did not set themselves clear and simple questions, the answers to which would aid them to make further progress. But although they did not arrive at any exact law, they nevertheless left many new experimental data as an inheritance to chemistry; they investigated, in particular, the transformations proper to metals, and for this reason chemistry was for long afterwards entirely confined to the study of metallic substances.

In their researches the alchemists made frequent use of two chemical processes which are now termed 'reduction' and 'oxidation.' The rusting of metals, and in general their conversion from a metallic into an earthy form, is called 'oxidation,' whilst the extraction of a metal from an earthy substance is called 'reduction.' Many metals—for instance, iron, lead, and tin—are oxidised by simply heating in air, and may be again reduced by heating with carbon. Such oxidised metals are found in the earth and represent one type of metallic ores. Metals such as tin, iron, and copper, may be extracted from these ores by heating them together with carbon. All these processes were studied by the alchemists. Thus the alchemists knew of two forms of chemical change: the oxidation of metals and the reduction of the oxides so formed into metals. The explanation of the nature of these

²⁴ Indeed, in the majority of cases, the first explanation of a phenomenon which does not repeat itself in everyday experience under various aspects, but always in one form, or only at intervals and infrequently, is wrong. Thus the daily rising and setting of the sun and stars evoke the erroneous idea that the heavens move and that the earth stands still. This apparent truth is far from being the real one, and, as a matter of fact, is contradictory to it. Similarly, everyday experience concludes that iron is incombustible, whereas it burns not only as filings (see note 14) but even as wire, as we shall see later. In ordinary life we often reason at first sight with perfect accuracy, only because we are taught a right judgment by our daily experience. Naturally, experiment itself cannot give truth, but it makes it possible to destroy erroneous representations and to confirm in all their consequences those which are true.

two classes of chemical phenomena was the means for the discovery of the most important chemical laws. The first hypothesis on their nature is due to Becker, and more particularly to Stahl, a surgeon to the King of Prussia. In his 'Fundamenta Chemiæ,' 1723, Stahl states that all substances consist of an imponderable fiery substance called 'phlogiston' (*materia aut principium ignis non ipse ignis*), and of another element having particular properties for each substance. The greater the capacity of a body to undergo oxidation or combustion, the richer it is in phlogiston. Carbon contains it in great abundance. In oxidation or combustion phlogiston is emitted, and in reduction it is consumed or enters into combination. Carbon reduces earthy substances because it is rich in phlogiston, a portion of which it gives up to the substance reduced. Thus Stahl supposed a metal to be a compound substance consisting of phlogiston and an earthy substance or oxide. This hypothesis is distinguished for its very great simplicity, and for this and other reasons it acquired many supporters.²⁵

Lavoisier proved by means of the balance that every case of rusting

²⁵ It is true that Stahl was acquainted with a fact which directly disproved his hypothesis. It was already known (from the experiments of Geber, and more especially those of Ray in 1630) that metals increase in weight on oxidation, whilst, according to Stahl's hypothesis, they should decrease in weight because phlogiston is given up. Stahl speaks on this point as follows:—'I am well aware that on oxidation (transformation into earths) metals increase in weight. Not only does this fact not disprove my theory, but, on the contrary, it confirms it, for phlogiston is lighter than air, and, in combining with substances, strives to lift them, and so decreases their weight; consequently a substance which has lost phlogiston must be heavier.' This argument, it will be seen, is founded on a confused idea of phlogiston itself, since it was first defined as imponderable. The conception of imponderable phlogiston tallies well with the habit and methods of the past century, when recourse was had to imponderable fluids for explaining a large number of phenomena. Heat, light, magnetism, and electricity were explained as being peculiar imponderable fluids. In this sense the doctrine of Stahl corresponds entirely with the spirit of his time. If heat be now regarded as motion or energy, then phlogiston also should be considered in this light. In fact, in combustion, of coals, for instance, heat and energy are evolved and not combined with the coal, although the oxygen and coal do combine. Consequently the doctrine of Stahl contains the essence of a true representation of the evolution of energy, but naturally this evolution is only a consequence of the combination occurring between the coal and oxygen. As regards the history of chemistry prior to Lavoisier, besides Stahl's work, Priestley's *Experiments and Observations on different Kinds of Air* (London, 1790), and also Scheele's *Opuscula Chimica et Physica* (Lips., 1788-89, 2 vols.), must be recommended as the two leading works of the English and Scandinavian chemists showing the condition of chemical learning before the propagation of Lavoisier's views, and containing also many important observations which lie at the basis of the chemistry of our times. A most interesting memoir on the history of phlogiston is that of Radwell, in the *Philosophical Magazine*, 1868, in which it is shown that the idea of phlogiston dates very far back, that Basil Valentine (1394-1415), in the *Cursus Triumphalis Antimonii*, Paracelsus (1493-1541), in his work *De Rerum Natura*, Glauber (1604-1668), and especially John Joachim Becher (1625-1682), in his *Physica Subterranea*, all referred to phlogiston, but under different names.

of metals or oxidation, or of combustion, is accompanied by an increase in weight at the expense of the atmosphere. He formed, therefore, the natural opinion that the heavier substance is more complex than the lighter one.²⁶ Lavoisier's celebrated experiment, made in 1774, gave indubitable support to his views, which in many respects were contradictory to Stahl's doctrine. Lavoisier poured four ounces of pure mercury into a glass retort (fig. 3), the neck of which was bent as shown in the drawing and dipped into the vessel R S, also full of mercury, the projecting end of the neck being covered with a glass bell-jar P. The weight of all the mercury taken, and the volume of air remaining in the apparatus, that is, in the upper portion of the retort and under the bell-jar, were determined before beginning the experiment. It was most important in this experiment to know the volume of air, in order to learn what part it played in the oxidation of

FIG. 3.—Lavoisier's apparatus for determining the composition of air and the reason of the increase in weight of metals when they are calcined in air.

the mercury, because, according to Stahl, phlogiston is emitted into the air, whilst, according to Lavoisier, the mercury in oxidising absorbs a portion of the air; consequently it was absolutely necessary to determine whether the amount of air increased or decreased during the oxidation of the metal. It was therefore most important to measure the volume of the air in the apparatus both before and after the

²⁶ An Englishman named Mayow, who lived a whole century before Lavoisier (in 1666), understood certain phenomena of oxidation in their true aspect, but was not able to develop his views with clearness or to support them by conclusive experiments; he cannot therefore be considered, like Lavoisier, as the founder of contemporary chemical learning. Science is a universal heritage, and therefore it is only just to give the highest honour in science, not to those who first enunciate a certain truth, but to those who are first able to convince others of its authenticity and to establish it for the general welfare. But scientific discoveries are rarely made all at once; as a rule, the first teachers do not succeed in convincing others of the truth they have discovered; with time, however, a true herald comes forward, possessing every means for making the truth apparent to all; but it must not be forgotten that such are indebted to the labours of many others and to the mass of data accumulated by them. Such was Lavoisier, and such are all the great founders of science.

experiment. For this purpose it was necessary to know the total capacity of the retort, the volume of the mercury poured into it, the volume of the bell-jar above the level of the mercury, and also the temperature and pressure of the air at the time of its measurement. From these data the volume of air contained in the apparatus and isolated from the surrounding atmosphere could be determined. Having arranged his apparatus in this manner, Lavoisier heated the retort for a period of twelve days at a temperature near the boiling point of mercury. The mercury became covered with a quantity of small red scales; that is, it was oxidised or converted into an earth (like lime). This substance is the same mercury oxide which has already been mentioned (example 3). After the lapse of twelve days the apparatus was cooled, and it was then seen that the volume of the air in the apparatus had diminished during the time of the experiment; a result directly contradictory to the views of the German investigator. Out of 50 cubic inches of air originally taken, there only remained 42. Lavoisier's experiment led to other equally important results. The weight of the air taken decreased by as much as the weight of the mercury increased in oxidising; that is, part of the air was not destroyed, but only combined with mercury. This portion of the air may be again separated from the mercury oxide, and has, as we have seen (example 3), properties different from those of air. It is called 'oxygen.' That portion of the air which remained in the apparatus and did not combine with the mercury does not oxidise metals, and cannot support either combustion or respiration, so that a lighted taper is immediately extinguished if it be dipped into the gas which remains in the bell-jar. 'It is extinguished in the residual gas as if it had been plunged into water,' writes Lavoisier in his memoirs. This gas is called 'nitrogen.' Thus air is not a simple substance, but consists of two gases, oxygen and nitrogen, and therefore the opinion that air is an elementary substance is erroneous. The oxygen of the air is absorbed in combustion and in the oxidation of metals, and the earths produced by the oxidation of metals are substances composed of oxygen and a metal. By mixing the oxygen with the nitrogen the same air as was originally taken is re-formed. It has also been shown by direct experiment that on reducing an oxide with carbon the oxygen contained in the oxide is transferred to the carbon, and gives the same gas as is obtained by the combustion of carbon in air. This gas is therefore a compound of carbon and oxygen, just as the earthy oxides are composed of metals and oxygen.

The many examples of the formation and decomposition of substances which are met with convince us that the majority of substances

with which we have to deal are compounds made up of several other substances. By heating chalk (or else copper carbonate, as in the second example) we obtain lime and the same carbonic acid gas which is produced by the combustion of carbon. On bringing lime into contact with this gas and water, at the ordinary temperature, we again obtain the compound, carbonate of lime, or chalk. Therefore chalk is a compound. So also are those substances from which it may be built up. Carbonic anhydride is formed by the combination of carbon and oxygen, and lime is produced by the oxidation of a certain metal called 'calcium.' By resolving substances in this manner into their component parts we arrive at last at such as are indivisible into two or more substances by any means whatever, and which cannot be formed from other substances. All we can do is to make such substances either combine with one another or act on other substances. Substances which cannot be formed from or decomposed into others are termed **simple substances** (elements). Thus all homogeneous substances may be classified into simple and compound substances. This view was introduced and established as a scientific fact during the lifetime of Lavoisier. The number of these elements is very small in comparison with the number of compound substances which are formed by them. At the present time only seventy-five elements are known with certainty to exist. Some of them are very rarely met with in nature, or are found only in very small quantities. The number of elements with whose compounds we commonly deal in everyday life does not exceed twenty-five at the present time.

Elements cannot be transmuted into one another—at least up to the present not a single case of such a transformation has been met with; it may therefore be said that as yet it is impossible to transmute one metal into another. And, notwithstanding the number of attempts which have been made in this direction, no fact has been discovered which could in any way support the idea of the complexity of such well-known elements²⁷ as oxygen, iron, sulphur, &c. Therefore, from its very conception, an element is not susceptible to reactions of decomposition.²⁸

²⁷ Many of the ancient philosophers assumed the existence of one elementary form of matter. This idea still appears in our times, in the constant efforts which are made to reduce the number of the elements; to prove, for instance, that bromine contains chlorine, or chlorine, oxygen. By many methods, founded both on experiment and theory, has it been tried to prove the compound nature of the elements. All labour in this direction has as yet been in vain, and the assurance that elementary matter is not so homogeneous (single) as the mind would desire in its first transport of rapid generalisation is strengthened from year to year.

²⁸ The weakest point in the idea of elements is the negative character of the determinative signs given them by Lavoisier, and from that time ruling in chemistry. They do

The quantity, therefore, of each element remains constant in all chemical changes ; a fact which may be deduced as a consequence of the law of the indestructibility of matter, and of the conception of the elements themselves. Thus the equation expressing the law of the indestructibility of matter acquires a new and still more important signification. If we know the quantities of the elements occurring in the reacting substances which yield, by means of chemical changes, a series of new compound substances, then the latter will together contain the same quantity of each of the elements as originally existed in the reacting substances. The essence of chemical change is embraced in the study of how and with what each element is combined before and after change.

In order to be able to express chemical changes by equations, it has been agreed to represent each element by the first or some two letters of its (Latin) name. Thus, for example, oxygen is represented by the letter O ; nitrogen by N ; mercury (hydrargyrum) by Hg ; iron (ferrum) by Fe ; and so on for all the elements, as is seen in the tables given later on. A compound substance is represented by placing side by side the symbols representing the elements of which it is made up. For example, red mercury oxide is represented by HgO , which shows that it is composed of oxygen and mercury. Besides this, the symbol of every element corresponds with a certain relative quantity of it by weight, called its ' combining ' weight, or the weight of an atom ; so that the chemical formula of a compound substance designates not only the nature of the elements of which it is composed, but also their quantitative proportion. Every chemical process may be expressed by an equation composed of the formulæ corresponding with the reacting and resulting substances. The amount by weight of each element in a chemical equation must be the same on either side of the equation, since no element is either formed or destroyed in a chemical change.

On pages 24 and 25 is given a list of the elements and their symbols; while the preface contains a table of the elements, with their combining or atomic weights, and we shall see later, on what basis the atomic weights are determined. At present we will only point out that a compound containing the elements A and B is designated by the formula $A_n B_m$, where m and n are the coefficients or multiples in which the combining weights of the elements enter into the composition of

not decompose, they do *not change* into one another. But it must be remarked that elements form the limiting horizon of our knowledge of matter, and it is always difficult to determine a positive side on the borderland of what is known. However, there is no doubt (from the results of spectrum analysis) that the elements are distributed as far as the most distant stars, and that they support the highest attainable temperatures without decomposing.

the substance. If we represent the combining weight of the substance A by a , and that of the substance B by b , then the composition of the substance A_nB_m will be expressed thus: it contains na parts by weight of the substance A and mb of B, and consequently 100 parts of our compound contain $\frac{na}{na+mb} 100$ parts by weight of the substance A and $\frac{mb}{na+mb} 100$ of the substance B. It is evident that, as a formula shows the relative amounts of all the elements contained in a compound, the actual weights of the elements contained in a given weight of the compound may be calculated from its formula. For example, the formula of table salt, NaCl, shows (since Na=23 and Cl=35.5) that 100 parts of it contain 39.3 parts of sodium and 60.7 of chlorine.

What has been said above clearly limits the range of chemical changes, because from substances of a given kind there can be obtained only such as contain the same elements. Even with this limitation, however, the number of possible combinations is infinitely great. Only a comparatively small number of compounds have yet been described or subjected to research, and anyone working in this direction may easily discover new compounds which have not before been obtained. It often happens, however, that such newly discovered compounds were foreseen by chemistry, whose object is the apprehension of that uniformity which rules over the multitude of compound substances, and the comprehension of the laws which govern their formation and properties. The conception of elements having been established, the next objects of chemistry were the determination of the properties of compound substances on the basis of the quantity and nature of the elements of which they are composed; the investigation of the elements themselves; the determination of the compound substances which can be formed from each element and the properties exhibited by these compounds; and the apprehension of the nature of the connection between the elements in the different compounds. An element thus serves as the starting-point, being taken as the primary conception on which all other substances are built up.

When we state that a certain element enters into the composition of a given compound (when we say, for instance, that mercury oxide contains oxygen), we do not mean that it contains oxygen as a gaseous substance, but only desire to express those transformations which mercury oxide is capable of undergoing; that is, we wish to say that it is possible to obtain mercury and oxygen from mercury oxide, and that it can give up oxygen to various other substances; in a word, we desire only to give expression to those transformations of which mercury oxide

is capable. Or, more concisely, it may be said that the **composition** of a compound is the expression of those transformations of which it is capable. It is useful in this sense to make a clear distinction between the conception of an element as a *separate* homogeneous *substance* and as a *material part* or *element* of a compound. Mercury oxide does not contain two simple bodies, a gas and a metal, but two elements, mercury and oxygen, which, when free, are a gas and a metal. Neither mercury as a metal nor oxygen as a gas is present in mercury oxide, which only contains the substance of these elements, just as steam only contains the substance of ice, but not ice itself; or as bread contains the substance of the corn, but not the corn itself. The existence of an element may be recognised without knowing it in the uncombined state by merely investigating its combinations, and by the knowledge that it gives, under all possible conditions, substances which are unlike other known combinations of substances. Fluorine is an example of this kind. It was for a long time unknown in the free state, but nevertheless was recognised as an element because its combinations with other elements were known, and their difference from all other similar compound substances was determined. In order to grasp the difference between the conceptions of the visible form of an element as we know it in the free state and of the intrinsic **element** (or 'radicle,' as Lavoisier called it), it should be remarked that compound substances also combine together, forming yet more complex compounds. The original compound may often be extracted from these new compounds by exactly those methods by which elements are extracted from their corresponding combinations. Further, many elements exist under various visible forms, whilst the intrinsic element contained in these various forms is something which is not subject to change. Thus carbon appears as charcoal, graphite, and diamond, but yet the element carbon, of which each consists, is one and the same. Carbonic anhydride contains carbon, and not charcoal, or graphite, or the diamond.

Many elements, although not all of them, have the peculiar lustre, opacity, malleability, and the high thermal and electrical conductivities peculiar to the metals and their mutual combinations known as alloys. But elements are far from all being **metals**. Those which do not possess the physical properties of metals are called **non-metals**. These two classes of elements are clearly distinguished in certain definite examples, but in some cases the distinction is not clear, and hence cannot serve as a basis for the exact division of the elements into two groups.

The conception of elements forms the basis of chemical knowledge,

and in giving a list of them at the very beginning of our work we wish to tabulate our present knowledge on the subject. Altogether about 80 elements are now authentically known, some of them—about six—are so rarely met with in nature, and have been obtained in such small quantities, that we possess but a very insufficient knowledge of them. The substances most widely distributed in nature contain a very small number of elements, and these have been more completely studied than the others, because a greater number of investigators have been able to make experiments and observations on them. The elements most widely distributed in nature are:—

Hydrogen,	H.	In water, and in animal and vegetable organisms.
Carbon,	C.	In organisms, coal, limestones.
Nitrogen,	N.	In air and in organisms.
Oxygen,	O.	In air, water, earth. It forms the greater part of the mass of the earth.
Sodium,	Na.	In common salt and in many minerals.
Magnesium,	Mg.	In sea-water and in many minerals.
Aluminium,	Al.	In minerals and clay.
Silicon,	Si.	In sand, minerals, and clay.
Phosphorus,	P.	In bones, ashes of plants, and soil.
Sulphur,	S.	In pyrites, gypsum, and in sea-water.
Chlorine,	Cl.	In common salt and in sea-water.
Potassium,	K.	In minerals, ashes of plants, and in nitre.
Calcium,	Ca.	In limestones, gypsum, and in organisms.
Iron	Fe.	In the earth, iron ores, and in organisms.

Besides these, the following elements, although not very largely distributed in nature, are all more or less well known from their applications to the requirements of everyday life or the arts, either in the free state or as compounds:—

Lithium	Li.	In medicine (Li_2CO_3), and in photography (LiBr).
Boron	B.	As borax, $\text{B}_4\text{Na}_2\text{O}_7$, and as boric acid, BH_3O_3 .
Fluorine,	F.	As fluor spar, CaF_2 , and as hydrofluoric acid, HF .
Chromium,	Cr.	As chromic anhydride, CrO_3 , and potassium dichromate, $\text{K}_2\text{Cr}_2\text{O}_7$.
Manganese,	Mn.	As manganese peroxide, MnO_2 , and potassium permanganate, MnKO_4 .
Cobalt,	Co.	In smalt and blue glass.
Nickel,	Ni.	For electro-plating other metals.
Copper,	Cu.	The well-known red metal.
Zinc,	Zn.	Used for the plates of batteries; in brass, &c.

Arsenic,	As.	White arsenic (poison), As_2O_3 .
Bromine,	Br.	A brown volatile liquid ; sodium bromide, NaBr .
Strontium,	Sr.	In coloured fires (SrN_2O_6).
Silver,	Ag.	The well-known white metal.
Cadmium,	Cd.	White metal. Yellow paint (CdS).
Tin,	Sn.	The well-known metal.
Antimony,	Sb.	In alloys such as type metal.
Iodine,	I.	In medicine and photography ; free, and as KI .
Barium,	Ba.	'Permanent white,' and as an adulterant in white lead, and in heavy spar, BaSO_4 .
Platinum,	Pt.	} Well-known metals.
Gold,	Au.	
Mercury,	Hg.	
Lead,	Pb.	
Bismuth,	Bi.	In medicine and fusible alloys.

The compounds of the following elements have fewer applications, but are well known, and are fairly frequently met with in nature, although in small quantities :—

Beryllium,	Be.	Palladium,	Pd.	Titanium,	Ti.
Cerium,	Ce.	Vanadium,	V.	Tungsten,	W.
Selenium,	Se.	Osmium,	Os.	Zirconium,	Zr.
Iridium,	Ir.	Molybdenum,	Mo.	Thallium,	Tl.
Thorium,	Th.	Uranium,	U.		

The compounds of the following elements are still more seldom met with in nature. They have no applications, but have been studied somewhat fully :—

Scandium,	Sc.	Germanium,	Ge.	Gallium,	Ga.
Rubidium,	Rb.	Yttrium,	Y.	Cæsium,	Cs.
Niobium,	Nb.	Lanthanum,	La.	Ruthenium,	Ru.
Neodymium,	Nd.	Praseodymium,	Pr.	Samarium,	Sm.
Rhodium,	Rh.	Ytterbium,	Yb.	Indium,	In.
Tantalum,	Ta.	Tellurium,	Te.	Erbium,	Er.

Then a special group is formed by those gaseous substances discovered by Ramsay which enter in small quantities into the composition of air, and differ from all others in that they, so far, have given no compounds with other elements ; Helium, He ; Neon, Ne ; Argon, Ar ; Krypton, Kr ; and Xenon, Xe . There are also grounds for recognising the individuality of the metals : Actinium, Polonium, and Radium (discovered by Madame Curie), which enter into the composition of

the so-called radio-active compounds, occurring in small quantities in the native compounds of Uranium and Thorium.

Besides these 77 elements may be enumerated:—Gadolinium, Terbium, Thulium, Holmium, Karolinium, and several others. But owing to their extreme rarity, their properties and combinations are very little known, and even the existence of some of them as independent substances ²⁹ is doubtful.

It has been incontestably proved, from observations on the spectra of the heavenly bodies, that many of the commoner elements (such as H, Na, Mg, Fe) occur on the far-distant stars. This fact confirms the belief that those forms of matter which appear on the earth as elements are widely distributed throughout the entire universe. But we do not yet know why the mass of some elements in nature should be greater than that of others.^{29a}

The capacity of an element to combine with other elements, and to form with them more or less stable compounds which are in a greater or less degree prone to give new and yet more complex substances, forms the fundamental character of that element. Thus sulphur combines readily with the metals, oxygen, chlorine, or carbon, whilst gold and silver enter into combination with difficulty, and form unstable compounds, which are easily decomposed by heat. We must now consider the cause or force which induces the elements to enter into chemical change, and also that which holds different substances in combination—that is, which endows the substances formed with their particular degree of stability. This cause or force is called **affinity** (*affinitas*, *affinité*, *Verwandtschaft*), or chemical affinity.³⁰ Since this force must be regarded exclusively as an attractive force like gravity, many writers (for instance, Bergmann at the end of the eighteenth, and Berthollet at the beginning of the nineteenth century) supposed affinity

²⁹ There can be no mention of such contestable and doubtful elements in a short general handbook of chemistry.

^{29a} Clark in America made an approximate calculation of the amounts of the different elements contained in the earth's crust (to a depth of 15 kilometres), and found that the chief mass (about 50 per cent.) is composed of oxygen; then come silicon (about 25 per cent.), Al, Fe, &c., while the amount of hydrogen is less than 1 per cent., carbon scarcely 0·21 per cent., nitrogen even less than 0·03 per cent. The relative masses of such metals as Cu, Ni, and Au are very minute. Judging from the density (see Chapter VIII.) of the earth, a large proportion of its mass must be composed of iron.

³⁰ This word, first introduced into chemistry, if I mistake not, by Glauber, is based on the idea of the ancient philosophers that combination can only take place when the substances combining have something in common. As is generally the case, another idea evolved itself in antiquity, and has lived until now, side by side with the first, to which it is exactly contradictory: this considers union as dependent on contrast, on polar difference, on an effort to fulfil a want.

to be essentially similar to the universal force of gravity, from which it only differs in that the latter acts at observable distances, whilst affinity only evinces itself at the smallest possible distances. But chemical affinity cannot be entirely identified with the universal attraction of gravity, for the latter is dependent only on mass and distance, and not on the quality of the material acting, whilst it is by the quality of matter that affinity is most forcibly influenced. Neither can it be entirely identified with cohesion, which gives to homogeneous solid substances their crystalline form, elasticity, hardness, ductility, and other properties, and to liquids their surface tension, drop formation, capillarity, and other properties, because affinity acts between the component parts of a substance and cohesion on a substance in its homogeneity, although both these forces act at imperceptible distances (by contact) and have much in common. Nor can chemical force, which makes one substance penetrate into another, be entirely identified even with those attracting forces which make different substances adhere to each other or hold together (as when two plane-polished surfaces of solid substances are brought into close contact), or which cause liquids to soak into solids or adhere to their surfaces, or gases and vapours to condense on the surfaces of solids. These forces must not be confounded with chemical forces, which cause one substance to penetrate into the substance of another and form a new substance, which is never the case with cohesion. But it is evident that the forces which determine cohesion form a connecting-link between mechanical and chemical forces, because they only act by intimate contact. For a long time, and especially during the first half of the nineteenth century, chemical attraction and chemical forces were identified with electrical forces. There is certainly an intimate relation between them, for electricity is evolved in chemical reactions, and has also a powerful influence on chemical processes—for instance, compounds are decomposed by the action of an electric current. And the exactly similar relation which exists between chemical phenomena and the phenomena of heat (heat being developed by chemical phenomena, and being able also to decompose compounds) only proves the unity of the forces of nature, the capability of one force to produce and to be transformed into others. But for this reason the identification of chemical force with electricity will not bear experimental proof.³¹ As of all the (molecular) phenomena

³¹ Especially conclusive are those cases of so-called metalepsis (Dumas, Chapter II.). Chlorine, in combining with hydrogen, forms a very stable substance called 'hydrochloric acid,' which is split up by the action of an electric current into chlorine and hydrogen, the chlorine appearing at the positive and the hydrogen at the negative pole. Hence electro-chemists considered hydrogen to be an electro-positive and chlorine an electro-negative element, the two being held together by virtue of their opposite electrical charges.

of nature those of heat are at present the best (comparatively) known, having been reduced to the simplest fundamental principles of mechanics (of energy, equilibrium, and movement), which since Newton have been subjected to strict mathematical analysis, it is quite natural that an effort, which has been particularly pronounced during the last ten years, should have been made to bring chemical phenomena into strict correlation with the already investigated phenomena of heat, without, however, aiming at any identification of chemical with thermal phenomena. The true nature of chemical force is still a secret to us, just as is the nature of the universal force of gravity; and yet, without knowing what gravity really is, by applying mechanical conceptions, astronomical phenomena have not only been subjected to exact generalisation, but have also been employed for the detailed prediction of a number of particular facts; and so, also, although the true nature of chemical affinity may be unknown, there is reason to hope for considerable progress in chemical science by applying to it the laws of the mechanical theory of heat. As yet this portion of chemistry has not been fully worked out, and therefore, while forming a current problem of the science, it is treated more fully in a particular branch which is termed either 'theoretical' or 'physical' chemistry, or, more correctly, *chemical mechanics*. As this province of chemistry requires a knowledge, not only of the various homogeneous substances which have as yet been obtained and of the chemical transformations which they undergo, but also of the phenomena (thermal and other kinds) by which these transformations are accompanied, it is only possible to enter on the study of chemical mechanics after becoming acquainted with the fundamental chemical conceptions and substances which form the subject of this book.³²

It appears, however, from *metalepsis* that chlorine can replace hydrogen (and, inversely, hydrogen can replace chlorine) without in any way either changing the grouping of the other elements in a compound or altering its chief chemical properties. For instance, acetic acid in which hydrogen has been replaced by chlorine is still capable of forming salts. It must be observed, while considering this subject, that the explanation suggesting electricity as the origin of chemical phenomena is unsound, since it attempts to explain one class of phenomena whose nature is almost unknown by another class which is no better known. It is most instructive to remark that together with the electrical theory of chemical attraction there arose and still survives a view which explains the galvanic current as being a transference of chemical action through the circuit—i.e. regards the origin of electricity as a chemical one. It is evident that the connection is very intimate, although the two phenomena are independent and represent different forms of molecular (atomic) motion, whose real nature is not yet understood. Nevertheless, the connection between the phenomena of both categories is not only in itself very instructive, but it extends the applicability of the general idea of the unity of the forces of nature: conviction of the truth of which held so important a place in the science of the last decade.

³² I consider that in an elementary textbook of chemistry, like the present, it is only

As the chemical changes to which substances are liable proceed from internal forces peculiar to these substances, as chemical phenomena certainly consist of motions of material parts, and as the investigation of mechanical and physical phenomena proves the **law of the indestructibility of forces**, or conservation of energy, we are inevitably obliged to acknowledge in all substances (and especially in the elements) the presence of a store of **chemical energy** or invisible motion inducing them to enter into combinations. If heat is evolved in a reaction, it means that a portion of the chemical energy is transformed into heat;³³ if heat is absorbed in a reaction,³⁴ that it is partly transformed (rendered latent) into chemical energy. The store of force or energy which can be used for the formation of new compounds may, after several combinations accomplished with loss of heat, finally diminish to such a degree that indifferent compounds will be obtained, although these, by combining with energetic elements or compounds, give more complex compounds capable of entering into chemical combination. Among elements, gold, platinum, and nitrogen have but little energy, whilst potassium, oxygen, and chlorine possess it in a very marked degree. When dissimilar substances enter into combination they often form substances of diminished energy. Thus sulphur and potassium when heated readily burn in the air, but when combined together they yield a compound which is neither inflammable nor capable of burning in air like its component parts. Part of the energy

advisable, or even possible, to mention, in reference to chemical mechanics, a few general ideas and some particular examples referring more especially to gases and such equilibrated systems as are met with in dissociation and in the passage from one physical or chemical state to another. However, during recent times, owing mainly to the labours of van't Hoff and Gibbs, this province has expanded so largely that it forms a vast section of physical (theoretical) chemistry. The present work, in treating of the general principles of chemistry, and more particularly of the theory of the elements, can only serve as an introduction to such branches of our science as organic, analytical, physical, and technical chemistry.

³³ The theory of heat gave the idea of a store of internal motion or energy, and it therefore became necessary to recognise also chemical energy, but there is no foundation whatever for identifying thermal with chemical energy. It may be assumed, but not positively affirmed, that heat motion is peculiar to molecules and chemical motion to atoms, but as molecules are made up of atoms, the motion of the one passes to the other, and for this reason heat strongly influences chemical reactions during which it also appears or disappears (is absorbed). These relations, which are apparent and hardly subject to doubt on general lines, still present much that is doubtful in detail, because all forms of molecular and atomic motion are able to pass into each other.

³⁴ The reactions which take place (at ordinary or at high temperatures) directly between substances may be clearly divided into exothermal, which are accompanied by an evolution of heat, and endothermal, which are accompanied by an absorption of heat. It is evident that for the latter to take place a source of heat is necessary, and this is furnished either by the surrounding medium, by a secondary reaction proceeding simultaneously, or by some other form of energy.

of the potassium and sulphur was evolved during their combination in the form of heat. Just as in the passage of substances from one physical state to another a portion of their store of heat is absorbed or evolved, so in combinations or decompositions, and in all other chemical processes, there occurs a change in the store of chemical energy and at the same time an evolution or absorption of heat.

For the comprehension of chemical phenomena as mechanical processes—i.e. the study of the *modus operandi* of chemical phenomena—it is most important to consider (1) the facts gathered from *stoichiometry*, or that part of chemistry which treats of the quantitative relations, by weight or volume, of the reacting substances; (2) the distinction between the different forms and classes of chemical reactions; (3) the changes in properties produced by alteration in composition; (4) the phenomena which accompany chemical transformation; (5) a generalisation of the conditions under which reactions occur. As regards stoichiometry, this branch of chemistry has been worked out most thoroughly, and comprises laws (of Dalton, Avogadro-Gerhardt, and others) which bear so deeply on all parts of chemistry that at the present time the chief problem of chemical research consists in the application of general stoichiometrical laws to concrete examples. Even the very signification of reactions of combination, decomposition, and rearrangement, acquired, as we shall see, a new and special character under the influence of the progress of exact ideas concerning the quantitative relations of substances entering into chemical changes. Furthermore, in this sense there arose a new—and, till then, unknown—division of compound substances into **definite** and **indefinite compounds**. Even at the beginning of the nineteenth century Berthollet had not made this distinction. But Prout showed that many compounds contain the substances of which they are composed or into which they break up, in exact definite proportions by weight, which are unalterable under any conditions. Thus, for example, red mercury oxide always contains sixteen parts by weight of oxygen for every 200 parts by weight of mercury, and this relation is expressed by the formula HgO . But in an alloy of copper and silver one or the other metal may be added at will, and in an aqueous solution of sugar the relative proportions of the sugar and water may be altered and yet a homogeneous whole with the sum of the independent properties will be obtained—i.e., in these cases there is indefinite chemical combination. Although in nature and chemical practice the formation of indefinite compounds (such as alloys and solutions) plays as essential a part as the formation of definite chemical compounds, yet, as the stoichiometrical laws at present apply chiefly to the latter, all data

concerning indefinite compounds suffer from inexactitude, and it is only during recent years that the attention of chemists has been directed to this province of chemistry.^{34a}

In chemical mechanics it is very important to distinguish clearly between **reversible** and **non-reversible reactions**. Substances capable of reacting on each other at a certain temperature produce substances which at the same temperature either can or cannot give back the original substances. For example, salt dissolves in water at the ordinary temperature, and the solution so obtained is capable of breaking up at the same temperature, the water being separated by evaporation and salt left behind. Carbon bisulphide is formed from sulphur and carbon at the same temperature as that at which it can be resolved into sulphur and carbon. At a certain temperature iron separates hydrogen from water, forming iron oxide, which, in contact with hydrogen at the same temperature, is able to produce iron and water. It is evident that if two substances, A and B, give two others C and D, and the reaction be reversible (that is, C and D form A and B), then, by taking definite masses of A and B, or corresponding masses of C and D, we shall obtain, in either case, all four substances—that is to say, there will be a state of **chemical equilibrium** (or distribution) existing between the reacting substances. By increasing the mass of one of the substances we obtain a new condition of equilibrium, so that reversible reactions present a means of studying the **influence of mass** on the *modus operandi* of chemical changes. Many of those reactions which occur with very complicated compounds or mixtures may serve as examples of non-reversible reactions. Thus, many of the compound substances of animal and vegetable organisms

^{34a} The question of indefinite chemical compounds, particularly of solutions and alloys and their intimate connection with definite compounds, deeply interested me from the very beginning of my scientific career (in the fifties and sixties of the nineteenth century), when but slight attention was being paid to these matters. Several of my investigations had reference to such subjects (for instance, *Specific Volumes*, 1856; *The Compounds of Alcohol with Water*, 1865; *The Study of Aqueous Solutions*, 1887, &c.), which have therefore a special charm for me. But the *Principles of Chemistry*, which deals mainly with the elements and is a textbook for beginners, can only just touch the subject. Consequently I only consider solutions and alloys cursorily in passing, and chiefly in the notes, although since the publication of van't Hoff and Gibbs's work they have formed the object of extensive research. Their study occupies an important place in recent physical and theoretical chemistry, to which I refer my readers for further details. Moreover, I am of the opinion that the position of contemporary knowledge in the sphere of indefinite compounds has not the requisite completeness and generality for it to have much influence on the general principles of chemistry (although I am convinced that in time this will be accomplished), and therefore it will be best for the beginner to attack this subject after he has become acquainted with so-called general inorganic chemistry. I therefore refrain from burdening my book with a detailed discussion of my views on the subject.

are broken up by heat, but can at no temperature be re-formed from their products of decomposition. Gunpowder, as a mixture of sulphur, nitre, and carbon, on being exploded forms gas and a powdery smoke from which the original substance cannot be re-formed at any temperature. In order to obtain them, recourse must be had to an indirect method of **combination at the moment of separation**. If A does not under any circumstances combine directly with B, it does not follow that it cannot give a compound A B. For A can often combine with C, and B with D, and if C has a great affinity for D, then the action of A C on B D produces not only C D, but also A B. As, on the formation of C D, the substances A and B (previously in A C and B D) are left in a peculiar state of separation, it is supposed that their mutual combination occurs because they meet together in this **nascent state** (*in statu nascendi*). Thus chlorine does not directly combine with charcoal, graphite, or diamond; there are, nevertheless, compounds of chlorine with carbon, and many of them are distinguished by their stability. They are obtained in the action of chlorine on hydrocarbons, as the separation products from the direct action of chlorine on hydrogen. Chlorine takes up the hydrogen, and the carbon liberated at the moment of its separation enters into combination with another portion of the chlorine, so that in the end the chlorine is combined with both the hydrogen and the carbon.

As regards the phenomena accompanying chemical action, the most important circumstance in reference to chemical mechanics is that not only do chemical processes produce mechanical displacement (a motion of particles), heat, light, electrical potential and current, but that all these agents are themselves capable of changing and governing chemical transformations. This reciprocity or reversibility naturally depends on the fact that all the phenomena of nature are only different kinds and forms of visible and invisible (molecular) motions. First sound, and then light, were shown to consist of vibratory motions, as the laws of physics have proved and developed beyond a doubt. The connection of heat with mechanical motion and work has ceased to be a supposition, and has become an accepted fact, the mechanical equivalent of heat (425 kilogram-metres of mechanical work correspond with one kilogram unit of heat, or calorie) giving a mechanical measure for thermal phenomena. It is known that both statical and dynamical electricity are produced by mechanical means (e.g. in the dynamo machines of Gramme and others), and, conversely, a current (in electric motors) can produce mechanical motion. Thus by passing a current between the poles of a Gramme dynamo it may be made to revolve, and, conversely, by rotating it an electric current is produced, which

demonstrates the reversibility of electricity and mechanical motion. Accordingly chemical mechanics must look for the fundamental lines of its advancement in the correlation of chemical with physical and mechanical phenomena. But this subject, owing to its complexity and comparative novelty, has not yet been expressed by an harmonious theory, or even by a satisfactory hypothesis, and we shall therefore not linger over it, but leave this province of physical chemistry as a special branch of our science.

A chemical change in a certain direction is accomplished not only by reason of the difference of masses, the composition of the substances concerned, the distribution of their parts, and their affinity or chemical energy, but also by reason of the **conditions** under which the substances occur. In order that a certain chemical reaction may take place between substances capable of reacting on each other, it is often necessary to have recourse to conditions which are very different from those under which the substances usually occur in nature. For example, not only is the presence of air (oxygen) necessary for the combustion of charcoal, but the latter must also be heated to redness. The red-hot portion of the charcoal burns—i.e. combines with the oxygen of the atmosphere—and in so doing evolves heat, which raises the temperature of the adjacent parts of the charcoal, so that they burn. Just as the combustion of charcoal is dependent on its being heated to redness, so also every chemical reaction only takes place under certain physical, mechanical, or other conditions. The following are the chief conditions which exert an influence on the progress of chemical reactions.

(a) *Temperature*.—Chemical reactions of combination only take place within certain definite limits of temperature, and cannot be accomplished outside these limits. We may cite as examples that the combustion of charcoal begins only at a red heat, whilst chlorine or salt only combines with water at a temperature below 0°. These latter compounds cannot be formed at a higher temperature, for they are then wholly or partially broken up into their component parts. In certain cases of combination the effect of a rise of temperature may be explained as causing one of the reacting bodies to change from a solid into a liquid or gaseous form. This conversion into the fluid state facilitates the progress of the reaction, because it aids the intimate contact of the particles reacting on each other. Another cause, and to this must be ascribed the chief influence of heat in exciting chemical action, is that the physical cohesion, or the internal chemical union, of the homogeneous particles is thereby weakened, and in this way the separation of the particles of the original substances and their transference

into new compounds are rendered easier. When a reaction absorbs heat—as in decomposition—the reason why heat is necessary is self-evident.

At the present day it may be asserted, upon the basis of existing data respecting the action of high temperatures, that all compound bodies undergo decomposition at a more or less high temperature. We have already seen examples of this in describing the decomposition of mercury oxide into mercury and oxygen, and the decomposition of wood under the influence of heat. Many substances are decomposed at very moderate temperatures; for instance, the fulminating salt employed in cartridges is decomposed at a little above 120° . The majority of those compounds which constitute the mass of animal and vegetable tissues are decomposed at 200° . On the other hand, at very low temperatures, no reaction whatever can take place. Thus plants cease to carry on their chemical processes during the winter. Raoul Pictet (1892), employing the very low temperatures (as low as -200° C.) obtained by the evaporation of liquefied gases (see Chap. II.), has proved that at temperatures below -120° , even such reactions as those between sulphuric acid and caustic soda or metallic sodium do not take place, while the coloration of litmus by acids only commences at temperatures above -80° . Every chemical reaction requires a temperature between certain limits for its accomplishment, and there is no doubt that many of the chemical changes observed by us cannot take place in the sun, where the temperature is very high, or on the moon, where it is very low.

The influence of heat on reversible reactions is particularly instructive. If, for instance, a compound which is capable of being reproduced from its decomposition products be heated up to the temperature at which decomposition begins, the decomposition of a mass of the substance contained in a definite volume will not be immediately completed. Only a certain fraction of the substance is decomposed, the other portion remaining unchanged; and if the temperature be raised, the quantity of the substance decomposed will increase. Furthermore, for a given volume the ratio between the part decomposed and the part unaltered has a certain value for every definite temperature up to that at which the compound is entirely decomposed. This partial decomposition under the influence of heat is called **dissociation**. It is possible to distinguish between the temperatures at which dissociation begins and ends. Should dissociation proceed at a certain temperature, yet should the product or products of decomposition not remain in contact with the still undecomposed portion of the compound, then decomposition will go on to the end. Thus, in a lime-kiln, limestone is

completely decomposed into lime and carbonic anhydride, because the latter is carried off by the draught of the furnace. But if a certain mass of limestone be enclosed in a definite volume—for instance, in a gun-barrel in which it is sealed up—and heated to redness, then, as the carbonic anhydride cannot escape, only a certain proportion of the limestone will be decomposed at each definite temperature higher than that at which dissociation begins. Decomposition will cease when the carbonic anhydride evolved exerts a maximum *dissociation pressure* corresponding with each temperature. If the pressure be increased by increasing the quantity of gas, then combination begins afresh; if the pressure be diminished decomposition will recommence. Decomposition in this case is exactly similar to evaporation; if the steam given off by evaporation cannot escape, its pressure will reach a maximum corresponding with the given temperature, and then evaporation will cease. Should steam be added it will be condensed in the liquid; if its quantity be diminished—i.e. if the pressure be lessened, the temperature being constant—then evaporation will go on. We shall afterwards discuss more fully these phenomena of dissociation, which were first discovered by Henri St. Claire Deville. We will only remark that the products of decomposition recombine with greater facility the nearer their temperature is to that at which dissociation begins, or, in other words, that the initial temperature of dissociation is near to the initial temperature of combination. In certain instances chemical change proceeds at a fixed temperature which may be determined like (and compared to) the melting or boiling point. A given compound will decompose above this temperature, while below it combination or formation of the compound takes place. This may be observed, not only with the aid of a thermometer, but also by the rapid change of volume (by the dilatometer) which takes place at this *critical temperature*. Thus, gypsum or dihydrated calcium sulphate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) decomposes at 107° (in a closed vessel, otherwise the water escapes as steam) into a pasty liquid mass containing three-fourths of its water in a free state and hemi-hydrated calcium sulphate ($\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$). At lower temperatures the solid dihydrated salt is again formed.

(b) *The influence of an electric current*, and of electricity in general, on the progress of chemical transformations is very similar to the influence of heat. The majority of compounds which conduct electricity are decomposed by the action of a galvanic current, and as there is great similarity in the conditions under which decomposition and combination proceed, combination often proceeds under the influence of electricity. Electricity, like heat, must be regarded as a peculiar form of molecular motion, and all that refers to the influence of

heat also refers to the phenomena produced by the action of an electric current, only with this difference, that a substance can sometimes be separated into its component parts with much greater ease by electricity, since the process goes on at the ordinary temperature. The most stable compounds may be decomposed by this means, and a very important fact is then observed—namely, that the component parts appear at the different poles or electrodes by which the current passes through the substance. Those substances which appear at the positive pole (anode) are called ‘electro-negative,’ and those which appear at the negative pole (cathode) ‘electro-positive.’ The majority of non-metallic elements, such as chlorine, oxygen, &c., and also acids and substances analogous to them, belong to the first group, whilst the metals, hydrogen, and analogous products of decomposition or ions, appear at the negative pole. Chemistry is indebted to the decomposition of compounds by the electric current for many most important discoveries. Many elements have been discovered by this method, the most important being potassium and sodium. Lavoisier and the chemists of his time were not able to decompose the oxygen compounds of these metals, but Davy showed that they might be decomposed by an electric current, the metals sodium and potassium appearing at the negative pole. Now that the dynamo gives the possibility of producing an electric current by the combustion of fuel, by water power, &c., this method of Davy is advantageously employed for obtaining metals, &c., on a large scale ; for instance, sodium from fused caustic soda, or chlorine from solutions of salt.

(c) *The action of light* also decomposes certain unstable compounds. Photography is based on such a decomposition of certain substances (for instance, the salts of silver). The mechanical energy of those vibrations which determine the phenomena of light is very small, and therefore only certain generally unstable compounds can be decomposed by light—at least under ordinary circumstances. But there is one class of chemical phenomena dependent on the action of light which forms as yet an unsolved problem in chemistry—viz., the processes accomplished in plants under the influence of light. We find here the most varied decompositions and combinations, which are often unattainable by artificial means. For instance, carbonic anhydride, which is so stable towards the influence of heat and electricity, is nevertheless decomposed, and evolves oxygen in plants under the influence of light. Chlorine combines with hydrogen, under the influence, not only of heat, but also of light, which shows that combination, as well as decomposition, can be determined by its action.

(d) *Mechanical influences*, like the foregoing agents, exert an

action on the processes of both chemical combination and decomposition. Many substances are decomposed by friction or by a blow—as, for example, the compound called iodide of nitrogen (which is composed of iodine, nitrogen, and hydrogen) and silver fulminate. Mechanical friction causes sulphur to burn at the expense of the oxygen contained in potassium chlorate. Pressure affects both the physical and chemical states of the reacting substances, and, together with the temperature, determines the condition of a substance. This is particularly evident when the substance occurs in an elastic-gaseous form, since the volume and hence also the number of points of encounter between the reacting substances are greatly altered by a change of pressure. Thus, if the temperature be kept constant, hydrogen when compressed acts more powerfully upon iodine and on the solutions of many salts than at the ordinary pressure.

(e) The *influence of time* on the progress of chemical reactions is manifested, not only by the fact that the interpenetration of bodies, giving the possibility of their reacting together, requires a mechanical translation which can only proceed with a certain velocity (thus the combustion of a solid in air is determined by the removal from it and access to it, of air, and these actions only take place with a certain limited velocity), but also in the fact that after perfect contact has taken place the internal translation, determining chemical reactions, requires time, or proceeds at a certain rate. The ageing of wine is a well-known instance, a peculiar ‘bouquet’ or aromatic essences appearing in the wine after the course of time. These essences proceed from the acids and alcohol, present in the new wine in a free state, reacting together (a double decomposition), and in the course of time forming water and aromatic esters. This reaction, which proceeds slowly at the ordinary temperature, is one of the reversible reactions (i.e. an ester and water are able to give an alcohol and an acid), taking place with a distinctly limited velocity whose value depends upon the temperature and other conditions. There are many such retardative reactions, but the majority of the more distinct chemical changes (which should form the first object of study for the beginner) proceed so rapidly that the element of time is not, as a rule, taken into consideration in their investigation.³⁵

(f) The progress of chemical reactions is also accelerated or retarded by the *condition of contact* in which the reacting bodies occur. Other conditions remaining constant, the rate of progress of a chemical reaction is accelerated by increasing the number of points of contact.

³⁵ The rate of reaction is considered more fully in *Physical Chemistry*. In the present work it is only touched upon cursorily.

It will be enough to point out the fact that sulphuric acid does not absorb ethylene under ordinary conditions of contact, but only after continued shaking, by which means the number of points of contact is greatly increased. To ensure complete action between solids, it is necessary to reduce them to very fine powder and to mix them as thoroughly as possible. Spring, the Belgian chemist, has shown that finely powdered solids which do not react on each other at the ordinary temperature may, however, do so under an increased pressure. Thus, under a pressure of 6,000 atmospheres, sulphur combines with many metals at the ordinary temperature, and mixtures of the powders of many metals form alloys.^{35a} It is evident that an increase in the number of points or surfaces must be regarded as the chief cause producing reaction, which is doubtless accomplished in solids, as in liquids and gases, in virtue of an internal motion of the particles, which motion must exist, although in different degrees and forms, in all the states of matter. It is very important to direct attention to the fact that the internal motion or condition of the particles of matter must be different on the surface of a substance from what it is inside; because in the interior of a substance similar particles are acting on all sides of any particle, whilst at the surface they act on one side only. Therefore the condition of a substance at its surfaces of contact with other substances must be more or less modified by them—possibly in a manner similar to that caused by an elevation of temperature. These considerations throw some light on the action in the large class of **contact reactions**; that is, such as appear to proceed owing to the mere presence (contact, catalysis) of certain special substances. Porous or powdery substances are very prone to act in this way, especially spongy platinum and charcoal. For example, sulphurous anhydride does not combine directly with oxygen; but this reaction takes place in the presence of spongy platinum.³⁶

^{35a} Spring, in 1888, showed that a mixture of finely powered dry non-hygroscopic salts—acetate of sodium, $C_2H_3NaO_2$, and nitrate of potassium, KNO_3 —forms a hygroscopic mass, even under the ordinary atmospheric pressure (by simply lying in dry air), owing to the formation by substitution, of a new hygroscopic salt, acetate of potassium, $C_2H_3KO_2$, and nitrate of sodium, $NaNO_3$, thus proving that solids are capable of reacting on each other.

³⁶ Contact phenomena are considered in detail in the work of Professor Konovaloff (1884). In my opinion the state of the internal motions of the atoms in molecules is modified at the points of contact of substances, and this state determines chemical reactions, so that reactions of combination, decomposition, and rearrangement are accomplished by contact. Professor Konovaloff showed that a number of substances, under certain conditions of their surfaces, act by contact; for instance, finely divided silica (from the hydrate) acts just like platinum, decomposing certain compound ethers. As reactions only take place when the reacting substances are in close contact, it is probable that those modifications in the distribution of the atoms in molecules which

The above general and introductory chemical conceptions cannot be thoroughly grasped in their true sense without a knowledge of the detailed facts of chemistry to which we shall now turn our attention. It was, however, absolutely necessary on the very threshold to become acquainted with such fundamental principles as the laws of the indestructibility of matter and the conservation of energy; since it is only by their acceptance, and under their direction and influence, that the examination of particular facts can give practical and fruitful results.

come about by contact phenomena prepare the way for them. By this the rôle of contact phenomena is considerably extended. Such phenomena should explain the fact that a mixture of hydrogen and oxygen yields water (explodes) at different temperatures, according to the nature of the heated substance which transmits the temperature. In chemical mechanics, phenomena of this kind have great importance; but as yet they have been but little studied. It must not be forgotten that contact is a necessary condition for every chemical reaction.

CHAPTER I

ON WATER AND ITS COMPOUNDS

WATER is found almost everywhere in nature, and in all three physical states. As vapour, water occurs in the atmosphere over the entire surface of the earth. The vapour of water in condensing forms snow, rain, hail, dew, and fog. One cubic metre (or 1,000 litres, or 35·316 cubic feet) of air can contain at 0° only 4·8 grams of water, at 20° about 17·0 grams, and at 40° about 50·7 grams ; but ordinary air only contains about 60 per cent. of this amount. Air containing less than 40 per cent. of the possible amount of moisture is felt to be dry, whilst air which contains more than 80 per cent. is considered as distinctly damp.¹

¹ In practice the chemist has to deal continually with gases, and gases are often collected over water; in this case a certain amount of water passes into vapour which mixes with the gases. It is therefore most important that he should be able to calculate the amount of **moisture in air and other gases**. Let us imagine a cylinder standing in a mercury bath, and filled with a dry gas whose volume equals v , temperature t° , and pressure h mm. (h millimetres of a column of mercury at 0°). We will introduce water into the cylinder in such quantity that a small part remains in the liquid state, and consequently the gas becomes saturated with aqueous vapour; the volume of the gas will then increase (if a large quantity of water be taken, some of the gas will be dissolved in it, and the volume may therefore be diminished). We will further suppose that, after the addition of the water, the temperature remains constant; then the pressure and volume are increased. In order to investigate the phenomenon we will artificially increase the pressure and reduce the volume to the original volume v . Then the pressure will be greater than h , namely, $h+f$, which means that by the introduction of aqueous vapour the pressure of the gas is increased. The researches of Dalton, Gay-Lussac, and Regnault showed that this increase f is equal to the maximum possible pressure of aqueous vapour at the temperature at which the observation is made. The maximum pressure f for all temperatures may be found in the tables made from observations on the pressure of aqueous vapour. This may be expressed thus: The maximum pressure of aqueous vapour (and of all others) is the same, no matter whether the space containing it is a vacuum or filled with a gas. This rule is known as **Dalton's law**. Thus we have a volume of dry gas v , under a pressure h , and a volume of moist gas, saturated with vapour, under a pressure $h+f$. The volume v of the dry gas under a pressure $h+f$ occupies, from Boyle's law, a volume $\frac{vh}{h+f}$; consequently the volume occupied by the aqueous vapour under the pressure $h+f$ equals $v - \frac{vh}{h+f}$, or $\frac{vf}{h+f}$. Thus the volumes of the dry gas and of the moisture which occurs in it, at a pressure $h+f$, are in the ratio $f:h$; and, therefore, if the aqueous vapour

Water in the liquid state, falling as rain and snow, soaks into the soil, and collects together into springs, lakes, rivers, seas, and oceans.

saturates a space at a pressure H , the volumes of the dry air and of the moisture which is contained in it are in the ratio $H-f : f$, where f is the pressure of the vapour according to the tables of vapour pressure. Thus, if a volume N of a gas saturated with moisture be measured at a pressure H , then the volume of the gas when dry will be equal to $N \frac{H-f}{H}$. We thus obtain the following practical rule: If a volume of a gas

saturated with aqueous vapour be measured at a pressure H mm., the volume of dry gas contained in it will be obtained by finding the volume corresponding with a pressure equal to H less the pressure due to the aqueous vapour at the temperature observed.

The preceding ratio gives the maximum quantity of water which can be held in a gas, and the degree of moisture shows what fraction of this maximum quantity occurs in any given case when the vapour does not saturate the space occupied by the gas. Thus, if it is required to measure the volume of a moist gas, it must be either thoroughly dried or quite saturated with moisture, or else the degree of moisture determined. The first and last methods are inconvenient, so that recourse is usually had to the second. For this purpose water is introduced into the cylinder holding the gas to be measured; it is left for a certain time so that the gas may become saturated, care being taken that a portion of the water remains in a liquid state; then the volume of the moist gas is determined, from which that of the dry gas may be calculated.

In order to find the **weight of the aqueous vapour** in a gas it is necessary to know the weight of a cubic measure at 0° and 760 mm. Knowing that one cubic centimetre of air under these conditions weighs 0.001293 gram, and that the density of aqueous vapour is 0.62, we find that one cubic centimetre of aqueous vapour at 0° and 760 mm. weighs 0.0008 gram, and at a temperature t° and pressure h the weight of 1 cubic centimetre will be $0.0008 \times \frac{h}{760} \times \frac{273}{273+t}$ gram. We already know that v volumes of a gas at a temperature t° and pressure h contain $v \times \frac{f}{h}$ volumes of aqueous vapour when saturated, so that the weight of the aqueous vapour held in v volumes of a gas will be

$$v \times 0.0008 \times \frac{f}{760} \times \frac{273}{273+t}.$$

Accordingly the weight of water which is contained in unit volume of a gas depends only on the temperature and not on the pressure (this is **Dalton's law**). From this it is clear that if the weight of the vapour, p , contained in a given volume of a gas be known, it is easy to determine the degree of moisture, $r = \frac{p}{v \times 0.0008} \times \frac{760}{t} \times \frac{273+t}{273}$. On this is founded the very exact determination of the degree of moisture of air from the weight of water contained in a given volume. It is easy to calculate from the preceding formula the number of grams, p , of water contained at any pressure in 1 cubic metre of a gas saturated with vapour at various temperatures; for instance, at 30° , $f = 31.5$; hence $p = 29.84$ grams.

The laws of Mariotte, Dalton, and Gay-Lussac, which are here applied to gases and vapours, are not perfectly exact, but are approximately true. In fact the pressure of aqueous vapour is slightly less in a gas than in a vacuum, and the weight of aqueous vapour held in a gas is slightly less than it should be according to Dalton's law, as was shown by the experiments of Regnault and others. The difference does not, however, exceed 5 per cent. of the total pressure of the vapours. This **decrement in vapour pressure** which occurs in the intermixture of vapours and gases, although small, indicates that there is then already, so to speak, a beginning of chemical change. The essence of the matter is that in this case there occurs, as on contact (see preceding

It is absorbed from the soil by the roots of plants, which when fresh contain from 40 to 80 per cent. of their weight of water. Animals contain about the same proportion of water. In a solid state, water appears as snow or ice, or in a state intermediate between these two, which is seen on mountains covered with perpetual snow. The water of rivers,²

footnote), an alteration in the motions of the atoms in the molecules, and therefore also a change in the motion of the molecules themselves.

In the uniform intermixture of air and other gases with aqueous vapour, and in the ability of water to pass into vapour and form a uniform mixture with air, we have an instance of a physical phenomenon which is analogous to chemical phenomena, and forms indeed a transition from the one class of phenomena to the other. Between water and dry air there exists a kind of affinity which obliges the water to saturate and mix with the air. But such a homogeneous mixture is formed (almost) independently of the nature of the gas into which evaporation takes place; even in a vacuum the phenomenon occurs in exactly the same way as in a gas, and therefore it is not the property of the gas, nor its relation to water, but the property of the water itself, which compels it to evaporate, so that in this case chemical affinity is not yet operative—or at least its action is not clearly pronounced. That it does, however, play a certain part is seen from the deviation from Dalton's law.

² In falling through **the atmosphere, water** dissolves the gases of the air, nitric acid, ammonia, organic compounds, salts of sodium, magnesium, and calcium, and mechanically washes out a mixture of dust and microbes suspended in the atmosphere. The amount of these and certain other constituents is very variable. Even between the beginning and end of the same rainfall a variation which is often very considerable may be remarked. Thus, for example, Bunsen found that rain collected at the beginning of a shower contained 3·7 grams of ammonia per cubic metre, whilst that collected at the end of the same shower contained only 0·64 gram. The water of the entire shower contained an average of 1·47 gram of ammonia per cubic metre. In the course of a year rain supplies an acre of ground with as much as 15 kilos of nitrogen in a combined form. Marchand found in one cubic metre of snow water 15·63, and in one cubic metre of rain water 10·07, grams of sodium sulphate. Angus Smith showed that after thirty hours' rainfall at Manchester the rain still contained 34·3 grams of salts per cubic metre. A considerable amount of organic matter, namely, 25 grams per cubic metre, has been found in rain water. The total amount of solid matter in rain water reaches 50 grams per cubic metre. Rain water generally contains very little carbonic acid, whilst in river water there is a considerable quantity of it. In considering the nourishment of plants it is necessary to keep in view the substances which are carried into the soil by rain.

River water contains from 50 to 1,600 parts by weight of salts in 1,000,000 parts. The amounts of solid matter per 1,000,000 parts by weight contained in the chief rivers are as follows:—The Don 124, the Loire 135, the St. Lawrence 170, the Rhone 182, the Dnieper 187, the Danube from 117 to 234, the Rhine from 158 to 317, the Seine from 190 to 432, the Thames at London from 400 to 450, in its upper parts 387, and in its lower parts up to 1,617, the Nile 1,580, and the Jordan 1,052. The Neva is characterised by the remarkably small amount of solid matter it contains. From the investigations of Prof. G. K. Trapp, a cubic metre of Neva water contains 32 grams of incombustible and 23 grams of organic matter, or altogether about 55 grams. This is one of the purest waters met with in a river. The large amount of impurities in river water, and especially of organic impurity produced by pollution with putrid matter, makes the water of many rivers unfit for use.

The chief part of the soluble substances in river water consists of calcium salts. A hundred parts of the solid residues contain the following amounts of calcium carbonate: from the water of the Loire 53, from the Thames about 50, the Elbe 55, the Vistula 65, the Danube 65, the Rhine from 55 to 75, the Seine 75, the Rhone from 82 to 94. The Neva contains 40 parts of calcium carbonate per 100 parts of saline matter. The considerable

springs, oceans and seas, lakes and wells, contains various substances in solution, mostly salts—that is, substances resembling common

amount of calcium carbonate which river water contains is very easily explained from the fact that water which contains carbonic acid in solution easily dissolves calcium carbonate, which occurs all over the earth. Besides calcium carbonate and sulphate, river water contains the chlorides and other salts of magnesium, sodium, potassium, aluminium, iron, and manganese. The presence of nitrates has been proved with certainty in almost all kinds of well-investigated river water. The quantity of calcium phosphate does not exceed 0.4 gram in the water of the Dnieper, and the Don does not contain more than 5 grams. The water of the Seine contains about 15 grams of nitrates, and that of the Rhone about 8 grams. The amount of ammonia is much less: thus in the water of the Rhine there is about 0.5 gram in June and 0.2 gram in October. The water of the Seine contains the same amount. This is less than in rain water. Notwithstanding this insignificant quantity, the water of the Rhine alone, which is not so very large a river, carries about 16 tons of ammonia into the ocean every day. The difference between the amounts of ammonia in rain and river water depends on the fact that the soil through which the rain water passes is able to retain the ammonia and also many other substances, such as phosphoric acid, potassium salts, &c.

The water of springs, rivers, wells, and in general of those places from which it is taken for drinking purposes, may be injurious to health if it contains much organic pollution, the more so as in such water the lower organisms (bacteria) may rapidly develop, and these organisms often serve as the carriers or causes of infectious diseases. For instance, certain pathogenic (disease-producing) bacteria are known to produce typhoid, the Siberian plague, and cholera. Thanks to the work of Pasteur, Metchnikoff, Koch, and many others, this province of research has made considerable progress. It is possible to investigate the number and properties of the germs in water. In *bacteriological researches* a gelatinous medium in which the germs can develop and multiply is prepared with gelatine and water, which has previously been heated several times, at intervals, to 100° (it is thus rendered sterile; that is to say, all the germs in it are killed). The water to be investigated is added to this prepared medium in a definite and small quantity (sometimes diluted with sterilised water to facilitate the calculation of the number of germs), protected from dust (which contains germs), and then left at rest until whole families of lower organisms are developed from the separate germs. These families (colonies) are visible to the naked eye (as spots), and may be counted; and by examining them under the microscope, and observing the number of organisms they produce, their significance may be determined. The majority of bacteria are harmless, but there are undoubtedly pathogenic kinds whose presence is one of the causes of malady and of the spread of certain diseases. The number of bacteria in 1 cubic centimetre of water sometimes attains the immense figures of hundreds of thousands and millions. Certain well, spring, and river waters contain very few bacteria, and are free from disease-producing bacteria under ordinary circumstances. By boiling water the bacteria in it are killed, and therefore boiled water is less harmful for drinking purposes than fresh water. The best kinds of water for drinking purposes do not contain more than 300 bacteria in a cubic centimetre.

The amount of the gases dissolved in river water is much more constant than that of its solid constituents. One litre, or 1,000 grams, of water contains 40 to 55 c.c. of gas measured at normal temperature and pressure. In winter the amount of gas is greater than in summer or autumn. Assuming that a litre contains 50 c.c. of gases, it may be admitted that these consist on an average of 20 vols. of nitrogen, 20 vols. of carbonic anhydride (proceeding in all likelihood from the soil and partly from the atmosphere), and 10 vols. of oxygen. If the total amount of gases be less, the constituent gases are still in about the same proportion; in most cases, however, carbonic anhydride predominates. The water of many deep and rapid rivers contains less carbonic anhydride, which shows that they have been rapidly formed from atmospheric water, and that they

table salt in their physical properties and chief chemical transformations.³ Further, the quantity and nature of these salts differ

have not succeeded during a long and slow course in absorbing a greater quantity of carbonic anhydride. Thus, for instance, the water of the Rhine, near Strassburg, according to Deville, contains 8 c.c. of carbonic anhydride, 16 c.c. of nitrogen, and 7 c.c. of oxygen per litre. From the researches of Prof. M. R. Kapoustin and his pupils, it appears that in determining the quality of a water for drinking purposes it is most important to investigate the composition of the dissolved gases, more especially as regards the oxygen present.

³ **Spring water** is formed from rain water percolating through the soil. Naturally a part of the rain water is evaporated directly from the surface of the earth and from the vegetation on it. It has been shown that out of 100 parts of water falling on the earth only 36 parts flow to the ocean; the remaining 64 are evaporated or percolate far underground. After flowing underground along some impervious strata, water comes out at the surface in many places as springs whose temperature is determined by the depth from which the water has flowed. Springs penetrating to a great depth may become considerably heated, and this is why hot mineral springs, with a temperature of 30° and higher, are often met with. When a spring water contains substances which endow it with a peculiar taste, and especially if these substances are such as are only found in minute quantities in river and other flowing waters, it is termed a **mineral water**. Many such waters are employed for medicinal purposes. Mineral waters are classed according to their composition into—(a) saline waters, which often contain a large amount of common salt; (b) alkaline waters, which contain sodium carbonate; (c) bitter waters, which contain magnesia; (d) chalybeate waters, which hold iron carbonate in solution; (e) aerated waters, which are rich in carbonic anhydride; (f) sulphuretted waters, which contain hydrogen sulphide. Sulphuretted waters may be recognised by their smell of rotten eggs, and by their giving a black precipitate with lead salts, and also by their tarnishing silver objects. Aerated waters, which contain an excess of carbonic anhydride, effervesce in the air, have a sharp taste, and redden litmus paper. Saline waters leave a large residue of soluble solid matter on evaporation, and have a salt taste. Chalybeate waters have an inky taste, and are coloured black by an infusion of galls; on being exposed to the air they usually give a brown precipitate. The character of a mineral water is generally a mixed one. In the table below, analyses are given of certain mineral springs which are valued for their medicinal properties. The quantity of the substances present in the water is expressed in millionths by weight.

in different waters. Everybody knows that there are salt, fresh, iron, and other waters. The presence of about $3\frac{1}{2}$ per cent. of salts renders sea water⁴ bitter to the taste and increases its specific gravity. Fresh water also contains salts, but only in a comparatively small quantity (not above 1 per cent.) Their presence may be easily proved by simply evaporating water. On evaporation the water passes away as vapour, whilst the salts are left behind. This is why a crust consisting of salts, previously in solution, is deposited on the insides of kettles, boilers, and other vessels in which water is boiled. Running water (rivers &c.) is charged with salts, owing to its being formed from the collection of rain water percolating through the soil. During this percolation the water dissolves certain parts of the soil. Thus water which filters or passes through saline or calcareous soils becomes charged with salts or calcium carbonate (chalk). Rain water and snow are much purer than river or spring water. Nevertheless, in passing through the atmosphere, rain and snow succeed in

average of analyses by Herman, Zinin, and Fritzsche. IV. Bougountouksky, alkaline spring No. 17, Essentoukah, Caucasus (temp. 21.6°), analysis by Fritzsche. V. Vichy water, France, analysis by Berthier and Puvy. XI. Paramo de Ruiz, Colombia, analysis by Levy. This water is distinguished by the amount of free acids present.

⁴ **Sea water** contains more non-volatile saline constituents than the common types of fresh water. This is explained by the fact that the waters flowing into the sea supply it with salts, and whilst a large quantity of vapour is given off from the surface of the sea the salts remain behind. Even the specific gravity of sea water differs considerably from that of pure water. It is generally about 1.02, but in this, and also in the amount of salts present, samples of sea water from different localities and from different depths present rather remarkable variations. It will be sufficient to point out that 1 cubic metre of water from the undermentioned localities contains the following quantity in grams of solid constituents:—Gulf of Venice, 19,122; Leghorn Harbour, 24,312; the Mediterranean, near Cetta, 37,665; the Atlantic Ocean, from 32,585 to 35,695; and the Pacific Ocean, from 34,708 to 35,233. In closed seas which do not communicate, or are in very distant communication, with the ocean, the difference is often still greater. Thus the Caspian Sea contains 6,300 grams; the Black Sea and Baltic, 17,700. Common salt forms the chief constituent of the saline matter of sea or ocean water; thus in 1 cubic metre of sea water there are 25,000–31,000 grams of common salt, 2,600–6,000 grams of magnesium chloride, 1,200–7,000 grams of magnesium sulphate, 1,500–6,000 grams of calcium sulphate, and 10–700 grams of potassium chloride. The small amount of the organic matter and of the salts of phosphoric acid in sea water is very remarkable. Sea water (the composition of which is partially discussed in Chapter X.) contains, in addition to salts of common occurrence, a certain and sometimes minute amount of the most varied elements, even gold and silver; and as the mass of water of the oceans is so enormous these ‘traces’ of rare substances amount to large quantities, so that it may be hoped that in time methods will be found to extract even gold from sea water, which by means of the rivers forms a vast reservoir for the numerous products of the changes taking place on the earth’s surface.

catching the dust held in it and in dissolving air, which is found in every water. When water is heated the dissolved gases of the atmosphere are partly disengaged, as bubbles, and, after long boiling, water is quite freed from these gases.

In general terms water is called pure when it is clear and free from insoluble particles held in suspension and visible to the naked eye, from which it may be freed by filtration through charcoal, sand, or porous (natural or artificial) stones, and when it possesses a clean fresh taste. It depends on the absence of any taste of decomposing organic matter, on the quantity of air⁵ and atmospheric gases in solution, and on the presence of mineral substances to the amount of about 300 grams per ton (or 1,000 kilograms per cubic metre, or, what is the same, 300 milligrams to a kilogram or a litre of water), and of not more than 100 grams of organic matter.⁶ Such water is suitable for drinking and

⁵ The taste of water is greatly dependent on the quantity of dissolved gases it contains. These gases are given off on boiling, and it is well known that, even when cooled, boiled water has, until it has absorbed gaseous substances from the atmosphere, quite a different taste from fresh water containing a considerable amount of gas. The dissolved gases, especially oxygen and carbonic anhydride, have an important influence on the health. The following instance is very instructive in this respect. The Grenelle artesian well at Paris when first opened supplied a water which had an injurious effect on men and animals. It appeared that this water did not contain oxygen, and was in general very poor in gases. As soon as it was made to fall in a cascade, by which it absorbed air, it proved quite fit for consumption. In long sea voyages fresh water is sometimes not taken at all, or only taken in a small quantity, because it spoils by keeping and becomes putrid, owing to the decomposition of the organic matter it contains. Fresh water may be obtained directly from sea water by distillation. The distilled water no longer contains sea salts, and is therefore fit for consumption, but it is very tasteless, and has the properties of boiled water. In order to render it palatable certain salts, which are usually present in fresh water, are added to it, and it is made to flow in thin streams exposed to the air in order that it may become saturated with the component parts of the atmosphere—that is, absorb gases.

⁶ **Hard water** is such as contains much mineral matter, and especially a large proportion of calcium salts. Such water, owing to the amount of lime it contains, does not form a lather with soap, prevents vegetables boiled in it from softening properly, and forms a large amount of incrustation on vessels in which it is boiled. When of a high degree of hardness it is injurious for drinking purposes, as is evident from the fact that in several large cities the death-rate has been found to decrease after introducing a soft water in place of a hard one. Water containing decomposed organic matter may be purified by means of Condylé's fluid (potassium permanganate). A solution of this substance, even if very dilute, is of a red colour; on adding it to a putrid water the permanganate oxidises and destroys the organic matter. It is added to water in such a quantity as to impart to it an almost imperceptible rose colour. It is especially salutary to add a small quantity of Condylé's fluid to impure water in times of epidemic.

The presence in water of 1 gram per litre, or 1,000 grams per cubic metre, of any substance whatsoever renders it unfit, and even injurious, for consumption, and this is so, no matter whether organic or mineral matter predominates. The presence of 1 per cent. of chlorides makes water quite salt, and produces thirst instead of assuaging it. A large amount of nitrates is only found in impure and usually injurious water, as they often indicate the presence of decomposing organic matter.

every practical application, but evidently it is not pure in a chemical sense. A **chemically pure water** is necessary not only for scientific purposes, as an independent substance having constant and definite properties, but also for many practical purposes—for instance, in photography and in the preparation of medicines—because many properties of substances in solution are changed by the impurities of natural waters. Water is usually purified by distillation, because the solid substances in solution are not transformed into vapours in this process, and any gases in solution are driven off during the boiling. Such **distilled** water is prepared by chemists and in laboratories by boiling water in closed metallic boilers or stills, and causing the steam produced to pass into a condenser—that is, through tubes (which should be made of tin, or, at all events, tinned, as water and its impurities do not act on tin) surrounded by cold water, and in which the steam, being cooled, condenses into water which is collected⁷ in a receiver. By standing exposed to the atmosphere, however, the water in time absorbs air, and dust carried in the air. Nevertheless, in distillation, water retains, besides air, a certain quantity of volatile impurities (mostly organic), and the walls of the distillation apparatus are partly

⁷ Distilled water may be prepared on a small scale in the laboratory in a glass retort (fig. 4) heated by a lamp. Fig. 4 illustrates the main parts of the usual glass laboratory

FIG. 4.—Distillation from a glass retort. The neck of the retort fits into the inner tube of the Liebig's condenser. The space between the inner and outer tubes of the condenser is filled with cold water, which enters by the tube *g* and flows out at *f*.

apparatus used for distillation. The steam issuing from the retort (on the right-hand side) passes through a glass tube surrounded by a larger tube, through which passes a stream of cold water, by which the steam is condensed and runs into a receiver (on the left-hand side).

corroded by the water, and a portion, although only a small one, of their substance renders the water not entirely pure, so that a residue is left on evaporation.⁸

For certain physical and chemical researches, however, it is necessary to have perfectly pure water. To obtain it, a solution of potassium permanganate is added to distilled water until the whole has a faint rose colour. By this means the organic matter in the water is destroyed (converted into gases or non-volatile substances). An excess of potassium permanganate does no harm, because in the next distillation it is left behind in the distillation apparatus. This second distillation should take place in a platinum retort with a platinum receiver. Platinum is a metal which is not acted on either by air or water, and therefore nothing passes from it into the water. The water obtained in the receiver still contains air. It must then be boiled for a long time, and afterwards cooled in a vacuum under the receiver of an air-pump, and must be kept in air-tight vessels. Pure water does not leave any residue on evaporation; does not in the least change, however long it is kept; does not decompose like water only once distilled or impure; and does not give bubbles of gas on heating, nor does it change the colour of a solution of potassium permanganate.

Water, purified as above described, has constant **physical and chemical properties**. For instance, it is of such water only that one cubic centimetre weighs one gram at 4° C.—i.e. it is only such pure water whose specific gravity equals 1 at 4° C.⁹ Water in a solid state

⁸ One of Lavoisier's first memoirs (1770) referred to this question. He investigated the formation of the earthy residue in the distillation of water in order to prove whether it was possible, as was affirmed, to convert water into earth, and he found that the residue was produced by the action of the water on the sides of the vessel containing it, and not from the water itself. He proved this to be the case by direct weighing.

⁹ Taking the generally accepted specific gravity of water at its greatest density—i.e. at 4°—as unity, it has been shown by experiment that the specific gravity of water at different temperatures is as follows:—

At	0°	.	.	.	0.99987	At	20°	.	.	.	0.99823
„	+ 10°	.	.	.	0.99973	„	30°	.	.	.	0.99568
„	15°	.	.	.	0.99913	„	100°	.	.	.	0.95859

A comparison of all the data at present known shows that the variation of the specific gravity S_t with the temperature t (determined by the hydrogen thermometer) may be expressed (Mendeléeff, 1896) between -5° and $+40^\circ$ C. by the formula

$$S_t = 1 - \frac{(t - 4)^2}{118932 + 1366.75t - 4.13t^2}.$$

If the temperature be determined by the mercurial thermometer, whose indications between 0° and 100° are slightly higher than those of the hydrogen thermometer (for example, about 0.1° C. at 20°), then a slightly higher sp. gr. will be obtained for a given t .

Water at 4° is taken as the basis for reducing measures of length to measures of weight and volume. The **metric or decimal system** of measuring weights and volumes is universally employed in science. The starting-point of this system is the metre (39.37

forms crystals of the hexagonal system,¹⁰ seen in snow, which generally consists of starlike clusters of several crystals, and also in the half-melted scattered ice floating on rivers in spring time. But ice also occurs, like many solids, in an amorphous (non-crystalline) form.

The temperatures at which water passes from one state to another are taken as fixed points on the thermometer scale; namely, the zero corresponds with the temperature of melting ice, and the temperature of the steam disengaged from water boiling at the normal barometric pressure (that is, 760 millimetres measured at 0°, at the latitude of 45°, at the sea level) is taken as 100° of the Celsius scale. Thus, the facts that ice liquefies at 0° and water boils at 100° are taken as characteristics of a definite chemical compound. The weight of a litre of water at 4° is 1,000 grams, and at 0°, 999.87 grams. The weight of a litre of ice at 0° is less—namely, 916 grams (according to Vincenna, 1902, the coefficient of cubical expansion of ice is 0.000152); the weight of the same cubic measure of water vapour at 760 mm. pressure and 100° is only 0.60 gram; the density of the vapour compared with that of air is 0.62, and compared with that of hydrogen, 9.

These data briefly characterise the physical properties of water as

inches) divided into decimetres (=0.1 metre), centimetres (=0.01 metre), millimetres (=0.001 metre), and microns (= one millionth of a metre). A cubic decimetre is called a **litre**, and is used for the measurement of volumes. The weight of a litre of water in a vacuum at 4° is called a kilogram. Platino-iridium standard samples of the **kilogram** and metre have been established by international treaty, and their prototypes have been distributed in many countries, with the object of establishing a uniformity of weights and measures. In Russia the law (1899) sanctions the use of the metric system on a par with the Russian by the mutual consent of the negotiating parties. The thousandth part of a kilogram weighs one **gram**. It is divided into decigrams, centigrams, and milligrams (=0.001 gram). An English pound equals 453.59 grams. The great advantage of this system is that it is a decimal one, and that it is universally adopted in science and in international relations. *All the measures cited in this work are metric.* The units most often used in science are:—Of length, the centimetre; of weight, the gram; of time, the second; of temperature, the degree Centigrade of the hydrogen thermometer.

According to the most trustworthy determinations the weight of a c. dcm. of water at 4° in vacuo is about 1 decigram less than a kilogram. For ordinary purposes the weight of a c. dcm. may be taken as equal to a kg. Hence the litre (or more truly the weight of water it holds) is equal to about 1000.1 cub. decimetres.

¹⁰ As solid substances appear in individual regular crystalline forms which are dependent, judging from their cleavage or lamination (in virtue of which mica breaks up into laminae, and Iceland spar, &c., into pieces bounded by faces inclined to each other at angles which are definite for each substance), on an inequality of attraction (cohesion elasticity) in different directions which intersect at definite angles, the determination of crystalline form affords one of the most important characteristics for identifying definite chemical compounds. The elements of crystallography, which is a special science, should therefore be familiar to all who desire to work in scientific chemistry. In this work we shall only have occasion to speak of a few crystalline forms, some of which are shown in figs. 5 to 11. But solids not only occur in crystalline forms determined by inequalities of cohesion and elasticity in different directions, by which (as also by their

a separate substance. To this may be added that water is a mobile liquid, colourless, transparent, without taste or smell, &c. Its latent

optical and electrical properties) they differ distinctly from liquids (which are of uniform structure in all directions, or isotropic), but also in an amorphous or isotropic state—without any difference of structure in different directions—which is best illustrated by

heat of vaporisation is 538 units, and that of liquefaction 79 units of heat.¹¹ The large amount of heat stored up in water vapour and also in

glass. When a solid forms by solidification from a liquid (i.e., from a molten state) it generally appears in an amorphous state, and only passes into a crystalline form by the agency of other bodies (especially crystals and such like substances) or under certain conditions of temperature and pressure. This subject, especially since Prof. Tamman's (Yurieff University, 1890–1902) recent researches, is of great interest, not only from a physico-mechanical, but also from a chemical point of view.

¹¹ Of all known liquids, water exhibits the greatest **cohesion** of particles. Indeed, it ascends in capillary tubes to a greater height than other liquids; for instance, two and a half times as high as alcohol, nearly three times as high as ether, and to a much greater height than oil of vitriol, &c. In a tube 1 mm. in radius, water at 0° ascends 15·3 mm., measuring from the height of the liquid to two-thirds of the height of the meniscus, and at 100° it rises 12·5 mm. The cohesion varies very uniformly with the temperature; thus at 50° the height of the capillary column equals 13·9 mm.—that is, the mean between the heights at 0° and 100°. This uniformity is not destroyed even at temperatures near the freezing-point, and hence it may be assumed that at high temperatures cohesion will vary as uniformly as at ordinary temperatures; so that at some temperature near 370° water should not ascend in a capillary tube. The cohesion between the particles of water would then be nil, and a peculiar critical state is attained of which mention will be made presently. Only certain solutions (sal-ammoniac and lithium chloride)—and these only with a great excess of water—rise higher than pure water in capillary tubes. The great cohesion of water doubtless determines many of both its physical and chemical properties.

The quantity of heat required to raise the temperature of one part by weight of water from 0° to 1°, i.e., by 1° C., is called the *unit of heat* or calorie; the **specific heat of liquid water** at 0° is taken as equal to unity. The variation of this specific heat with rise of temperature is inconsiderable in comparison with the variation exhibited by the specific heats of other liquids. The specific heat of water at 20° is 0·993, and at 100°, 1·073. The specific heat of water is greater than that of any other known liquid; for example, the specific heat of alcohol at 0° is 0·55—i.e., the quantity of heat which raises the temperature of 55 parts of water 1° raises that of 100 parts of alcohol 1°. The specific heat of oil of turpentine at 0° is 0·41, of ether 0·53, of acetic acid 0·5274, and of mercury 0·033. Hence water is the best condenser or absorber of heat. This property of water has an important significance in practice and in nature. Water prevents rapid cooling or heating, and thus tempers cold and heat. The specific heats of ice and aqueous vapour are much less than that of water, that of ice being 0·504, and that of steam 0·48.

With an increase in pressure equal to one atmosphere, the compressibility of water is 0·000047, of mercury 0·00000352, and of ether 0·00012 at 0°. The addition of various substances to water generally decreases both its compressibility and cohesion. The compressibility of other liquids increases with a rise of temperature, but for water it decreases up to 53° and then increases as with other liquids.

The **expansion of water** by heat (note 9) also exhibits many peculiarities which are not found in other liquids. The expansion of water at low temperatures is very small compared with that of other liquids: at 4° it is almost zero, and at 100° it is equal to 0·0008; below 4° it is negative—i.e., water on cooling does not then decrease in volume, but expands. In passing into the solid state, the specific gravity of water decreases; at 0° 1 c.c. of water weighs 0·99987 gram, and 1 c.c. of ice at the same temperature weighs only 0·916 gram. The ice formed, however, contracts on cooling like the majority of other substances. Thus 100 volumes of ice are produced from 92 volumes of water—that is, water expands considerably on freezing, which fact determines a number of natural phenomena. The freezing-point of water falls with an increase in pressure (0·007° per atmosphere), because water in freezing expands (Thomson), whilst with substances which contract in solidifying, the melting-point rises with an increase in

liquid water (for its specific heat is greater than that of other liquids)

pressure; thus, paraffin under one atmosphere melts at 46° , and under 100 atmospheres at 49° . The above proves that, under very considerable pressures, the densities of water and ice tend to become equal, and that a point may be reached where ice will sink under water. This has been confirmed by Tamman's researches (1890-1902) on the influence of temperature and pressure on the formation of amorphous and crystalline solids from liquids.

When liquid water passes into vapour the cohesion of its particles must be destroyed, as the particles are removed to such a distance from each other that their mutual attraction no longer exhibits any influence. As the cohesion of aqueous particles varies at different temperatures, the quantity of heat which is expended in overcoming this cohesion—or the **latent heat of evaporation**—will for this reason alone be different at different temperatures. The quantity of heat which is consumed in the transformation of one part by weight of water, at different temperatures, into vapour was determined with great accuracy by Regnault, Griffiths (1895), and others. It is found that one part by weight of water at 0° , in passing into vapour having a temperature t° , consumes $640 + (t - 100) 0.6$ units of heat; that is, at 100° , 640, and at 200° , 700 heat units. But this quantity includes also the quantity of heat required for heating the water from 0° to t° —i.e., besides the latent heat of evaporation, also that heat which is used in heating the water in a liquid state to a temperature t° . On deducting this amount of heat, we obtain the latent heat of evaporation of water as 598 at 0° , 538 at 100° , and 478 at 200° . From this we may conclude that at a certain temperature no heat would be required for the conversion of water into vapour. At this temperature, water passes into vapour, whatever be the pressure (see Chap. II. The absolute boiling-point of water is about 365°). It must here be remarked that water, in presenting a greater cohesion, requires a larger quantity of heat for its conversion into vapour than other liquids.

The whole amount of heat which is consumed in the conversion of water into vapour is not used in overcoming the cohesion—that is, in internal work accomplished in the liquid. A part of this heat is employed in moving the aqueous particles; in fact, aqueous vapour at 100° occupies a volume 1,650 times greater than that of water (at the ordinary pressure); consequently a portion of the heat or work is employed in lifting the aqueous particles, in overcoming pressure, or in external work, which may be usefully employed, and which is so employed in steam engines. In order to determine this work let us consider the variation of the maximum **vapour pressure of steam** at different temperatures. The observations of Regnault in this connection, as on those preceding, deserve special attention owing to their comprehensiveness and accuracy. The pressure of aqueous vapour at various temperatures is given in the subjoined table, and is expressed in millimetres of the barometric column reduced to 0° .

Temperature	Pressure	Temperature	Pressure
-20°	0.9	70°	233.3
-10°	2.1	90°	525.4
0°	4.6	100°	760.0
$+10^{\circ}$	9.1	105°	906.4
15°	12.7	110°	1075.4
20°	17.4	115°	1269.4
25°	23.5	120°	1491.3
30°	31.5	150°	3581.0
50°	92.0	200°	11689.0

This table shows the boiling-points of water at different pressures. Thus on the summit of Mont Blanc, where the average pressure is about 424 mm., water boils at 84.4° ; and at a pressure of five atmospheres (five times the ordinary atmospheric pressure—i.e., $5 \times 760 = 3,800$ mm.) the temperature of the water would be 152° . As a column of mercury 1 mm. high exerts a pressure of 13.596 grams on a

renders it available in both forms for heating purposes.¹² The chemical reactions which water undergoes, and by means of which it is formed,

surface of 1 sq. cm., the pressure of the atmosphere, 760 mm., corresponds with a pressure of 1033·28 grams per square centimetre. This means that if a cylinder be taken whose sectional area equals 1 sq. cm., and if water be poured into it and it be closed by a piston weighing 1,033 grams, then on heating it *in a vacuum* to 100° no steam will be formed, because the steam cannot overcome the pressure of the piston; and if at 100° 538 units of heat be transmitted to each unit of weight of water, then the whole of the water will be converted into vapour having the same temperature. The question now arises, to what height does the piston rise under these circumstances; that is, in other words, what is the volume occupied by the steam under a known pressure? For this we must know the weight of a cubic centimetre of steam at various temperatures. It has been shown by experiment that the density of steam, with reference to air at the same temperature and pressure, is 0·62. Steam which saturates a space varies in density at different temperatures, but this difference is very small, and its average density with reference to air is 0·64. Now one cubic centimetre of air at 0° and 760 mm. weighs 0·001293 gram, while at 100° and under the same pressure it will weigh $\frac{0·001293}{1·368}$ or

about 0·000946 gram, and consequently one cubic centimetre of steam whose density is 0·64 will weigh 0·000605 gram at 100°, and one gram of aqueous vapour will occupy a volume of about 1,653 c.c. Consequently the piston in the cylinder of 1 sq. cm. sectional area, and in which the water occupied a height of 1 cm., will be raised 1,653 cm. on the conversion of this water into steam. This piston, as has been mentioned, weighs 1,033 grams, therefore the **external work of the steam**—that is, that work which the water does in its conversion into steam at 100°—is equal to lifting a piston weighing 1,033 grams to a height of 1,653 cm., or 17·07 kilogram-metres of work—i.e., is capable of lifting 17 kilograms 1 metre, or 1 kilogram 17 metres. One gram of water requires for its conversion into steam 538 gram units of heat or 0·538 kilogram unit of heat—i.e., the quantity of heat absorbed in the evaporation of one gram of water is equal to the quantity of heat which is capable of heating 1 kilogram of water 0·538°. Each unit of heat, as has been shown by accurate experiment, is capable of doing 425 kilogram-metres of work. Hence, in evaporating, one gram of water expends $425 \times 0·538 =$ (almost) 227 kilogram-metres of work. The external work was found to be only 17 kilogram-metres; therefore 210 kilogram-metres are expended in overcoming the internal cohesion of the aqueous particles, and consequently about 92 per cent. of the total heat or work is consumed in overcoming the internal cohesion.

The work necessary for overcoming the internal cohesion of water in its passage into vapour decreases with the rise in temperature; that is, corresponds with the decrease of cohesion; and the variations which take place in this case are very similar to those which are observed in the heights to which water rises in capillary tubes at different temperatures. It is evident, therefore, that the amount of external—or, as it is termed, useful—work which water can supply by its evaporation is very small compared with the amount which it expends in its conversion into vapour.

It is evident from the above considerations that, even in a physical change of state, the greatest part of the work done is employed in overcoming cohesion, but an enormous amount of internal energy must be expended in overcoming chemical cohesion or affinity.

¹² When it is necessary to heat a considerable mass of liquid in different vessels, it would be very uneconomical to make use of metallic vessels and to construct a separate furnace for each. Such cases are continually met with in practice. Steam from a boiler is introduced into the liquid, or, in general, into the vessel which it is required to heat. The steam, in condensing and passing into a liquid state, parts with its latent heat; and as this is very considerable a small quantity of steam will produce a considerable heating effect. If it be required, for instance, to heat 1,000 kilos of water from 20° to 50°, which requires approximately 30,000 units of heat, steam at 100° is passed into the water

are so numerous, and so closely allied to the reactions of many other substances, that it is impossible to describe the majority of them at this early stage of chemical exposition. We shall become acquainted with many of them afterwards, but at present we shall only cite certain compounds formed by water. In order to see clearly the nature of the various kinds of compounds formed by water, we will begin with the most feeble, which are determined by purely mechanical superficial properties of the reacting substances.

Water is mechanically attracted by many substances: it adheres to their surfaces just as dust adheres to objects, or one piece of polished glass adheres to another. Such attraction is termed 'moistening,' 'soaking,' or 'absorption of water.' Thus water is absorbed by the soil, sand, and clay, and does not flow away from them, but lodges itself between their particles. Similarly, water soaks into a sponge, cloth, hair, or paper, &c.; but fat and greasy substances in general are not moistened. Attraction of this kind does not alter the physical or chemical properties of water. For instance, under these circumstances water, as is known from everyday experience, may be expelled from objects by drying. Water which is in any way held mechanically may be dislodged by mechanical means, by friction, pressure, centrifugal force, &c. Thus water is squeezed from wet cloth by pressure or centrifugal machines. But objects which in practice are called dry (because they do not feel wet) often still contain moisture, as may be proved by heating the object in a glass tube closed at one end. On placing a piece of paper, dry earth, or any similar object (especially porous substances) in such a glass tube, and heating that part of the tube where the object is situated, it will be remarked that water condenses on the cooler portions of the tube. The presence of such absorbed, or 'hygroscopic,' water is generally best detected in non-volatile substances by drying them either at 100° , or under the receiver of an air-pump and over substances which attract water chemically. By weighing a substance before and after drying, it is easy to determine the amount of hygroscopic water from the loss in weight.¹³ But in

from a boiler. Each kilogram of water at 50° contains about 50 units of heat, and each kilogram of steam at 100° contains 640 units of heat; therefore each kilogram of steam in cooling to 50° gives up 590 units of heat, and consequently 51 kilos of steam are capable of heating 1,000 kilos of water from 20° to 50° . Water is very often applied for heating in chemical practice. For this purpose metallic vessels or pans, called 'water-baths,' are made use of. They are closed by a cover formed of concentric rings lying on each other. The vessels—such as beakers, evaporating basins, retorts, &c.—containing liquids, are placed on these rings, and the water in the bath is heated. The steam given off heats the bottom of the vessels to be heated, and thus effects the evaporation or distillation.

¹³ In order to dry any substance at about 100° —that is, at the boiling-point of water

this case the amount of water must be judged with care, because the loss in weight may sometimes proceed from the decomposition of the

(hygroscopic water passes off at this temperature)—an apparatus called a 'drying-oven' is employed. It consists of a double copper box; water is poured into the space between the internal and external boxes, and the oven is then heated over a stove or by any other means, or else steam from a boiler is passed between the walls of the two boxes. When the water boils, the temperature inside the inner box will be approximately 100°C . The substance to be dried is placed inside the oven, and the door is closed. Several holes are cut in the door to allow the free passage of air, which carries off the aqueous vapour by the chimney on the top of the oven. Often, however, desiccation is carried on in copper ovens heated directly over a lamp (fig. 12). In this case any desired temperature may be obtained, and is determined by a thermometer fixed in a special orifice. In order to determine directly the amount of water in a substance which

FIG. 12.—Drying oven, constructed of brazed copper. It is heated by a lamp. The object to be dried is placed on the gauze inside the oven. The thermometer indicates the temperature.

does not part with anything except water at a red heat, the substance is placed in a bulb tube. By first weighing the tube empty and then with the substance to be dried in it, the weight of the substance taken may be found. The tube is then connected on one side with a gas-holder full of air, which, on opening a stop-cock, passes first through a flask containing sulphuric acid, and then into a

FIG. 13.—Determination of the quantity of water in a substance by heating it (in D) in a stream of air proceeding from A and dried in B and C; the water from the substance in D is collected in E and weighed.

vessel containing lumps of unice-stone moistened with sulphuric acid. In passing through these vessels

substance itself, with disengagement of gases or vapour. In making exact weighings the hygroscopic capacity of substances—that is, their capacity to absorb moisture—must be continually kept in view, as otherwise the weight will be untrue owing to the presence of moisture. The quantity of moisture absorbed depends on the degree of moisture of the atmosphere (that is, on the pressure of the aqueous vapour in it) in which a substance is situated. In a perfectly dry atmosphere, or in a vacuum, the hygroscopic water is expelled, being converted into vapour; therefore substances containing hygroscopic water may be completely dried by placing them in a dry atmosphere or in a vacuum. The process is aided by heat, which increases the pressure of the aqueous vapour. Phosphoric anhydride (a white powder), liquid sulphuric acid, solid and porous calcium chloride, and the white powder of ignited copper sulphate, are most generally employed in drying gases. They absorb the moisture contained in air and all gases to a considerable, but not unlimited, extent. Phosphoric anhydride and calcium chloride deliquesce, become damp, sulphuric acid changes from a thick oily liquid into a more mobile one, and ignited copper sulphate becomes blue; after which changes these substances partly lose their capacity of holding water, and can, if it be in excess, even give up their water to the atmosphere. We may remark that the order in which these substances are placed above corresponds with the order in which they stand in respect to their capacity for absorbing moisture. Air dried by calcium chloride still contains a certain amount of moisture, which it can give up to sulphuric acid. The most complete desiccation takes place with phosphoric anhydride. Water is also removed from many substances by placing them in a dish over a vessel containing a substance absorbing water under a glass bell jar.¹⁴

the air is thoroughly dried, having given up all its moisture to the sulphuric acid. Thus dry air will pass into the bulb tube. The moisture given up by the substance in the tube will be carried off by the air passing through it. This damp air then passes through a **U**-shaped tube full of pieces of pumice-stone moistened with sulphuric acid, which absorbs all the moisture given off from the substance in the bulb tube. Thus all the water expelled from the substance will collect in the **U**-tube; and so, if this be weighed before and after, the difference will show the quantity of water expelled from the substance. If only water (and no gases) come over, the increase of the weight of the **U**-tube will be equal to the decrease in the weight of the bulb tube.

¹⁴ Instead of under a glass bell jar, drying over sulphuric acid is often carried on in a desiccator consisting of a shallow wide-mouthed glass vessel, closed by a well-fitting ground-glass cover. Sulphuric acid is poured over the bottom of the desiccator, and the substance to be dried is placed on a glass stand above the acid. A lateral glass tube with a stop-cock is often fused into the desiccator in order to connect it with an air pump, and so allow drying under a diminished pressure, when the moisture evaporates more rapidly. The fact that, in the usual form of desiccator, the desiccating substance (sulphuric acid) is placed beneath the substance to be dried has the disadvantage that the moist air, being lighter than dry air, distributes itself in the upper portion of the desiccator and not below.

The bell jar, like the receiver of an air pump, should be hermetically closed. In this case desiccation takes place because the sulphuric acid, for instance, first dries the air in the bell jar by absorbing its moisture, the substance to be dried then parting with its moisture to the dry air from which it is again absorbed by the sulphuric acid, &c. Desiccation proceeds still better under the receiver of an air pump, for then the aqueous vapour is formed more quickly than in a bell jar full of air.

From what has been said above, it is evident that the transference of moisture to gases and the absorption of hygroscopic moisture present great resemblance to, but still are not, chemical combinations with water. Water, when combined as hygroscopic water, does not lose its properties and does not form new substances.¹⁵

The attraction of water for substances which dissolve in it is of a different character. In the solution of substances in water a peculiar kind of indefinite combination goes on, a new homogeneous substance being formed from the two substances taken. But here also the bond connecting the substances is very unstable. Water containing different substances in solution boils at a temperature near to its usual boiling-point. From the solution of substances which are lighter than water; as, for example, in the solution of alcohol in water; whilst a heavier substance in dissolving in water gives it a higher specific gravity. Thus salt water is heavier than fresh.¹⁶

Aqueous solutions have a special interest because they are constantly being formed on the earth and in the waters of the earth, in plants and in animals, in chemical processes and in the arts; and these solutions play an important part in the chemical transformations which are everywhere taking place, because a substance in solution presents the most favourable conditions for the execution of chemical changes, which require a mobility of parts and a possible distension of

Hempel, in his desiccator (1891), avoids this by placing the absorbent above the substance to be dried. The process of desiccation can be further accelerated by cooling the upper portion of the desiccator, and so inducing ascending and descending currents of air within the apparatus.

¹⁵ Chappuis, however, determined that in the wetting of 1 gram of charcoal with water, 7 units of heat are evolved, and on pouring carbon bisulphide over 1 gram of charcoal as much as 24 units of heat are evolved. Alumina (1 gram), when moistened with water, evolves $2\frac{1}{2}$ calories. This indicates that in respect to evolution of heat moistening already represents a step towards exothermal combinations (those evolving heat in their formation).

¹⁶ Strong acetic acid ($C_2H_4O_2$), whose specific gravity at 15° is 1.055, does not become lighter on the addition of water (a lighter substance, sp. gr. = 0.999), but heavier, so that a solution of 80 parts of acetic acid and 20 parts of water has a specific gravity of 1.074; and even a solution containing equal parts of acetic acid and water (50 per cent.) has a sp. gr. of 1.065, which is still greater than that of acetic acid itself. This shows the high degree of contraction which takes place on solution. In fact, solutions—and, in general, liquids—on mixing with water, usually decrease in volume.

parts. In dissolving, a solid substance acquires a mobility of parts, and a gas loses its elasticity, and therefore reactions which do not proceed in the undissolved substances often take place in solutions. Further, a substance, distributed in water, evidently breaks up—that is, becomes more like a gas. All these considerations require that, in describing the properties of substances, particular attention should be paid to their relation to water as a universal solvent.

To demonstrate the solubility of gases in water, a gas should be taken which has a high coefficient of solubility—for instance,

FIG. 14.—Method of transferring a gas into a cylinder filled with mercury, the open end of which is immersed under the mercury in a bath having two glass sides. The apparatus containing the gas is represented on the right. Its upper extremity is furnished with a tube extending under the cylinder. The lower part of the vessel communicates with a vertical tube. If mercury be poured into this tube, the pressure of the gas in the apparatus is increased, and it passes through the gas-conducting tube into the cylinder, where it displaces the mercury, and can be measured or subjected to the action of absorbing agents, such as water.

ammonia. This is introduced into a bell jar (or cylinder, as in fig. 14), which is previously filled with mercury and stands in a mercury bath. If water be then introduced into the cylinder, the mercury will rise, owing to the water dissolving the ammonia gas. If the column of mercury be less than the barometric column, and if there be sufficient water to dissolve the gas, all the ammonia will be absorbed by the water. The water is introduced into the cylinder by a glass pipette with a bent end. The bent end is put into water, and the air is sucked out from the upper end. When full of water, its upper end is

closed with the finger, and the bent end placed in the mercury bath under the orifice of the cylinder. On blowing into the pipette the water will rise, owing to its lightness, to the surface of the mercury in the cylinder. The solubility of a gas like ammonia may be demonstrated by taking a flask full of the gas, and closed by a cork with a tube passing through it. On placing the tube under water, the water will rise into the flask (this may be accelerated by previously warming the flask), and begin to play like a fountain inside it. Both the rising of the mercury and the fountain clearly show the considerable affinity of water for ammonia gas, and the force acting in this dissolution is rendered evident. A certain period of time is required both for the homogeneous intermixture of gases (diffusion) and the process of solution, which depends not only on the extent of the surface of the participating substances, but also on their nature. This may be seen from experiment. Solutions of different substances heavier than water, such as salt or sugar, are poured into tall jars. Pure water is then very carefully poured into these jars (through a funnel) on to the top of the solutions, so as not to disturb the lower stratum, and the jars are then left undisturbed. The line of demarcation between the solution and the pure water will be visible, owing to the difference of their coefficients of refraction. Notwithstanding, however, that the solutions taken are heavier than water, after some time complete intermixture will ensue. Gay-Lussac convinced himself of this fact by this particular experiment, which he conducted in the cellars under the Paris Astronomical Observatory. These cellars are well known as the locality where numerous interesting researches have been conducted, because, owing to their great depth under ground, they have a uniform temperature during the whole year; the temperature does not change during the day, and this was indispensable for the experiments on the diffusion of solutions, in order that no doubt as to the results should arise on account of a daily change of temperature (the experiment lasted several months), which would set up currents in the liquids and intermix their strata. Notwithstanding the uniformity of the temperature, the substance in solution in time ascended into the water and distributed itself uniformly through it, proving that there exists between water and a substance dissolved in it a particular kind of attraction or striving for mutual interpenetration in opposition to the force of gravity. Further, this effort, or rate of diffusion, is different for salt or sugar or other substances.^{16a} It follows therefore that a

^{16a} Graham in the jelly formed by gelatine, and De Vries in gelatinous silica (Chapter XVIII.), most frequently employed coloured (tinted) substances, for instance, $K_2Cr_2O_7$, which showed the rate of diffusion with very great clearness. Prof. Oumoff

peculiar force acts in solution, just as in actual chemical combinations, and solution is determined by a particular kind of motion (by the chemical energy of a substance) which is proper to the substance dissolved and to the solvent.

Graham made a series of experiments similar to those described above, and showed that the **rate of diffusion of solutions**¹⁷ into water is very variable—that is, a uniform distribution of a substance in the water dissolving it is attained in different periods of time with different solutions. Graham compared diffusive capacity with volatility. There are substances which diffuse easily, and there are others which diffuse with difficulty, just as there are more and less volatile substances. Seven hundred cubic centimetres of water were poured into a jar, and by means of a siphon (or a pipette) 100 cubic centimetres of a solution containing 10 grams of a substance were cautiously poured in so as to occupy the lower portion of the jar. After a lapse of several days successive layers of 50 cubic centimetres were taken from the top downwards, and the quantity of substance dissolved in the different layers determined. Thus, common table salt, after fourteen days, gave the following amounts (in milligrams) in the respective layers, beginning from the top: 104, 120, 126, 198, 267, 340, 429, 535, 654, 766, 881, 991, 1,090, 1,187, and 2,266 in the remainder; whilst albumin in the same time gave a very small amount in the first seven layers, and beginning from the eighth layer, 10, 15, 47, 113, 343, 855, 1,892, and in the remainder 6,725 milligrams. Thus, the diffusive power of a solution depends on time and on the nature of the substance dissolved; which fact may serve not only for explaining the process of solution, but also for distinguishing one substance from another. Graham showed that substances which diffuse rapidly through liquids are able to pass rapidly through membranes and to crystallise, whilst substances which diffuse slowly and do not crystallise are **colloids**, that is, resemble glue, and penetrate through a membrane

employed for this purpose glass bulbs of known density which were heavier than water and lighter than the liquid whose diffusion was being studied, and observed the rate of diffusion from the position of the bulbs, which showed the density of the solution and its composition in a given layer.

¹⁷ The researches of Graham, Fick, Nernst, and others showed that the quantity of a dissolved substance which is transmitted (rises) from one stratum of liquid to another in a vertical cylindrical vessel is not only proportional to the time and to the sectional area of the cylinder, but also to the amount of the substance dissolved in a stratum of liquid, so that to every dissolved substance there corresponds its own coefficient of diffusion. The cause of the diffusion of solutions must be considered as essentially the same as that of the diffusion of gases—that is, as dependent on motions peculiar to their molecules—but here most probably those purely chemical, although feebly developed, forces, which incline the substances dissolved to the formation of indefinite compounds with the water, also play their part.

slowly,¹⁸ and form jellies, as will be explained in speaking of silica (Chapter XVIII.)

Hence, if it be desired to increase the rate of solution, recourse must be had to stirring, shaking, or some such mechanical motion.

¹⁸ The rate of diffusion—like the rate of transmission—through membranes, or **dialysis** (which plays an important part in the vital processes of organisms and also in technical processes), presents, according to Graham's researches, a sharply defined change in passing from such crystallisable substances as the majority of salts and acids to substances which are capable of giving jellies (gum, gelatin, &c.) The former diffuse into solutions and pass through membranes much more rapidly than the latter, and Graham therefore distinguishes between **crystalloids**, which diffuse rapidly, and **colloids**, which diffuse slowly. On breaking solid colloids into pieces, a total absence of cleavage is remarked. The fracture of such substances is like that of glue or glass, and is termed 'conchoidal.' Almost all the substances of which animal and vegetable bodies consist are colloids, and this is, at all events partly, the reason why animals and plants have such varied forms, which have no resemblance to the crystalline forms of the majority of mineral substances. The colloid solid substances in organisms—that is, in animals and plants—almost always contain water, and take most peculiar forms, such as networks, granules, hairs, shapeless mucous masses, &c., which are quite different from the forms taken by crystalline substances. When colloids separate out from solutions, or from a molten state, they present a form which is similar to that of the liquid from which they are formed. Glass may be taken as the best example of this. Colloids are distinguishable from crystalloids, not only by the absence of crystalline form, but by many other properties which admit of clearly distinguishing these two classes of solids, as was shown by Graham. Nearly all colloids are capable of passing, under certain circumstances, from a soluble into an insoluble state. The best example is shown by white of eggs (albumin) in the raw and soluble form, and in the hard-boiled and insoluble form. The majority of col-

FIG. 15. - Dialyser. Apparatus for the separation of substances which pass through a membrane from those which do not. Description in text.

loids, on passing into an insoluble form in the presence of water, give substances having a gelatinous appearance, which is familiar to everyone in starch, solidified glue, jelly, &c. Thus gelatine or common carpenter's glue, when soaked in water, swells up into an insoluble jelly. If this jelly is heated, it melts, and is then soluble in water, but on cooling it again forms a jelly which is insoluble in water. One of the properties which distinguish colloids from crystalloids is that the former pass very slowly through a membrane, whilst the latter penetrate very rapidly. This may be shown by taking a cylinder, open at both ends, and by covering its lower end with a bladder or with vegetable parchment (unsized paper immersed for two or three minutes in a mixture of sulphuric acid and half its volume of water, and then washed), or any other membranous substance (all such substances are themselves colloids in an insoluble form). The membrane must be firmly tied to the cylinder, so as not to leave any opening. Such an apparatus is called a **dialyser** (fig. 15), and the process of separation of crystalloids from colloids by means of such a membrane is termed **dialysis**. An aqueous solution of a crystalloid or colloid, or a mixture of both, is poured into the dialyser, which is then placed in a vessel containing water, so that the bottom of the membrane is covered with

But if once a uniform solution is formed, it will remain uniform, no matter how heavy the dissolved substance, or how long the solution be left at rest; which fact again shows the presence of a force holding together the particles of the dissolved body and of the solvent.¹⁹

water. Then, after a certain period of time, the crystalloid passes through the membrane, whilst the colloid, if it does pass through at all, does so at an incomparably slower rate. The crystalloid passes through into the water until finally the solution attains the same strength on both sides of the membrane. By replacing the outside water with fresh water, a fresh quantity of the crystalloid may be separated from the dialyser. While the crystalloid is passing through the membrane the colloid remains almost entirely in the dialyser, and therefore mixed solutions of these two kinds of substances may be separated from each other by a dialyser.

¹⁹ The formation of solutions may be considered in two aspects, from a physical and from a chemical point of view; and it is more evident in solutions than in any other department of chemistry how closely these provinces of natural science are allied. On the one hand solutions form a particular case of a physico-mechanical interpenetration of homogeneous substances, and a juxtaposition of the molecules of the substance dissolved and of the solvent, similar to the juxtaposition which is exhibited in homogeneous substances. From this point of view the diffusion of solutions is exactly similar to the diffusion of gases, with only this difference, that the nature and store of energy are different in gases from what they are in liquids, and that in the latter there is considerable friction, whilst in gases there is comparatively little. The penetration of a dissolved substance into water is likened to evaporation, and solution to the formation of vapour. This resemblance was clearly expressed even by Graham, and the Dutch chemist van't Hoff has developed this view of solutions in great detail, having shown (in a memoir in the *Transactions of the Swedish Academy of Science*, 'Lois de l'équilibre chimique dans l'état dilué, gazeux ou dissous,' 1886) that for dilute solutions the *osmotic pressure* follows the same laws (of Boyle, Mariotte, Gay-Lussac, and Avogadro-Gerhardt) as do gases. The **osmotic pressure** of a substance dissolved in water is determined by means of membranes which allow water, but not a substance dissolved in it, to pass through them. This property is found in animal protoplasmic membranes and in porous substances covered with an amorphous precipitate, such as is obtained by the action of copper sulphate on potassium ferrocyanide (Pfeffer, Traube). If a 1 per cent. solution of sugar is placed in such a vessel, which is then closed and placed in water at 70°, the water passes through the walls of the vessel and increases the pressure by 50.5 cm. of the barometric column (= 0.664 atmosphere). If the pressure be artificially increased inside the vessel, then the water will be expelled through the walls. De Vries found a convenient method of determining *isotonic* solutions (those presenting a similar osmotic pressure) by means of the cells of plants. For this purpose a portion of the soft part of the leaves of the *Tradescantia discolor*, for instance, is cut away and moistened with the solution of a given salt and of a given strength. If the osmotic pressure of the solution taken be less than that of the sap contained in the cells, the latter will change their form or shrink; if, on the other hand, the osmotic pressure be greater than that of the sap, then the cells will expand, as can easily be seen under the microscope. By altering the amount of the different salts in solution it is possible to find for each salt the strength of solution at which the cells begin to swell, and at which they will consequently have an equal osmotic pressure. As it increases in proportion to the amount of a substance dissolved per 100 parts of water, it is possible, knowing the osmotic pressure of a given substance—for instance, sugar at various degrees of concentration of solution—and also the composition of isotonic solutions compared with sugar, to determine the osmotic pressure of all the substances investigated. The osmotic pressure of dilute solutions determined in this manner directly or indirectly (from observations made by Pfeffer and De Vries) was shown to follow the same laws as those of the pressure of gases; (1) by doubling or increasing the quantity of a salt (in a given volume) n times, the pressure is

In the consideration of the process of solution, besides the conception of diffusion, another fundamental conception is necessary—namely, that of **saturated solutions**.

doubled or increases n times. Thus, for example, in a solution containing one part of sugar per 100 parts of water, the osmotic pressure (according to Pfeffer) is 53.5 cm. of mercury; if 2 parts of sugar are present, 101.6; if 4 parts, 208.2, and so on; which proves that the ratio is true within the limits of experimental error. (2) Equally concentrated solutions of different substances show very different osmotic pressures, just as equal weights of gases in equal volumes show different pressures. (3) If, for a given dilute solution at 0° , the osmotic pressure equal p_0 , then at t° it will be greater and equal to $p^\circ (1 + 0.00367t)$, i.e., it increases with the temperature in exactly the same manner as the pressure of gases increases. (4) If in dilute solutions of such substances as do not conduct an electric current (for instance, sugar, acetone, and many other organic bodies) the substances be taken in the ratio of their molecular weights (expressed by their formulæ, see Chapter VII.), then not only will the osmotic pressure be the same in all cases, but its magnitude will be determined by that pressure which would be exerted by the vapours of the given substances if they were contained in the space occupied by the solution, just as the pressure of the vapours of molecular quantities of the given substances in equal volumes will be equal, and determined by the laws of Gay-Lussac, Mariotte, and Avogadro-Gerhardt. Those formulæ (Chapter VII., Notes 23 and 24) by which the gaseous state of matter is determined, may also be applied in the present case. Thus, for example, the osmotic pressure p , in centimetres of mercury, of a 1 per cent. solution of sugar, may be calculated according to the formula for gases—

$$Mp = 6200 s (273 + t),$$

where M is the molecular weight, s the weight in grams of a cubic centimetre of vapour, and t its temperature. For sugar $M = 342$ (because its molecular composition is $C_{12}H_{22}O_{11}$). The specific gravity of the solution of sugar is 1.003, so that the weight of sugar s contained in a 1 per cent. solution = 0.01003 gram. The observation was made at $t = 14^\circ$. Hence, according to the formula, we find $p = 52.2$ centimetres. And experiments carried on at 14° gave 53.5 centimetres, which is very near to the above number. (5) For the solutions of salts, acids, and similar substances, which conduct an electric current, the calculated pressure is usually (but not always) a definite or multiple number of times i less than the observed value, and this i for dilute solutions of $MgSO_4$ is nearly 1; for CO_2 , 1; for KCl , $NaCl$, KI , KNO_3 greater than 1 and approximating to 2; for $BaCl_2$, $MgCl_2$, K_2CO_3 , and others between 2 and 3; for HCl , H_2SO_4 , $NaNO_3$, CaN_2O_6 and others nearly 2, and so on. It should be remarked that the above deductions are only applicable (with any degree of accuracy) to dilute solutions. Nevertheless, the arithmetical relation found by van't Hoff between the formation of vapours and the transition into dilute solutions forms an important scientific discovery, which should facilitate the explanation of the nature of solutions, while the osmotic pressure of solutions already forms a very important aspect of their study. In this respect it is necessary to mention that Prof. Konovaloff (1891, and subsequently others also) discovered the dependence (and it may be a sufficient explanation) of the osmotic pressure upon the differences of the pressures of aqueous vapours and aqueous solutions; this, however, takes us into a special province of physical chemistry (certain data are given in Note 49 and following), and to this physical side of the question belongs also one of the extreme consequences of the resemblance of osmotic pressure to gaseous pressure, which is that the concentration of a uniform solution varies in parts which are heated or cooled. Soret (1881) indeed observed that a solution of copper sulphate containing 17 parts of the salt at 20° only contained 14 parts after heating the upper portion of the tube to 80° for a long period of time; that is to say, the lower portion of the solution was richer in salt.

This aspect of solution, which is now being very carefully and fully worked out, may be called the *physical* side. Its other aspect is purely *chemical*, for solution does not take place between any two substances, but requires a special and particular attraction or

Just as moist air may be diluted with any desired quantity of dry air, so also an indefinitely large quantity of a liquid solvent may be taken, and yet a uniform solution will be obtained. But more than a definite quantity of aqueous vapour cannot be introduced into a certain volume of air at any given temperature. The excess above that re-

chemical affinity between them. A vapour or gas permeates any other vapour or gas, but a salt which dissolves in water may not be in the least soluble in alcohol, and is quite insoluble in mercury. In considering solutions as a manifestation of chemical force (and of chemical energy), it must be acknowledged that they are here developed to so feeble an extent that the definite compounds (that is, those formed according to the law of multiple proportions) formed between water and a soluble substance dissociate even at the ordinary temperature, forming a homogeneous system—that is, one in which both the compound and the products into which it decomposes (water and the aqueous compound) occur in a liquid state. The chief difficulty in the comprehension of solutions depends on the fact that the mechanical theory of the structure of liquids has not yet been so fully developed as the theory of gases. The conception of solutions as dissociated definite liquid chemical compounds is based on the following considerations: (1) that there exist certain undoubtedly definite crystallised chemical compounds (such as $\text{H}_2\text{SO}_4, \text{H}_2\text{O}$; or $\text{NaCl}, 2\text{H}_2\text{O}$; or $\text{CaCl}_2, 6\text{H}_2\text{O}$, &c.) which melt on a certain rise of temperature, and then form true solutions; (2) that metallic alloys in a molten condition are real solutions, but on cooling they often give entirely distinct and definite crystallised compounds; (3) that between the solvent and the substance dissolved there are formed, in a number of cases, many undoubtedly definite compounds, such as compounds with water of crystallisation; (4) that the physical properties of solutions, and especially their specific gravities (a property which can be very accurately determined), vary with a change in composition, and in such a manner as would be required by the formation of one or more definite but dissociating compounds. Thus, for example, on adding water to fuming sulphuric acid its density is observed to decrease until it attains the definite composition H_2SO_4 , or $\text{SO}_3 + \text{H}_2\text{O}$, when the specific gravity increases, although on further diluting with water it again falls. Moreover (Mendeléeff, *The Investigation of Aqueous Solutions from their Specific Gravities*, 1887), the increase in specific gravity (ds) varies in all well-known solutions with the proportion of the substance dissolved (dp), and this dependence can be expressed by a formula ($\frac{ds}{dp} = A + Bp$) between the limits of definite compounds whose existence in solutions must be admitted. Thus, for instance, from H_2SO_4 to $\text{H}_2\text{SO}_4 + \text{H}_2\text{O}$ (both of which substances exist as definite compounds in a free state), the fraction $\frac{ds}{dp} = 0.0729 - 0.000749p$ (where p is the percentage amount of H_2SO_4 present). For alcohol, $\text{C}_2\text{H}_6\text{O}$, whose aqueous solutions have been more accurately investigated than all others, the definite compound, $\text{C}_2\text{H}_6\text{O} + 3\text{H}_2\text{O}$, and others must be acknowledged in its solutions.

The two aspects of solution above mentioned and the hypotheses which have up to the present time been applied to the examination of solutions, although they have somewhat different starting-points, will doubtless lead to a general theory of solutions, because the same general laws govern both physical and chemical phenomena, inasmuch as the properties and motions of molecules, which determine physical properties, depend on the motions and properties of atoms, which determine chemical reactions. For details of the questions dealing with theories of solution, recourse must now be had to special memoirs and to works on physical chemistry; for this subject forms one of special interest at the present epoch of the development of our science. In working out chiefly the chemical side of solutions, I consider it to be necessary to reconcile the two aspects of the question: this seems to me to be all the more possible, as the physical side is limited to dilute solutions only, whilst the chemical side deals mainly with strong solutions (see Note 49 and Chap. VII.)

quired for saturation will remain in the liquid state.²⁰ The relation between water and substances dissolved in it is similar. More than a definite quantity of a substance cannot, at a certain temperature, dissolve in a given quantity of water; the excess does not unite with the water. Just as air or a gas becomes saturated with vapour, so water becomes saturated with a substance dissolved in it. If an excess of a substance be added to water which is already saturated with it, it will remain in its original state, and will not diffuse through the water. The quantity of a substance (by volume with gases, or by weight with solids and liquids) which is capable of saturating 100 parts of water is called its **coefficient of solubility** or its **solubility**. In 100 grams of water at 15°, there can be dissolved not more than 35·86 grams of common salt. Consequently its solubility at 15° is equal to 35·86.²¹

²⁰ In the case of limited solution of liquids in liquids, the difference between the solvent and the substance dissolved is clearly seen. The former (that is, the solvent) may be added in an unlimited quantity, and yet the solution obtained will always be uniform, whilst only a definite saturating proportion of the substance dissolved can be taken. Let us take water and ordinary (sulphuric) ether. On shaking the ether with the water, it will be remarked that a portion of it dissolves in the water. If the ether be taken in such a quantity that it saturates the water and a portion of it remains undissolved, then this remaining portion will act as a solvent, and water will become diffused through it and form a saturated solution of water in the ether. Thus two saturated solutions will be obtained. One solution will contain ether dissolved in water, and the other, water dissolved in ether. These two solutions will arrange themselves in two layers, according to their density, the ethereal solution of water being at the top. If the upper ethereal solution be poured off from the aqueous solution, any quantity of ether may be added to it: this shows that the dissolving substance is ether. If water be added to it, it will no longer be dissolved in it, indicating that water saturates the ether; so that here water is the substance dissolved. If we deal in the same way with the lower layer, we shall find that water is the solvent and ether the substance dissolved. By taking different amounts of ether and water, the degree of solubility of ether in water, and that of water in ether, may be easily determined. Water dissolves approximately $\frac{1}{10}$ of its volume of ether, and ether dissolves a very small quantity of water. According to Schuncke (1894) the ethereal solution contains 2·7 per cent. of water at 10°–20°, while the aqueous solution contains 9·6 per cent. of ether at 10°, and 7·5 per cent at 20°. Let us now imagine that the liquid poured in dissolves a considerable amount of water, and that water dissolves a considerable amount of the liquid. Two layers could not be formed, because the saturated solutions would resemble each other, and would therefore intermix in all proportions, as occurs with alcohol and water. This is, consequently, a case of a phenomenon where two liquids present considerable coefficients of solubility in each other, but where it is impossible to say what these coefficients are because it is impossible to obtain a saturated solution.

²¹ The solubility, or coefficient of solubility, of a substance may be determined by various methods. Either a solution is expressly prepared at a given temperature, and using an evident excess of the soluble substance and the quantity of water and of the substance dissolved in it determined by evaporation, desiccation, or other means; or else, as is done with gases, definite quantities of water and of the soluble substance are taken, the amount of the latter remaining undissolved being then determined. So that the solubility is always determined by the presence of an excess of the soluble substance, i.e., it corresponds with a state of equilibrium between the solution, taken in a known quantity (which is one 'phase' or homogeneous substance), and the soluble body (the

It is most important to turn attention to the **existence of the solid insoluble substances of nature**, because on them depends the shape of

other 'phase,' according to the prevalent nomenclature regarding the equilibrium of substances in contact). The theory of solutions and the practical methods of determining the solubility of substances in water and other liquids must be sought for in works on physical chemistry, as this subject now forms a considerable section of itself, and cannot be treated in sufficient detail in the present work, which is chiefly devoted to the study of the chemical elements.

The following description of the mode of determining the solubility of gases must therefore be regarded as an individual example to give the student some idea of the methods practised in the complicated subject of solutions.

The solubility of a gas in water is determined by means of an apparatus called an **absorptiometer** (fig. 16). It consists of an iron stand *f*, on which rests an indiarubber ring. A wide glass tube is placed on this ring, and is pressed down on it by the ring *h* and the screws *i i*. The tube is thus firmly fixed on the stand. A cock *r*, communicating with a funnel *r*, passes into the lower part of the stand. Mercury can be poured into the wide tube through this funnel, which is therefore made of steel, as copper would be affected by the mercury. The upper ring *h* is furnished with a cover *p*, which can be firmly pressed down on to the wide tube, and hermetically closes it by means of an indiarubber ring. The tube *r r* can be raised at will, and so by pouring mercury into the funnel the height of the column of mercury, which produces a pressure inside the apparatus, can be increased. The pressure can also be diminished at will, by letting mercury out

FIG. 16.—Buisen's absorptiometer. Apparatus for determining the solubility of gases in liquids.

the substances of the earth's surface, and of plants and animals. There is so much water on the earth's surface that were the surface of

through the cock *r*. A graduated tube *e*, containing mercury and also the gas and liquid to be experimented on, is placed inside the wide tube. This tube is graduated in millimetres for determining the pressure, and it is calibrated in volumes, so that the number of volumes occupied by the gas and liquid dissolving it can be readily calculated. This tube can also be easily removed from the apparatus. The lower portion of this tube when removed from the apparatus is shown to the right of the figure. It will be observed that its lower end is furnished with a male screw *b*, fitting into a nut *a*. The lower surface of the nut *a* is covered with indiarubber, so that on screwing up the tube its lower end presses upon the indiarubber, and thus hermetically closes the whole tube, for its upper end is fused up. The nut *a* is furnished with arms *c c*, and in the stand *f* there are corresponding spaces, so that when the screwed-up internal tube is fixed into the stand *f*, the arms *c c* fix into these spaces, thus enabling the internal tube to be fixed on to the stand *f*. When the internal tube is fixed in the stand, the wide tube is placed in position, and mercury and water are poured into the space between the two tubes, communication being then opened between the inside of the tube *e* and the mercury between the interior and exterior tubes. This is done by either revolving the inner tube *e*, or by a key turning the nut about the bottom part of *f*. The tube *e* is filled with gas and water as follows: the tube is removed from the apparatus, filled with mercury, and the gas to be experimented on is passed into it (over a pneumatic trough). The volume of the gas is measured, the temperature and pressure determined, and the volume it would occupy at 0° and 760 mm. calculated. A known volume of water is then introduced into the tube. The water must be previously boiled, so as to be quite freed from air in solution. The tube is then closed by screwing it down on to the india-rubber on the nut. It is then fixed on to the stand *f*, mercury and water are poured into the intervening space between it and the exterior tube, which is then screwed up and closed by the cover *p*, and the whole apparatus left at rest for some time, so that the tube *e* and the gas in it may attain the same temperature as that of the surrounding water, which is marked by a thermometer *k* tied to the tube *e*. The inner tube is then again closed by turning it in the nut, the cover *p* again shut, and the whole apparatus shaken in order that the gas in the tube *e* may completely saturate the water. After several shakings, the tube *e* is again opened by turning it in the nut, and the apparatus left at rest for a certain time; it is then closed and again shaken, this being repeated until the volume of the gas does not diminish after a fresh shaking—that is, until saturation ensues. Observations are then made of the temperature, the height of the mercury in the inner tube, and the level of the water in it, and also of the level of the mercury and water in the outer tube. All these data are necessary in order to calculate the pressure under which the solution of the gas takes place, and what volume of gas remains undissolved, and also the quantity of water which serves as the solvent. By varying the temperature of the surrounding water, the amounts of gas dissolved at different temperatures may be determined. By means of this apparatus Bunsen, Carius, and many others determined the solubilities of various gases in water, alcohol, and certain other liquids. If in a determination of this kind it is found that *n* cubic centimetres of water at a pressure *h* dissolve *m* cubic centimetres of a given gas, measured at 0° and 760 mm., when the temperature at which solution took place was *t*°, then it follows that at the temperature *t* **the coefficient of solubility of the gas** in 1 volume of the liquid will be equal to $\frac{m}{n} \times \frac{760}{h}$.

This formula is very clearly understood from the fact that the coefficient of solubility of a gas is that quantity (by volume or weight) measured at 0° and 760 mm., which is absorbed at a pressure of 760 mm. by 1 part or 100 parts of a liquid. If *n* cubic centimetres of water absorb *m* cubic centimetres of a gas, then one cubic centimetre absorbs $\frac{m}{n}$.

If $\frac{m}{n}$ c.c. of a gas are absorbed under a pressure of *h* mm., then, according to the law of

substances formed of soluble matters it would constantly change, and, however substantial their forms might be, mountains, river banks and sea shores, plants and animals, or the habitations and coverings of men, could not exist for any length of time.²²

Substances which are easily soluble in water bear a certain resemblance to it. Thus sugar and salt in many of their superficial features remind one of ice. Metals, which are not soluble in water, have no points in common with it, whilst on the other hand they dissolve each other in a molten state, forming alloys, just as oily substances dissolve each other; for example, tallow is soluble in petroleum and in olive oil, although they are all insoluble in water. From this it is evident that the **analogy between the substances forming a solution** is of some the variation of solubility of a gas with the pressure, there would be dissolved, under a pressure of 760 mm., a quantity standing in the same ratio to $\frac{m}{n}$ as 760 : h . In determining the residual volume or weight of gas, its moisture (note 1) must be taken into consideration. L. Winkler (1888–1902) of Buda-Pesth determined the solubility of gases by a more perfect method.

The solubility (expressed in volumes) of many gases in water is given in note 30. Below are given the numbers of grams of several substances saturating 100 grams of water—that is, their coefficients of solubility by weight at three different temperatures under a pressure of 760 mm.

—		At 0°	At 20°	At 100°
Gases	Oxygen, O ₂	$\frac{6}{1000}$	$\frac{4}{1000}$	—
	Carbonic anhydride, CO ₂	$\frac{35}{100}$	$\frac{18}{100}$	—
	Ammonia, NH ₃	90.0	51.8	7.3
Liquids	Phenol, C ₆ H ₆ O	4.9	5.2	∞
	Amyl alcohol, C ₅ H ₁₂ O	4.4	2.9	—
	Sulphuric acid, H ₂ SO ₄	∞	∞	∞
Solids	Gypsum, CaSO ₄ · 2H ₂ O	$\frac{1}{2}$	$\frac{1}{4}$	$\frac{1}{5}$
	Alum, AlKSO ₄ · 12H ₂ O	3.3	15.4	357.5
	Anhydrous sodium sulphate, Na ₂ SO ₄	4.5	20	43
	Common salt, NaCl	35.7	36.0	39.7
	Nitre, KNO ₃	13.3	31.7	246.0

Sometimes a substance is so slightly soluble that it may be considered as insoluble. Many such substances are met with both in solids and liquids, and such a gas as oxygen, although it does dissolve, does so in so small a proportion by weight that it might be considered as zero did not the solubility of even so little oxygen play an important part in nature (as in the respiration of fishes), and were not an infinitesimal quantity of a gas by weight so easily measured by volume. The sign ∞, which stands on a line with sulphuric acid in the above table, indicates that it intermixes with water in all proportions. This is the case with many liquids.

²² Just as the existence must be admitted of substances which are completely undecomposable (chemically) at the ordinary temperature—and of substances which are entirely non-volatile at such a temperature (as wood and gold), although capable of decomposing (wood) or volatilising (gold) at a higher temperature—so also the existence must be admitted of substances which are totally insoluble in water. It must be remarked, besides, that water in a number of cases does not dissolve a substance as such, but acts on it chemically and forms a soluble substance. Thus glass and many rocks, especially if taken as powder, are chemically changed by water, but are not directly soluble in it.

importance, and as aqueous and all other solutions are liquids, there is good reason to believe that in the process of solution solid and gaseous substances change physically and pass into a liquid state. These considerations elucidate many points of solution—as, for instance, the variation of the coefficient of solubility with the temperature and the evolution or absorption of heat in the formation of solutions.

The solubility—that is, the quantity of a substance necessary for saturation—**varies with the temperature**, and, further, with a rise in temperature the solubility of solid substances generally increases, whilst that of gases decreases: this might be expected, as solid substances by heating, and gases by cooling, approach to a liquid or dissolved state.²³ A graphic method is often employed to express the variation of solubility with temperature. On the axis of abscissæ or on a horizontal line, temperatures are marked out and perpendiculars are raised corresponding with each temperature and having lengths determined by the solubilities of the salt at the various temperatures—expressing, for instance, one part by weight of a salt in 100 parts of water by one unit of length, such as a millimetre. By joining the summits of the perpendiculars, a curve is obtained which expresses the degree of solubility at different temperatures. For solids, the curve is generally an ascending one—i.e., it recedes from the horizontal line as the temperature rises. These curves clearly show by their inclination the degree of rapidity of increase in solubility with the temperature. Having determined several points of a curve—that is, having made determinations of the solubilities for several temperatures—the solubilities at intermediate temperatures may be determined from the form of the curve so obtained: in this way the empirical law of solubility may be examined.^{23a}

²³ Beilby (1883) experimented on paraffin, and found that one litre of solid paraffin at 21° weighed 874 grams, and in the liquid state at its melting-point, 38°, 783 grams; at 49°, 775 grams, and at 60°, 767 grams; hence the weight of a litre of liquefied paraffin would be 795.4 grams at 21°, supposing that it could remain liquid at that temperature. By dissolving solid paraffin in lubricating oil at 21°, Beilby found that 795.6 grams occupy one cubic decimetre, from which he concluded that the solution contained liquefied paraffin.

^{23a} Gay-Lussac was the first to have recourse to such a graphic method of expressing solubility, and he considered, in accordance with the general opinion, that by joining up the summits of the ordinates in one harmonious curve it is possible to express the entire change of solubility with the temperature. Now, there are many reasons for doubting the accuracy of such an admission, for there are undoubtedly critical points in curves of solubility (for example, of sodium sulphate, as shown further on), and it may be that definite compounds of dissolved substances with water, in decomposing within known limits of temperature, give critical points more often than would be imagined; it may even be, indeed, that, instead of a continuous curve, solubility should be expressed—if not always, then not infrequently—by straight or broken lines. The modern theory of phases (which is treated more fully in *Physical Chemistry*; see also Chap. XXIV., note 9a) fully explains such breaks in the curve of solubility, which occur when the soluble substance and water are able to form crystals of various compositions (different crystallohydrates) and crystalline forms (see note 24). According to Ditte, the solubility of

The results of research have shown that the solubility of certain salts—as, for example, common table salt—varies comparatively little with the temperature, whilst for other substances the solubility increases by equal amounts for equal increments of temperature. Thus, for example, for the saturation of 100 parts of water by potassium chloride there is required 29·2 parts of the salt at 0°, 34·7 at 20°, 40·2 at 40°, 45·7 at 60°, and so on, the solubility increasing by 2·75 parts by weight of the salt for every 10°. Therefore the solubility of the potassium chloride in water may be expressed by a simple equation: $a = 29·2 + 0·275t$, where a represents the solubility at t° . For other salts more complicated equations are required. For example, for nitre: $a = 13·3 + 0·574t + 0·01717t^2 + 0·0000036t^3$, which shows that when $t = 0^\circ$, $a = 13·3$; when $t = 10^\circ$, $a = 20·8$, and when $t = 100^\circ$, $a = 246·0$.

The variation in the solubility of salts, &c., with a rise or fall of temperature is often taken advantage of, especially in technical work, for the separation of salts mixed with each other. Thus a mixture of potassium and sodium chlorides (a mixture met with in nature at Stassfurt) is separated by subjecting a saturated solution alternately to boiling (evaporation) and cooling. The sodium chloride separates out in proportion to the amount of water expelled from the solution by sodium nitrate, NaNO_3 , per 100 parts of water is expressed by the following figures:—

0°	4°	10°	15°	21°	29°	36°	51°	68°
66·7	71·0	76·3	80·6	85·7	92·9	99·4	113·6	125·1

In my opinion (1881) these data should be expressed with exactitude by a straight line, $67·5 + 0·87t$. The experiments made by Ditte showed that all saturated solutions between 0° and $-15·7^\circ$ have such a composition, and that at the latter temperature the solution completely solidifies into one homogeneous whole whose composition is approximately $\text{NaNO}_3, 7\text{H}_2\text{O}$. Thus the solubility of sodium nitrate is expressed by a broken straight line. Étard (1888) discovered a similar phenomenon in many of the sulphates. Brandes, in 1830, showed a diminution in solubility below 100° for manganese sulphate. The percentage by weight (i.e., per 100 parts of the solution, and not of water) of saturated ferrous sulphate (FeSO_4) solution from -2° to $+65^\circ$ is given by $13·5 + 0·3784t$ —that is, the solubility of the salt increases. From 65° to 98° the solubility remains constant, and from 98° to 150° it falls and is expressed by $104·35 - 0·6685t$. Hence, at about $+156^\circ$ the solubility should become zero; and this has been confirmed by experiment. I find that Étard's formula gives 38·1 per cent. of salt at 65° and 38·8 per cent. at 92°, and this maximum amount of salt in solution corresponds very nearly with the composition $\text{FeSO}_4, 14\text{H}_2\text{O}$, which requires 37·6 per cent. From what has been said, it is evident that the data concerning solubility require a new method of investigation, which should take into account the entire scale of solubility—from the formation of completely solidified solutions (cryohydrates, which we shall speak of presently) to either the separation of salts from their solutions, should this take place at a higher temperature (for manganese and cadmium sulphates there is complete separation, according to Étard), or the attainment of a constant solubility (for potassium sulphate the solubility, according to Étard, remains constant from 163° to 220° and equals 24·9 per cent.). The following are Étard's data for several salts (parts of salt per 100 parts of solution). KNO_3 : up to 70°, $24·0 + 0·7100t$; from 70° to 125°, $59·5 + 0·3727t$; from 125° to 338°, $80·0 + 0·0938t$. For NaNO_3 : from 5° to 64°, $39·0 + 0·2825t$; from 64° to 313°, $58·5 + 0·1666t$. For NaCl : from 0° to 250°, $25·8 + 0·0248t$ (see Chap. XII., note 4, &c.)

boiling, and is removed, whilst the potassium chloride separates out on cooling, as the solubility of this salt decreases rapidly as the temperature falls. Nitre, sugar, and many other soluble substances are purified (refined) in a similar manner.

Although in the majority of cases the solubility of solids increases with rise of temperature, yet there are some solid substances whose solubilities decrease on heating. A particularly instructive example is found in the case of Glauber's salt, or sodium sulphate. If this salt be taken after ignition (deprived of its water of crystallisation), its solubility in 100 parts of water varies with the temperature in the following manner: at 0° , 5 parts of the salt form a saturated solution; at 20° , 20 parts of the salt, while at 33° more than 50 parts are required. The solubility, as will be seen, increases with the temperature, but above 33° it suddenly diminishes, and at a temperature of 40° less than 50 parts, at 60° only 45 parts, and at 100° about 43 parts, dissolve in 100 parts of water. This phenomenon may be traced to the following facts: First, this salt forms various compounds with water, as will be afterwards explained; secondly, at 33° the compound $\text{Na}_2\text{SO}_4 + 10\text{H}_2\text{O}$, formed from the solution at lower temperatures, melts; and thirdly, on evaporation at a temperature above 33° an anhydrous salt, Na_2SO_4 , separates out, while at lower temperatures the anhydrous salt converts the water into a solid state without itself passing into solution (see Chap. XII., note 8). It will be seen from this example how complicated such an apparently simple phenomenon as solution really is; and all data concerning solutions lead to the same conclusion.²⁴ This complexity becomes evident also

²⁴ First of all we must remember that saturation of a solution can only refer to the substance which is present in the solution, and not to that which was originally taken for making the solution. Thus, for instance, if a given salt occurs in two crystalline forms A and B (that is, it is dimorphous), stable within certain limits of temperature, these will possess different solubilities. Suppose A to be more soluble than B. A saturated solution of B will be able to dissolve a further amount of A until saturation be reached. If we now pour off this solution from the excess of A, and add a further quantity of B, then a portion of the salt will separate out from the solution in the form B, although the same solution, if evaporated in the presence of an excess of A, would deposit the variety A; and since many anhydrous salts deposit solid, frequently dimorphous, compounds with water from their solutions, it is evident that the different phenomena concerned in saturation may be most complex (see, for instance, Chap. XIV., note 50, for CaCl_2 ; Chap. XXII., note 23, for Fe_2Cl_6). As an instance of this, we may take the solubility of sodium carbonate calculated as parts of anhydrous salt per 100 parts of water:

Solid phase	At 0°	At 20°
$\text{Na}_2\text{CO}_3, 10\text{H}_2\text{O}$	7	22
$\text{Na}_2\text{CO}_3, 7\text{H}_2\text{O}$ – cubic	20	39
$\text{Na}_2\text{CO}_3, 7\text{H}_2\text{O}$ – rhombic	31	46

The solubility of the anhydrous salt, Na_2CO_3 , cannot be given, because at these

on investigating the **heat of solution**. If solution consisted of a physical change only, then in the solution of gases there would be evolved—and in the solution of solids there would be absorbed—just that amount of heat corresponding with the change of state; but in reality a larger amount of heat is always evolved in the solution of gases, and less is absorbed in the solution of solids than is required by theory, owing to the fact that in the process of solution chemical combination takes place, accompanied by an evolution of heat. Seventeen grams of ammonia (this weight corresponds with its formula NH_3), in passing from a gaseous to a liquid state, evolve 4,400 units of heat (latent heat), that is, the quantity of heat necessary to raise the temperature of 4,400 grams of water 1° . The same quantity of ammonia, in dissolving in an excess of water, evolves twice as much heat—namely, 8,800 units—showing that the combination with water is accompanied by the evolution of 4,400 units of heat. Further, the chief part of this heat is generated when the gas dissolves in small quantities of water, so that 17 grams of ammonia, in dissolving in 18 grams of water (this weight corresponds with its composition H_2O), evolve 7,535 units of heat, and therefore the formation of the solution $\text{NH}_3 + \text{H}_2\text{O}$ evolves 3,135 units of heat beyond that due to the change of state. Since in the solution of gases the heats of liquefaction (of physical change of state) and of chemical combination with water are both positive (+), it follows that in the *solution of gases* in water *heat is always evolved*. This phenomenon is different in the solution of solid substances, because the passage from a solid to a liquid state is accompanied by an absorption of heat (—heat), whilst their chemical combination with water is accompanied by an evolution of heat (+heat); consequently their sum may either be a cooling effect, when the positive (chemical) portion of the heat is less than the negative (physical), or it may be, on the contrary, a heating effect. This is actually found to be the case. 124 grams of sodium thiosulphate (employed in photography), $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$, in melting (at 48°) absorb 9,700 units of heat, but in dissolving in a large quantity of water at the ordinary temperature they absorb 5,700 units of heat, which shows that, notwithstanding the cooling effect observed in the process of solution, an evolution of heat (about +4,000 units) takes place in the act of the chemical combination of the salt with water.²⁵ But in most cases

temperatures it forms a solid crystallhydrate, and *if brought into solution in excess, it precipitates a portion of the salt from the solution* in the form of the solid phase of the crystallhydrate (compare Chap. XII., note 8).

²⁵ The latent heat of fusion is determined at the temperature of fusion, whilst solution takes place at the ordinary temperature; and one must think that at this temperature the latent heat would be different, just as the latent heat of evaporation varies with

solid substances in dissolving in water evolve heat, notwithstanding the passage into a liquid state, indicating so considerable an evolution of (+) heat in the act of combination with water as to exceed the absorption of (−) heat dependent on the passage into a liquid. Thus, for instance, calcium chloride, CaCl_2 , magnesium sulphate, MgSO_4 , and many other salts evolve heat in dissolving; for example, 60 grams of magnesium sulphate evolve about 10,000 units of heat. Therefore, *in the solution of solids or liquids in water either a cooling*²⁶ *or a* the temperature (see note 11). Besides which, in the process of solution, disintegration of the particles of both the solvent and the substance dissolved takes place; a change which in its mechanical aspect resembles evaporation, and must therefore consume much heat. The heat emitted in the solution of a solid must therefore be considered (Personne) as composed of three factors: (1) positive, the effect of combination; (2) negative, the effect of transference into a liquid state; and (3) negative, the effect of disintegration. In the solution of a liquid by a liquid the second factor is removed; and therefore if the heat evolved in combination is greater than that absorbed in disintegration a heating effect is observed, and in the reverse case a cooling effect; and, indeed, sulphuric acid, alcohol, and many other liquids evolve heat in dissolving in each other. But the solution of chloroform in carbon bisulphide (Bussy and Binget), or of phenol (or aniline) in water (Alexéeff) produces cold. In the solution of a small quantity of water in acetic acid (Abasheff), or hydrocyanic acid (Bussy and Binget), or amyl alcohol (Alexéeff), cold is produced, whilst when these substances are dissolved in an excess of water heat is evolved.

The relation existing between the solubility of solid bodies and the heat and temperature of fusion and solution has been studied by many investigators, and more especially (1893) by Schröder, who states that in the solution of a solid body in a solvent which does not act chemically upon it a very simple process takes place, which differs but little from the intermixture of two gases which do not react chemically upon each other. To such a case the following relation between the heat of solution Q and the heat of fusion p is applicable: $\frac{p}{T_0} = \frac{Q}{T} = \text{constant}$, where T_0 and T are the absolute (from -273°)

temperatures of fusion and saturation. In the case of naphthalene, for instance, the calculated and observed magnitudes of the heat of solution differ but slightly from each other.

The fullest information concerning the solution of liquids in liquids has been obtained by W. T. Alexéeff (1883–1885); but these data are, however, far from being sufficient to solve the mass of problems respecting this subject. He showed that the solubility of phenol, $\text{C}_6\text{H}_5\text{O}$, in water, and the converse, is limited up to 70° , whilst above this temperature the two intermix in all proportions. This is seen from the following figures, where p is the percentage amount of phenol and t the temperature at which the solution becomes turbid—that is, that at which it is saturated:—

$p=7.12$	10.20	15.31	26.15	28.55	36.70	48.86	61.15	71.97
$t=1^\circ$	45°	60°	67°	67°	67°	65°	53°	20°

It is exactly the same with the solutions of benzene, aniline, and other substances in molten sulphur. Alexéeff discovered a similar complete intermixture for secondary butyl alcohol and water at about 107° ; at lower temperatures the solubility is not only limited, but between 50° and 70° it is at its minimum, both for solutions of the alcohol in water and for water in the alcohol; and at a temperature of 5° both solutions exhibit a fresh change in their scale of solubility, so that a solution of the alcohol in water, which is saturated between 5° and 40° , will become turbid when heated to 60° . In the solution of liquids in liquids Alexéeff observed a lowering in temperature (an absorption of heat) and an absence of change in specific heat (contrary to the calculated results for the mixture) much more frequently than had been done by previous observers.

²⁶ The cooling effect produced in the solution of solids (and also in the expansion of gases and in evaporation) is applied to the **production of low temperatures**. Ammonium

*heating*²⁷ effect is produced, according to the difference of the reacting affinities. When they are considerable—that is, when water is with difficulty separated from the resultant solution, and only with a rise of temperature—then much heat is evolved in the process of solution, just as in many reactions of direct combination, and therefore a considerable heating of the solution is observed. Of such a kind, for instance, are the solutions of sulphuric acid (oil of vitriol, H_2SO_4), and of caustic soda (NaHO), &c., in water.²⁸

nitrate is very often used for this purpose; in dissolving in water it absorbs 77 units of heat for each part by weight. On evaporating the solution thus formed, the solid salt is re-obtained. The application of the different **freezing mixtures** is based on the same principle. Snow or broken ice frequently enters into the composition of these mixtures, advantage being taken of its latent heat of fusion in order to obtain the lowest possible temperature (without altering the pressure or employing heat, as in other methods of obtaining a low temperature). For laboratory work recourse is most often had to a mixture of three parts of snow and one part of common salt, which causes the temperature to fall from 0° to -21° C. Potassium thiocyanate, KCNS , mixed with water ($\frac{3}{4}$ by weight of the salt) gives a still lower temperature. By mixing ten parts of crystallised calcium chloride, $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$, with seven parts of snow, the temperature may even fall from 0° to -55° .

²⁷ The heat which is evolved in solution, or even in the dilution of solutions, is also sometimes made use of in practice. Thus caustic soda (NaHO), in dissolving or on the addition of water to a strong solution of it, evolves so much heat that it can replace fuel. In a steam boiler, which has been previously heated to the boiling-point, another boiler is placed containing caustic soda, and the exhaust steam is made to pass through the latter; the formation of steam then goes on for a fairly long time without any further heating. Norton makes use of this for smokeless street locomotives.

²⁸ The temperatures obtained by mixing monohydrated sulphuric acid, H_2SO_4 , with

FIG. 17.—Curves expressing the contraction, quantity of heat, and rise of temperature produced by mixing sulphuric acid with water. Percentage of H_2SO_4 is given along the axis of abscissæ.

Solution is a reversible reaction ; for, if the water be expelled from a solution, the substance originally taken is obtained again. But it must be borne in mind that the expulsion of the water taken for solution is not always accomplished with equal facility, because water has different degrees of chemical affinity for the substance dissolved. Thus, if a solution of sulphuric acid, which mixes with water in all proportions, be heated, it will be found that very varying temperatures are required to expel the water. When in a large excess, water is given off at a temperature slightly above 100° ; but if it be in only a small proportion, there is such an affinity between it and the sulphuric acid that at 120° , 150° , 200° , and even at 300° , water is still retained by the sulphuric acid. The bond between the remaining quantity of water and the sulphuric acid is evidently stronger than that between the sulphuric acid and the excess of water. The force acting in solutions is consequently of different intensity, starting from so feeble an attraction that the properties of water—as, for instance, its power of evaporation—are but very little changed, and ending with strong attraction between the water and the substance dissolved in or chemically combined with it.

The solubility of gases, which is usually measured by the volume of gas ²⁹ (at 0° and 760 mm. pressure) per 100 volumes of water, varies

different quantities of water are shown on the lowest curve in fig. 17, the relative proportions of the two substances being expressed in percentages by weight along the horizontal axis. The greatest rise of temperature is 149° . It corresponds with the greatest evolution of heat (given on the middle curve) for a definite volume (100 c.c.) of the solution produced. The top curve expresses the degree of contraction corresponding with 100 volumes of the solution produced. The greatest contraction, as also the greatest rise of temperature, corresponds with the formation of a trihydrate, $\text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$ (containing 73.1 per cent. H_2SO_4). Similar relations probably hold for other solutions, although all the phenomena (contraction, evolution of heat, and rise of temperature) are very complex, and are dependent on many circumstances. One would think, however, judging from the above examples, that all other influences are feebler in their action than chemical attraction, especially when this is so considerable as it is between sulphuric acid and water.

²⁹ If a volume of gas v be measured under a pressure of h mm. of mercury (at 0°) and at a temperature t° Centigrade, then, according to the combined laws of Boyle, Mariotte, and Gay-Lussac, its volume at 0° and 760 mm. will equal the product of v into h divided by the product of 760 into $1 + at$, where a is the coefficient of expansion of gases, which is equal to 0.00360. The weight of the gas will be equal to its volume at 0° and 760 mm., multiplied by its density referred to air and by the weight of one volume of air at 0° and 760 mm., the weight of a litre of air under these conditions being 1.293 gram. If the density of the gas be given in relation to hydrogen, this must be divided by 14.4 to make it refer to air. If the gas be measured when saturated with aqueous vapour, then it must be reduced to the volume and weight of the gas when dry, according to the rules given in note 1. If the pressure be determined by a column of mercury having a temperature t° , then by dividing the height of the column by $1 + 0.00018t$ the corresponding height at 0° is obtained. If the gas be enclosed in a tube in which a liquid stands above the level of the mercury, the height of the column of the

not only with the nature of the gas (and also of the solvent), and with the temperature, but also with the pressure, because gases themselves change their volume considerably with change of pressure. As might be expected, (1) gases which are easily liquefied (by pressure and cold) are more soluble than those which are liquefied only with difficulty. Thus, in 100 volumes of water only two volumes of hydrogen or nitrogen dissolve at 0° and 760 mm., three volumes of carbonic oxide, four volumes of oxygen, &c., for these are gases which are liquefied with difficulty; whilst there dissolve 180 volumes of carbonic anhydride, 130 of nitrous oxide, and 437 of sulphurous anhydride, for these are gases which are fairly easily liquefied. (2) The solubility of a gas is diminished by heating, this being easily intelligible from what has been said previously—the elasticity of a gas becomes greater, that is, it is removed further from a liquid state. Thus 100 volumes of water at 0° dissolve 2·5 volumes of air, but at 20° only 1·7 volume. For this reason cold water, when brought into a warm room, parts with a portion of the gas dissolved in it.³⁰ (3) The quantity of the gas liquid being H and its density D, then the gas will be under a pressure equal to the barometric pressure less $\frac{HD}{13\cdot59}$, 13·59 being the density of mercury. By these methods

the **quantity of a gas** is determined, and its observed volume reduced to normal conditions or to parts by weight. The physical data concerning vapours and gases must be continually kept in sight in dealing with and measuring gases. The student must become perfectly familiar with the calculations relating to gases.

³⁰ According to Bunsen, Winkler, Timoféeff, and others, 100 vols. of water under a pressure of one atmosphere absorb the following volumes of gas (measured at 0° and 760 mm.) :—

	1	2	3	4	5	6	7	8	9	10	11
0°	4·82	2·35	2·15	179·7	3·54	130·5	437·1	688·6	5·4	104960	7·38
20°	3·10	1·54	1·83	90·1	2·32	67·0	290·5	362·2	3·5	65400	4·71

1, oxygen; 2, nitrogen; 3, hydrogen; 4, carbonic anhydride; 5, carbonic oxide; 6, nitrous oxide; 7, hydrogen sulphide; 8, sulphurous anhydride; 9, marsh gas; 10, ammonia; 11, nitric oxide. The decrease of solubility with rise of temperature varies for different gases and increases with the molecular weight of the gas. It is shown by calculation that this decrease varies (Winkler at Buda-Pesth) as the cube root of the molecular weight of the gas. This is seen from the following table:

Decrease of solubility per 20° in per cent.		Cube root of molecular weight	Ratio between decrease and cube root of mol. wt.
H ₂	15·32	1·259	12·17
N ₂	34·33	3·037	11·30
CO	34·44	3·037	11·34
NO	36·24	3·107	11·66
O ₂	36·55	3·175	11·51

The decrease in the coefficient of absorption with rise of temperature must be connected with a change in the physical properties of the water. Winkler (1891) observed a certain relation between the internal friction and the coefficient of absorption at various temperatures.

dissolved varies directly with the pressure. This rule is called the **law of Henry and Dalton**, and is applicable to those gases which are slightly soluble in water. Therefore in a vacuum a gas becomes separated from its solution in water, and water saturated with a gas under great pressure parts with it if the pressure is diminished. For instance, many mineral springs are saturated underground with carbonic anhydride under the great pressure of the column of water above them. On coming to the surface, the water of these springs boils and foams on giving up the excess of dissolved gas. Sparkling wines and aërated waters are saturated under pressure with the same gas. They retain the gas so long as they are kept in a well-corked vessel. When the cork is removed, and the liquid comes into contact with air at a lower pressure, part of the gas, unable to remain in solution at a lower pressure, is separated as froth with the hissing sound familiar to all. It must be remarked that the law of Henry and Dalton belongs to the class of *approximate laws*, like the laws of gases (Gay-Lussac's and Mariotte's)—that is, it expresses only a portion of a complex phenomenon or the limit towards which the phenomenon tends. The matter is rendered complicated by the influence exerted by the degree of solubility and by the affinity of the dissolved gas for water. Gases which are little soluble—for instance, hydrogen, oxygen, and nitrogen—follow the law of Henry and Dalton the most closely. Carbonic anhydride exhibits a decided deviation from the law (Wroblewski, 1882); at 0° a cubic centimetre of water absorbs 1.8 cubic centimetre of the gas under a pressure of one atmosphere; under 10 atmospheres, 16 cubic centimetres (and not 18, as it should be according to the law); under 20 atmospheres, 26.6 cubic centimetres (instead of 36); and under 30 atmospheres, 33.7 cubic centimetres.³¹ However, as is shown by the researches of Sechenoff, the absorption of carbonic anhydride within certain limits of change of pressure, and at the ordinary temperature, by water—and even by solutions of salts which are not chemically changed by

³¹ These figures show that the coefficient of solubility decreases with an increase of pressure, notwithstanding that the carbonic anhydride approaches more nearly to a liquid state. As a matter of fact, liquefied carbonic anhydride does not mix with water. This indicates, in the first place, that solution does not consist in liquefaction, and in the second place that the solubility of a substance is determined by a peculiar attraction of water for the substance dissolving. Wroblewski even considered it possible to admit that a dissolved gas retains its properties as a gas. This he deduced from experiments showing that the rate of diffusion of gases in a solvent is, for gases of different densities, inversely proportional to the square roots of their densities, as is the case with the velocities of gaseous molecules (see note 34). Wroblewski demonstrated the affinity of water, H_2O , for carbonic anhydride, CO_2 , by showing that on expanding moist carbonic anhydride, compressed at 0° under a pressure of 10 atmospheres (a fall in temperature takes place from the expansion), a very unstable definite crystalline compound, $\text{CO}_2 + 8\text{H}_2\text{O}$, is obtained.

it, or do not form compounds with it—follows very closely the law of Henry and Dalton, the chemical bond between this gas and water being so feeble that the breaking up of the solution with separation of the gas is accomplished by a decrease of pressure alone.³² The case is different if a considerable affinity exists between the dissolved gas and the water. It might then be even expected that the gas would not be entirely separated from water in a vacuum, as should be the case with gases following the law of Henry and Dalton. As examples, ammonia and hydrochloric acid gas may be taken. The former is separated by boiling and decrease of pressure, while the latter is not; but they both deviate distinctly from the law.

Pressure in mm. of mercury	Ammonia dissolved in 100 grams of water at 0°	Hydrochloric acid gas dissolved in 100 grams of water at 0°
	Grams	Grams
100	28.0	65.7
500	69.2	78.2
1,000	112.6	85.6
1,500	165.6	—

It will be remarked, for instance, from this table that, whilst the pressure increases ten times, the solubility of ammonia only increases 4 times.

A number of examples might be cited of cases of the absorption of gases by liquids which do not in any way, even approximately, agree with the law of Henry and Dalton. Thus, for instance, carbonic anhydride is absorbed by a solution of caustic potash in water, and if sufficient caustic potash be present the gas will not be evolved from the solution by decreasing the pressure. This is a case of more intimate chemical combination. A correlation less patent, but similar and clearly chemical, appears in certain cases of the solution of gases in water, and we shall afterwards find an example of this in the solution of hydrogen iodide; but we will first stop to consider a remarkable application of the law of Henry and Dalton³³ to the case of the solution

³² As, according to the researches of Roscoe and his collaborators, ammonia exhibits a considerable deviation at low temperatures from the law of Henry and Dalton, whilst at 100° the deviation is small, it would appear that the dissociating influence of temperature affects all gaseous solutions; that is, at high temperatures the solutions of all gases will follow the law, whilst at lower temperatures there will in all cases be a deviation from it.

³³ The ratio between the pressure and the amount of gas dissolved was discovered by Henry in 1805, while Dalton in 1807 pointed out the applicability of this law to cases of gaseous mixtures, introducing the conception of partial pressures which is absolutely necessary for a right comprehension of Henry's law. The conception of partial pressures enters essentially into that of the diffusion of vapours in gases (footnote 1); for the

of a mixture of two gases, this being all the more necessary because the phenomena which there take place cannot be foreseen without a clear theoretical representation of the nature of gases.³⁴

pressure of damp air is equal to the sum of the pressures of dry air and of the aqueous vapour in it, and it is admitted as a corollary to Dalton's law that evaporation in dry air takes place as in a vacuum. It is, however, necessary to remark that the volume of a mixture of two gases (or vapours) is only approximately equal to the sum of the volumes of its constituents (the same, naturally, also refers to their pressures)—that is to say, in mixing gases a change of volume occurs, which, although small, is quite apparent when carefully measured. For instance, in 1888 Brown showed that on mixing equal volumes of sulphurous anhydride (SO_2) and carbonic anhydride (at the same pressure—760 mm.—and temperature) a decrease of pressure of 3.9 millimetres of mercury takes place. The possibility of chemical action in such mixtures is evident from the fact that equal volumes of sulphurous and carbonic anhydrides at -19° form, according to Pictet's researches in 1888, a liquid which may be regarded as an unstable chemical compound, or as a solution similar to that given when sulphurous anhydride and water combine to an unstable chemical whole.

³⁴ The origin of the now generally accepted **kinetic theory of gases**, according to which their molecules are animated by a rapid progressive motion, is very ancient (Bernouilli and others in the last century had already developed a similar representation), but it was only generally accepted after the mechanical theory of heat had been established, and after the work of Krönig (1855), and especially after its mathematical side had been worked out by Clausius and Maxwell. The pressure, elasticity, diffusion, and internal friction of gases, the laws of Boyle, Mariotte, and of Gay-Lussac and Avogadro-Gerhardt are not only explained (deduced) by the kinetic theory of gases, but also expressed with perfect exactitude; thus, for example, the magnitude of the internal friction of different gases was foretold with exactitude by Maxwell by applying the theory of probabilities to the impact of gaseous particles. The kinetic theory of gases must therefore be considered as one of the most brilliant acquisitions of the latter half of the nineteenth century. The velocity of the progressive motion of the particles of a gas, one cubic centimetre of which weighs d grams, is found, according to the theory, to be equal to the square root of the product of $3p \cdot D \cdot g$ divided by d , where p is the pressure under which d is determined expressed in centimetres of the mercury column, D the weight of a cubic centimetre of mercury in grams ($D=13.59$, $p=76$; consequently the normal pressure = 1,033 grams on a sq. cm.), and g the acceleration of gravity in centimetres ($g=980.5$ at the sea level and lat. 45° and 981.92 at St. Petersburg; in general it varies with the latitude and altitude of the locality). Therefore at 0° the velocity of hydrogen is 1,843, and that of oxygen 461, metres per second. This is the average velocity, and (according to Maxwell and others) it is probable that the velocities of individual particles are different; that is, they occur, as it were, in different conditions of temperature, which it is very important to take into consideration in investigating many phenomena proper to matter. It is evident from the above determination of the velocity that different gaseous molecules, at the same temperature and pressure, have average velocities inversely proportional to the square roots of their densities: this is also shown by direct experiment on the flow of gases through a fine orifice, or through a porous wall. This *dissimilar velocity of flow* for different gases is frequently taken advantage of in chemical researches (see Chap. II. and also Chap. VII.) in order to separate two gases having different densities and velocities. The difference of the velocity of flow of gases also determines the phenomenon cited in the following footnote for demonstrating the existence of an internal motion in gases.

If for a certain mass of a gas which follows exactly the laws of Mariotte and Gay-Lussac the temperature t and the pressure p be changed simultaneously, then the entire change would be expressed by the equation $pv=C(1+\alpha t)$, or, what is the same, $pv=RT$, where $T=t+273$ and C and R are constants which vary not only with the units taken but also with the nature of the gas and its mass. But as there are

The law of partial pressures is as follows:—The solubility of gases mixed with each other does not depend on the influence of the total pressure acting on the mixture, but on the influence of that portion of the total pressure which is due to the volume of each separate gas in the mixture. Thus, for instance, if oxygen and carbonic anhydride were mixed in equal volumes and exerted a pressure of 760 millimetres, then water would dissolve as much of each of these gases as would be dissolved if each separately exerted a pressure of half an atmosphere, and in this case, at 0°, one cubic centimetre of water would dissolve 0.90 cubic centimetre of carbonic anhydride. If the pressure of a gaseous mixture equal h , and in n volumes of the mixture there be a volumes of a given gas, then its solution will proceed as though this gas were dissolved under a pressure $\frac{h \times a}{n}$. That portion of the pressure under the influence of which the solution proceeds is termed the 'partial' pressure.

In order to clearly understand the cause of the law of partial pressures, an explanation must be given of the fundamental properties of gases according to the views of contemporary science. Gases are elastic and disperse in all directions. We are led, from what we know of gases, to the assumption that these fundamental properties are due to a rapid progressive motion, in all directions, proper to the smallest particles (molecules) of the gases.³⁵ These molecules in impinging against

discrepancies from both the fundamental laws of gases (which will be discussed in the following chapter), and as, on the one hand, a certain attraction between the gaseous molecules must be assumed, while, on the other hand, the molecules of gases themselves must occupy a certain portion of space, hence for ordinary gases, within any considerable variation of pressure and temperature, recourse should be had to **van der Waals' formula**—

$$\left(p + \frac{a}{v^2} \right) (v - b) = R (1 + \alpha t),$$

where α is the coefficient of expansion of gases.

The formula of van der Waals has an especially important significance in the case of the passage of a gas into the liquid state, because the fundamental properties of both gases and liquids are equally well expressed by it, although only in their general features.

The further development of the questions referring to the subjects here touched upon, which are of especial interest for the theory of solutions, must be looked for in special memoirs and works on theoretical and physical chemistry. A small part of this subject will be partially considered in the footnotes of the following chapter.

³⁵ Although the actual motion of gaseous molecules, which is accepted by the kinetic theory of gases (note 34), cannot be seen, yet its existence may be rendered evident by taking advantage of the difference in the velocities, undoubtedly belonging to different gases which are of different densities, under equal pressures. The molecules of a light gas must move more rapidly than the molecules of a heavier gas in order to produce the same pressure. Let us take, therefore, two gases, hydrogen and air: the former is 14.4 times lighter than the latter, and hence the molecules of hydrogen must

an obstacle produce a pressure, and the greater the number of molecules impinging against an obstacle in a given time, the greater the pressure. The pressure of a separate gas or of a gaseous mixture depends on the sum of the pressures of all the molecules—on the number of blows in a unit of time on a unit of surface, and on the mass and velocity (or the *vis viva*) of the impinging molecules. The nature of the different molecules is of no account; the obstacle is acted on by a pressure due to their total *vis viva*. But in a chemical action such as the solution of gases, the nature of the impinging molecules plays, on the contrary, a most important part. In impinging against a liquid, a portion of the gas enters into the liquid itself, and is held by it so long as other gaseous molecules impinge against the liquid, that is, exert a pressure on it. As regards the solubility of a given gas, for the number of blows it makes on the surface of a liquid, it is immaterial whether other molecules of gases impinge side by side with it or not. Hence, the solubility of a given gas will be proportional, not to the total pressure of a gaseous mixture, but to that portion of it which is due to the given gas separately. Moreover, the saturation of a liquid by a gas depends on the fact that the gaseous molecules that have entered the liquid do not remain at rest in it—although they enter into an harmonious kind of motion with the molecules of the liquid—but throw themselves off from its surface (just like the vapour of a volatile liquid). If in a unit of time an equal number of molecules penetrate into (leap into) and leave (or leap out of) a liquid, it is saturated. It is in a condition of mobile equilibrium, and not of rest. Therefore, if the pressure be diminished, the number of molecules departing from the liquid will exceed the number of molecules entering into the liquid, and a fresh state of mobile equilibrium only takes place on the attainment of a fresh equality between the number of molecules departing from and entering the liquid. In this manner are explained the main features of solution, and furthermore of that special (chemical) attraction

move almost four times more quickly than air (more exactly 3·8). Consequently, if a porous cylinder containing air is introduced into an atmosphere of hydrogen, then, in a given time, the volume of hydrogen which succeeds in entering the cylinder will be greater than the volume of air leaving the cylinder, and therefore the pressure inside the cylinder will rise until the gaseous mixture (of air and hydrogen) attains an equal density both inside and outside of the cylinder. If now the experiment be reversed and air surround the cylinder, and hydrogen be inside the cylinder then more gas will leave than enter the cylinder, and hence the pressure inside the cylinder will be diminished. In these considerations we have replaced the idea of the number of molecules by the idea of volumes. We shall learn subsequently that equal volumes of different gases contain the same number of molecules (the law of Avogadro-Gerhardt), and therefore instead of speaking of the number of molecules we can speak of the number of volumes. If the cylinder be partially immersed in water the rise and fall of the pressure can be observed directly, and the experiment consequently rendered self-evident.

(penetration and harmonious motion) of a gas for a liquid which determines both the measure of the solubility and the degree of stability of the solution produced.

The consequences of the law of partial pressures are exceedingly numerous and important. In nature all liquids are in contact with the atmosphere, which, as we shall afterwards see more fully, consists of a mixture of gases, chiefly four in number—oxygen, nitrogen, carbonic anhydride, and aqueous vapour. A hundred volumes of air contain, approximately, 78 volumes of nitrogen and about 21 volumes of oxygen; the quantity of carbonic anhydride, by volume, does not exceed 0.05. Under ordinary circumstances, the amount of aqueous vapour is much greater than this, but it varies with climatic conditions. We conclude from these numbers that the solution of nitrogen in a liquid in contact with the atmosphere will proceed under a partial pressure of $\frac{78}{100} \times 760$ mm. (if the atmospheric pressure equal 760 mm.), that is, under a pressure of 600 mm. of mercury; whilst the solution of the oxygen will proceed under a partial pressure of about 160 mm., and the solution of the carbonic anhydride under the very small pressure of 0.4 mm. As, however, the solubility of oxygen in water is twice that of nitrogen (note 30), the ratio of oxygen to nitrogen dissolved in water will be greater than the ratio in air. It is easy to calculate what quantity of each of the gases will be contained in water, and taking the simplest case we will calculate what quantities of these gases will be dissolved from air containing 21 per cent. of oxygen and 79 per cent. of nitrogen at 0° and 760 mm. pressure. Under a pressure of 760 mm., 1 cubic centimetre of water dissolves 0.0235 cubic centimetre of nitrogen, and under the partial pressure of 600 mm. it will dissolve $0.0235 \times \frac{600}{760}$, or 0.0185 cubic centimetre; of oxygen, $0.0482 \times \frac{160}{760}$, or 0.0102 cubic centimetre, will be dissolved. Hence 100 cubic centimetres of water will contain at 0° altogether 2.87 cubic centimetres of atmospheric gases, containing about 65 per cent. of nitrogen and 35 per cent. of oxygen by volume—i.e., about $\frac{1}{3}$ by volume of oxygen, although in the atmosphere this gas only occupies $\frac{1}{5}$ by volume.^{35a}

According to the law of partial pressures, whatever gas be dissolved in water will be expelled from the solution in an atmosphere of another gas. This depends on the fact that gases dissolved in water escape from it in a vacuum, because the pressure is nil, and an atmosphere of another gas acts like a vacuum towards a gas dissolved in water.

^{35a} The amount of carbonic anhydride held (dissolved) in river water is usually greater than the amount obtained by calculation from its content in air. This is due to the oxidation of organic matter and to the exhalations of the fish, &c., in the water, with the consequent formation of carbonic anhydride.

Evolution of gas then proceeds, because molecules of the dissolved gas no longer impinge upon the liquid, and are therefore not dissolved in it, and those previously held in solution leave the liquid in virtue of their elasticity.³⁶ For the same reason a gas may be entirely expelled from a gaseous solution by boiling—at least, in many cases, when it does not form particularly stable compounds with water. In fact, on the surface of the boiling liquid there will be aqueous vapour, and therefore all the pressure acting on the gas will be due to the aqueous vapour. On this account the partial pressure of the dissolved gas will be very inconsiderable, and this is the sole reason why *a gas separates from solution on boiling the liquid containing it*. At the boiling-point of water the solubility of gases in water is still sufficiently great for a considerable quantity of a gas to remain in solution. The gas dissolved in the liquid is carried away, together with the aqueous vapour, and if boiling be continued for a long time, all the gas will finally be given up.³⁷

³⁶ Here two cases occur: either the atmosphere surrounding the solution may be limited, or it may be proportionally so vast as to be unlimited, like the earth's atmosphere. If a gaseous solution be brought into an atmosphere of another gas which is limited—for instance, as in a closed vessel—then a portion of the gas held in solution will be expelled, and thus pass over into the atmosphere surrounding the solution, and will produce its partial pressure, under the influence of which a portion of the gas will remain in solution. But where the atmosphere into which the gaseous solution is introduced is not only that of another gas but also unlimited, then the gas dissolved will, on passing out from the solution, diffuse into this atmosphere, and produce an infinitely small pressure in the unlimited atmosphere. Consequently, no gas can be retained in solution under this infinitely small pressure, and it will be entirely expelled from the solution. For this reason water saturated with a gas which is not contained in air, will be entirely deprived of the dissolved gas if left exposed to the air. Water also passes off from a solution into the atmosphere, and it is evident that there might be such a case as a constant proportion between the quantity of water vaporised and the quantity of a gas expelled from a solution, so that not the gas alone, but the entire gaseous solution, would pass off. A similar case to this is met with in solutions which are not decomposed by heat (such as those of hydrogen chloride and iodide), as will afterwards be considered.

³⁷ However, in those cases where the variation of the coefficient of solubility with the temperature is not sufficiently great, and where certain quantities of aqueous vapour and gas pass off from a solution at the boiling-point, an atmosphere may be obtained having the same composition as the liquid itself. In this case the amount of gas passing over into such an atmosphere will not be greater than that held by the liquid, and therefore such a gaseous solution will distil over unchanged. The solution will then represent, like a solution of hydriodic acid in water, a liquid which is not altered by distillation, while the pressure under which this distillation takes place remains constant. Thus, in all its aspects, solution presents gradations from the most feeble affinity to intimate chemical combination between the solvent and dissolved substance. The **amount of heat** evolved in the solution of equal volumes of different gases stands in direct relation to these variations of stability and solubility of the gases. 22.3 litres of the following gases (at 760 mm. pressure) evolve the following numbers of (gram) units of heat on dissolving in a large mass of water; carbonic anhydride 5,600; sulphurous anhydride 7,700; ammonia 8,800; hydrochloric acid 17,400; and hydriodic acid 19,400. The last two gases, which are not expelled from their solutions by boiling, evolve approximately twice as

It is evident that the conception of the partial pressures of gases should be applied not only to the formations of solutions, but also to all cases of chemical action of gases. Especially numerous are its applications to the physiology of respiration, for in these cases it is only the oxygen of the atmosphere that acts.³⁸

The solution of **solids**, while depending in a small measure on the pressure under which solution takes place (because solids and liquids are almost incompressible), is very often greatly dependent on the temperature. In the majority of cases the solubility of solids in water increases as the temperature rises; and, further, the rapidity of solution increases also. The latter is determined by the rapidity of diffusion of the solution formed into the remainder of the water. The solution of a solid in water, although it is, as with gases, a physical change into a liquid state, is determined by its chemical affinity for water: this is clearly shown from the fact that in solution there occurs a diminution in volume, changes in the boiling-point of the water, in the pressure of its vapour, in the freezing point, and in many similar properties. If solution were a physical, and not a chemical, phenomenon, it would naturally be accompanied by an increase and not by a diminution of volume, because, in melting, solids generally increase in volume (their density diminishes). **Contraction** is the usual phenomenon accompanying solution, and takes place even on the addition of solutions to water,³⁹

much heat as gases like ammonia, which are separated from their solutions by boiling, whilst gases which are only slightly soluble evolve very much less heat.

³⁸ With regard to the numerous researches treating of this subject, certain results obtained by Paul Bert are cited in Chapter III., and we will here point out that Prof. Sechenoff, in his researches on the absorption of gases by liquids, investigated very fully the phenomena of the solution of carbonic anhydride in solutions of various salts, and arrived at many important results, which showed that, on the one hand, in the solution of carbonic anhydride in solutions of salts on which it is capable of acting chemically (for example, sodium carbonate, borax, ordinary sodium phosphate), there is not only an increase of solubility, but also a distinct deviation from the law of Henry and Dalton; whilst, on the other hand, solutions of salts which are not acted on by carbonic anhydride (for example, the chlorides, nitrates, and sulphates) absorb less of it, owing to the 'competition' of the salt already dissolved, and follow the law of Henry and Dalton, but at the same time show undoubted signs of a chemical action between the salt, water, and carbonic anhydride. Sulphuric acid (whose coefficient of absorption is 92 vols. per 100), when diluted with water, absorbs less and less carbonic anhydride, until the hydrate $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$ is formed, when the coefficient of absorption equals 66 vols.; then, on further addition of water, the solubility again rises.

³⁹ Kremers made this observation in the following simple way:—He took a narrow-necked flask with a mark on the narrow part (like that on a litre flask used for accurately measuring liquids), poured water into it, and then inserted a funnel, having a fine tube which reached to the bottom of the flask. Through this funnel he carefully poured a solution of any salt, and (having removed the funnel) allowed the liquid to attain a definite temperature (in a water-bath); he then filled the flask up to the mark with water. In this manner two layers of liquid were obtained, the heavy saline solution below and water above. The flask was then shaken in order to accelerate diffusion, and

and on the solution of liquids in water,⁴⁰ just as happens in the combination of substances with the production of chemically new substances.⁴¹ The contraction which takes place in solution is, however, very small; a fact which depends on the small compressibility of solids and liquids, and on the insignificance of the compressing force acting in solution.⁴² The change of volume which takes place in the solution of solids and liquids, or the alteration in specific gravity⁴³ and many other physical properties corresponding with it, depends on

it was observed that the volume became less if the temperature remained constant. This can be proved by calculation, if the specific gravity of the solutions and water be known. Thus at 15°, 1 c.c. of a 20 per cent. solution of common salt weighs 1.1500 gram, so that 100 grams of it occupy a volume of 86.96 c.c. As the sp. gr. of water at 15° is 0.99916, 100 grams of water occupy a volume of 100.08 c.c. The sum of the volumes is 187.04 c.c. After mixing, 200 grams of a 10 per cent. solution are obtained. Its specific gravity is 1.0725 (measured at 15° and referred to water at its maximum density); hence the 200 grams will occupy a volume of 186.48 c.c. The contraction is consequently equal to 0.56 c.c.

⁴⁰ The contractions produced in the case of the solution of sulphuric acid in water are shown in the diagram, fig. 17 (page 74). The maximum is 10.1 c.c. per 100 c.c. of the solution formed. A maximum contraction of 4.15 at 0°, 3.78 at 15°, and 3.50 at 30° takes place on dissolving 46 parts by weight of anhydrous alcohol in 54 parts of water. This signifies that if, at 0°, 46 parts by weight of alcohol be taken and 54 parts by weight of water, then the sum of their separate volumes will be 104.15, whilst after mixing their total volume will be 100.

⁴¹ This subject will be considered later in this work, and we shall then see that the contraction produced in reactions of combination (of solids or liquids) is very variable in its amount, and that there are, although rarely, reactions of combination in which contraction does not take place, or when an increase of volume is produced. Solutions exhibit a similar phenomenon.

⁴² The compressibility of solutions of common salt is less, according to Grassi, than that of water. At 18° the compression of water is 48 vols. per million for a pressure of one atmosphere; for a 15 per cent. solution of common salt it is 32, and for a 24 per cent. solution 26 vols. Similar determinations were made by Brown (1887) for saturated solutions of sal-ammoniac (38 vols.), alum (46 vols.), common salt (27 vols.), and sodium sulphate at + 1°, when the compressibility of water is 47 per million volumes. This investigator also showed that substances which dissolve with an evolution of heat and with an increase in volume (as, for instance, sal-ammoniac) are partially separated from their saturated solutions by an increase of pressure (this experiment was particularly conclusive in the case of sal-ammoniac), whilst the solubility of substances which dissolve with an absorption of heat or diminution in volume increases, although very slightly, **with an increase of pressure**. Sorby observed the same phenomenon with common salt (1863).

⁴³ The most trustworthy data relating to the variation of the specific gravity of solutions with a change of their composition and temperature are collected and discussed in my work cited in footnote 19. The practical (the amount of a substance in solution being determined by the aid of the specific gravities of solutions, both in works and in laboratory practice) and the theoretical (for specific gravity can be more accurately observed than other properties, and because a variation in specific gravity governs the variation of many other properties) interest of this subject, besides the strict rules and laws to which it is liable, make one wish that this province of data concerning solutions may soon be enriched by further observations of as accurate a nature as possible. Their carrying out does not present any great difficulty, although requiring much time and attention.

peculiarities of the dissolving substances and of water, and, in the majority of cases, is not proportional to the quantity of the substance dissolved,⁴⁴ showing the existence of a chemical force between the solvent and the substance dissolved, which is of the same nature as in all other forms of chemical reaction.⁴⁵

⁴⁴ Owing to the degree of change, exhibited in many properties on the formation of solutions, not being large, and to the insufficient accuracy of observations, a proportionality between this change and change of composition may, especially within narrow limits of change of composition, easily be imagined in cases where it does not exist. The conclusion of Michel and Kraft is particularly instructive in this respect; in 1854, on the basis of their researches, they assumed that the increment of the specific gravity of solutions was proportional to the increment of salt in a given volume of a solution, which is only true for determinations of specific gravity exact merely to the second decimal place—an accuracy insufficient even for technical determinations. Accurate measurements do not confirm a proportionality either in this case or in many others where such has been generally accepted; as, for example, in the rotatory power (of the plane of polarisation) of solutions, and in their capillarity, &c. Judging by the results obtained in my researches on the specific gravity of solutions, I think that in many cases it would be nearer the truth to take the change of properties as proportional, not to the amount of a substance dissolved, but to the product of this quantity and the amount of water in which it is dissolved; the more so since many chemical relations vary in proportion to the reacting masses, and a similar ratio has been established for many phenomena of attraction studied by mechanics.

⁴⁵ All the different forms of chemical reaction may be said to take place in the process of solution: (1) *Combinations* between the solvent and the substance dissolved, yielding compounds more or less stable (more or less dissociated). This form of reaction is the most likely to occur, and is that most often observed. (2) Reactions of *substitution* or of *double decomposition* between the molecules. Thus it may be supposed that in the solution of sal-ammoniac, NH_4Cl , the action of water produces ammonia, NH_4HO , and hydrochloric acid, HCl , which are dissolved in the water and simultaneously attract each other. As these solutions and many others do indeed exhibit signs, sometimes indisputable, of such double decompositions (thus solutions of sal-ammoniac yield a certain amount of ammonia), it is probable that this form of reaction is more often met with than is generally thought. (3) *Isomeric changes* also probably take place in solution, all the more so since here molecules of different kinds come into intimate contact, and it is very likely that under these influences the configuration of the atoms in the molecules is somewhat different from what it was in its original and isolated state. One is led to this supposition especially from observations made on solutions of substances which rotate the plane of polarisation (and observations of this kind are very sensitive with respect to the atomic structure of molecules), because they show, for example (according to Schneider, 1881), that strong solutions of malic acid rotate the plane of polarisation to the right, whilst its ammonium salts in all degrees of concentration rotate to the left. (4) Reactions of *decomposition* under the influences of solution are not only rational in themselves, but have in recent years been recognised by Arrhenius, Ostwald, and others, particularly on the basis of electrolytic determinations. If some of the molecules of a solution occur in a condition of decomposition, the rest may occur in a still more complex state of combination, just as the velocities of different gaseous molecules may be far from being the same (see note 34).

It is, therefore, very probable that the reactions taking place in solution vary both quantitatively and qualitatively with the mass of water in the solution, and the great difficulty of arriving at a definite conclusion as to the nature of the chemical relations in solution will be understood; and as also the existence of a physico-mechanical process like the sliding between and interpenetration of two homogeneous liquids must also be recognised in solution, the complexity of the problem as to the actual nature of solutions,

The feeble development of the chemical affinities acting in solutions of solids becomes evident on considering the different methods by which **their solutions are decomposed**, with the separation of either their component parts or their definite compounds with water. The water contained in solutions is removed from them as vapour, or, by freezing, in the form of ice,⁴⁶ but **the pressure of the vapour of the water**⁴⁷ present in a solution is less than that of water in a free state, and the **temperature of the formation of ice** from solutions is lower than 0° . Further, both the diminution of vapour pressure and the lowering of the freezing-point are, in dilute solutions, very nearly proportional to the amount of a substance dissolved.⁴⁸ Thus, if for every 100 grams of water there be in solution 1, 5, or 10 grams of common salt (NaCl), then at 100° the vapour pressure of the solution will be 4, 21, or 43 mm. less than 760 mm.—the vapour pressure of water—while the freezing-points are -0.58° , -2.91° , and -6.10° respectively. The above figures⁴⁹ are almost proportional to the amounts

which is now to the fore, appears in its true light. But it would not be expedient to discuss this complex subject and the numerous researches upon it in a short exposition of the principles of chemistry. It requires to be specially and fully treated in physical chemistry (see Chapter VII., note 27).

⁴⁶ In separating as ice or vapour, water makes, with a solution, a heterogeneous system (made up of substances in different physical states) similar, for instance, to the formation of a precipitate or volatile substance in reactions of double decomposition.

⁴⁷ If the substance dissolved is non-volatile (like salt or sugar), or only slightly volatile, then the whole of the pressure of the vapour given off is due to the water; but if a solution of a volatile substance—for instance, a gas or a volatile liquid—evaporates, then only a portion of the pressure belongs to the water, and the whole pressure observed consists of the sum of the pressures of the vapours of the water and of the substance dissolved. The majority of researches bear on the first case, which will be spoken of presently, whilst the observations of D. P. Konovaloff (1881) refer to the second case. He showed that in the case of two volatile liquids, mutually soluble in each other, forming two layers of saturated solutions (for example, ether and water, note 20, p. 65), both solutions have an equal vapour pressure in the case in point the pressure of each is equal to 431 mm. of mercury at 19.8°). Further, he found that for solutions which are formed in all proportions, the pressure is either greater (solutions of alcohol and water) or less (solutions of formic acid) than that corresponding with the rectilinear change (proportional to the composition) from the pressure of water to the pressure of the substance dissolved; thus the pressure, for example, of a 70 per cent. solution of formic acid is less, at all temperatures, than the pressure of water or that of formic acid. In this case the pressure of a solution is never equal to the sum of the pressures of the dissolving liquids, as Regnault already showed when he distinguished this case from that in which a mixture of liquids, which are insoluble in each other, evaporates. From this it is evident that a mutual action occurs in solution, which diminishes the vapour pressure proper to the individual substances, as would be expected on the supposition of the formation of compounds in solutions, because the elasticity then always diminishes.

⁴⁸ This amount is usually expressed by the weight of the substance dissolved per 100 parts by weight of water. Probably it would be better to express it by the quantity of the substance in a definite volume of the solution—for instance, in a litre—or by the ratio of the numbers of molecules of water and of the dissolved substance.

⁴⁹ The variation of the vapour pressure of solutions has been the subject of many

of salt in solution (1, 5, and 10 per 100 of water). Furthermore, it has investigations. The best known researches are those of Wüllner in Germany (1858–1860) and of Tamman in Russia (1887). The researches on the temperature of the formation of ice by various solutions are also very numerous; Blagden (1788), Rüchdorff (1861), and De Coppet (1871) were the first to start such work, which, however, takes its chief interest from the work of Raoult, begun in 1882 on aqueous solutions, and afterwards continued with solutions in various other easily frozen liquids—for instance, benzene, C_6H_6 (melts at 4.96°), acetic acid, $C_2H_4O_2$ (16.75°), and others. Especial interest is attached to these **cryoscopic** investigations made by Raoult, in France, on the *depression* of the freezing-point, because he took solutions of many well-known carbon-compounds and discovered a simple relation between the molecular weights of the substances and the temperatures of crystallisation of the solvent, which enabled this method of research to be applied to the investigation of the nature of substances. We shall meet with the application of this method later on (see also Chapter VII.), and at present will only cite the deduction arrived at from these results. The solution of one-hundredth part of that molecular gram weight which corresponds with the formula of a substance (for example, $NaCl = 58.5$, $C_2H_6O = 46$, &c.) in 100 parts of a solvent lowers the freezing-point of water 0.185° , of benzene 0.49° , and of acetic acid 0.39° or twice as much as with water. And as in dilute solutions the depression or fall of freezing-point is proportional to the amount of the substance dissolved, the fall of freezing-point for all other solutions may be calculated by means of this rule. Thus, for instance, the weight which corresponds with the formula of acetone, C_3H_6O , is 58; solutions containing 2.42, 6.22, and 12.35 grams of acetone per 100 grams of water form ice (according to the determinations of Beckmann) at -0.770° , -1.930° , and -3.820° , and these figures show that with a solution containing 0.58 gram of acetone per 100 of water the fall of the temperature of the formation of ice will be 0.185° , 0.180° , and 0.179° . It must be remarked that the law of proportionality between the fall of temperature of the formation of ice and the concentration of a solution is in general only approximate, and is only applicable to weak solutions (Pickering and others).

We may here remark that the theoretical interest of this subject was strengthened on the discovery of the connection existing between the fall of vapour pressure, the depression of the temperature of the formation of ice, the diminution of osmotic pressure (van't Hoff, note 19), and the electrical conductivity of solutions, and we shall therefore supplement what we have already said on the subject by some short remarks on the method of cryoscopic investigations, although the details of the matter form the subject of more special works on physical chemistry.

In order to determine the **temperature of the formation of ice** (or of crystallisation of other solvents), a solution of known strength is prepared and poured into a cylindrical vessel surrounded by a second similar vessel, leaving between the two a layer of air which, being a bad conductor, prevents any rapid change of temperature. Still better results are obtained if the air be exhausted from the space between the two vessels and the sides of both be silvered. The transfer of heat then proceeds very slowly. The bulb of a sensitive and corrected thermometer is immersed in the solution, and also a bent platinum wire for stirring the solution; the whole is then cooled (by immersing the apparatus in a freezing mixture), and the temperature at which ice begins to separate observed. The temperature may fall slightly below its final value, but it rises and remains constant when ice begins to form. By then allowing the liquid to become slightly warmer, and again observing the temperature of the formation of ice, an exact determination may be arrived at. It is still better to take a large mass of solution, and induce the formation of the first crystals by dropping into the solution, already partially over-cooled, a small lump of ice, which only imperceptibly changes the composition of the solution. The observation should be made at the point of formation of only a very small amount of crystals, as otherwise the composition of the solution will become altered owing to their separation. Every precaution must be taken to prevent the access of moisture to the interior of the apparatus, as this might also alter the composition of the solution or the properties of the solvent (for instance, when using acetic acid).

been shown by experiment that the ratio of the diminution of vapour

With respect to the depression of dilute solutions it is known: (1) That the depression increases in almost direct proportion to the amount of the substance in solution (always per 100 parts of water); for example, for KCl when the solution contains 1 part of salt (per 100 parts of water) the depression is 0.45° , when it contains 2 parts of salt, 0.90° , or with 10 parts of salt, 4.4° . (2) The greater the molecular weight expressed by the formula (see Chapter VII.), and designated by M , the less, under similar conditions, will be the depression d , and therefore if the concentration of a solution (the amount by weight of substance dissolved per 100 parts of water) be designated by p , then the fraction $M \frac{d}{p}$ or the molecular depression for a given class of substances will be a constant quantity; for example, in the case of methyl alcohol in water 17.3 , for acetone about 18.0 , and for sugar about 18.5 . (3) In general the molecular depression for substances whose solutions do not conduct an electric current is about 18.5 , while for acids, salts, and such like substances whose solutions do conduct electricity, it is i times greater; for instance, for HCl, KI, HNO_3 , KHO, &c., about 36 (i being nearly 2), for borax about 66 , and so on, i varying in the same manner as it does in the case of the osmotic pressure of solutions (note 19). (4) Different solvents (water, acetic acid, benzene, &c.) have each their corresponding constants of molecular depression (which have a certain remote connection with their molecular weight); for example, for acetic acid the molecular depression is about 39 and not 19 (as it is for water); for benzene, 49 ; for methyl alcohol about 17 , &c. (5) If the molecular weight M of a substance be unknown, then in the case of non-conductors of electricity or for a given group, it may be found by determining the depression, d , for a given concentration, p ; for example, in the case of peroxide of hydrogen, which is a non-conductor of electricity, the molecular weight, M , was found to be nearly 34 , corresponding with the formula H_2O_2 (see Chapter VII.).

Similar results have also been found for the fall in the vapour pressure of solutions (note 51), and for the rise of their boiling-points and for other properties of the substances dissolved (Chapter VII.), and for the osmotic pressure (note 19). A variation in the magnitude of i , in passing from solutions which do not conduct an electric current to those which do conduct electricity, is everywhere remarked, so that it was natural to seek here that causal connection which Arrhenius (1888), Ostwald, and others think they have found in the supposition that a portion of the substance of the electrolyte is decomposed, in the very act of solution, into its ions (for example, NaCl into Na and Cl), or into the atoms of those individual substances which make their appearance in electrolysis, and in this way to explain the fact that i is greater for those bodies which conduct an electric current. We will not here consider this supposition, known as the hypothesis of 'electrolytic dissociation,' not merely because it belongs entirely to the special branch of physical chemistry, and gives scarcely any help towards explaining the chemical relations of solutions (particularly their passage into definite compounds, their reactions, and their very formation, but also because: (1) all the above data (for constant depression, osmotic pressure, &c.) refer only to dilute solutions, and are not applicable to strong solutions; whilst the chemical interest in strong solutions is not less than in dilute solutions, and the transition from the former to the latter is consecutive and inevitable; (2) because in any homogeneous body (although it may be insoluble and not an electrolyte) some of the atoms may always be supposed (Clausius) to be in the act of passing from one molecule to another (Chap. X. note 20), and hence in a dissociated state, but there are no reasons for believing that such a phenomenon is peculiar to the solutions of electrolytes; (3) because no essential difference is observed between the solution of electrolytes and non-conductors, although this might well be expected, according to Arrhenius's hypothesis; (4) because it is more reasonable to assume, in the act of solution, the formation of new, more complex, but unstable and easily dissociated compounds, than a decomposition even partial, of the substances taken; (5) because, if Arrhenius's hypothesis be accepted, it becomes necessary to admit the existence in solutions of free ions, like the atoms Cl or Na, without any

pressure in a given solution to the vapour pressure of water is an

apparent expenditure of the energy necessary for their disruption; and although on this supposition it can be explained why i then = 2, it is not at all clear why solutions of MgSO_4 give $i = 1$, although they also conduct an electric current; (6) because in dilute solutions, the approximative proportionality between the depression and concentration may be recognised, while admitting the formation of hydrates, with as much right as in admitting the solution of anhydrous substances, and if the formation of hydrates be recognised it is easier to assume that these are partially decomposed than to accept the breaking up into ions; (7) because the best conductors of electricity are solutions of substances like the sulphates, in which it is necessary to recognise the formation of associated systems or hydrates; (8) because the cause of electro-conductivity can be sooner looked for in this affinity and this combination of the substance dissolved with the solvent, as is seen from the facts that (D. P. Konovaloff) neither aniline nor acetic acid alone conducts an electric current, a solution of aniline in water conducts it badly (and here the affinity is very small), while a solution of aniline in acetic acid forms a good electrolyte, in which, without doubt, chemical forces are acting, bringing aniline, like ammonia, into combination with the acetic acid; and, lastly, (9) because I, together with many of the chemists of the present day, cannot regard the hypothesis of electrolytic dissociation, in the form given to it up to now by Arrhenius and Ostwald, as accounting for the sum total of the chemical data respecting solutions and dissociation in general. The hypothesis of 'electrolytic dissociation' (of the electrolytes dissolved, i.e., their splitting up on solution into imaginary ions, which, according to this hypothesis, are formed even without a current) which is lamely applied to explain the increase of the value of i , but which adds nothing to our comprehension of solutions in general, suffers, moreover, in its endeavour to penetrate into the province of ordinary chemical phenomena by affirming that reaction proceeds, as a rule, only between free ions; for instance, that in the action of AgNO_3 on NaCl , the free ions of Ag , on meeting the ions of Cl , give AgCl . The followers of the hypothesis have applied this view to a number of phenomena (such as coloration, distribution, &c.) and reactions. For my part I consider this side of the question still less satisfactory and less in accordance with fact, and in illustration of this I will cite the following two (out of many) instances. (1) Liveing (1900) showed that the absorption spectrum (see Chap. XIII.) of solutions of a certain salt of didymium remains unchanged, notwithstanding a variation in the amount of water (concentration), if only the ray of light passing through the solution encounters the same quantity of the didymium salt (for instance, if in one case A grams of salt per litre be taken and the column of solution be n centimetres long, and in another case xA grams of the salt be present per litre and the column be n/x centimetres long). But according to the followers of the electrolytic dissociation hypothesis, the more diluted the solution the greater the proportion of free ions, and the coloration and absorption spectra of solutions are determined by these free ions. (2) L. Kahlenberg (1902) showed that on mixing a solution of dry oleate of copper, $\text{Cu}x_2$ (where $x = \text{C}_{18}\text{H}_{33}\text{O}_2$), in dry benzene with a benzene solution of perfectly dry hydrochloric acid, 2HCl (non-conductors of electricity, and therefore, according to the hypothesis, containing no free ions), they immediately give a precipitate of chloride of copper, CuCl_2 , because the latter is insoluble in benzene. But according to the hypothesis of electrolytic dissociation, this could in nowise be expected, because as the above solutions do not conduct an electric current they should contain no free ions, and therefore instantaneous reaction should not take place. I do not consider the hypothesis in question to be in accordance with fact, and therefore refrain from giving a detailed exposition of it in this work. Thus, although I consider it superfluous to discuss further the evolution of the above theory of solutions, still I think that it would be most useful for students of chemistry to consider all the data referring to this subject, which can be found in the *Zeitschrift für physikalische Chemie*, first published in 1887. Besides which, I think it well to point out that in my opinion (note 45) the nature of solutions is very complex, and there is reason for recognising a portion of the substances present to be in a state of combination and another portion in a state of dissociation, having nothing in common with the still obscure

almost constant quantity at different temperatures,⁵⁰ and that for every (dilute) solution the ratio between the depressions of the vapour pressure and of the freezing-point is also a tolerably constant quantity.⁵¹

The diminution of the vapour pressure of solutions explains the rise in boiling-point occasioned by the solution of solid non-volatile bodies in water. The temperature of a vapour is the same as that of the solution from which it is generated, and therefore it follows that the aqueous vapour given off from a solution will be superheated. A saturated solution of common salt boils at 108·4°, a solution of 335 parts of nitre in 100 parts of water at 115·9°, and a solution of 325 parts of potassium chloride in 100 parts of water at 179°, if the temperature of ebullition be determined by immersing the thermometer bulb in the liquid itself. This is another proof of the bond which exists between the water and the dissolved substance. And this bond is indicated still more clearly in those cases (for example, in the solution of nitric or formic acid in water) where the solution boils at a higher temperature than either water or the volatile substance dissolved in it. For this reason the solutions of certain gases—for instance hydriodic or hydrochloric acid—boil above 100°.

The separation of ice from solutions⁵² explains both the phenomenon, well known to sailors, that the ice formed from salt water gives

force of electricity. I consider that the recognition of dissociation and association in solutions will become necessary for their right comprehension, and I think that the modern conception of electrolytic dissociation, although retarding the progress of the theory of solution, is useful in giving the motive for collecting a store of experimental data to be embraced by a true theory in the future.

⁵⁰ This fact, which was established by Gay-Lussac, Pierson, and v. Babo, is confirmed by the latest observations, and enables us to express not only the fall of pressure ($p - p'$) itself, but its ratio to the pressure of water $\left(\frac{p - p'}{p}\right)$. It is to be remarked that in the absence of any chemical action, the pressure is equal, according to the law of Dalton, to the sum of the pressures of the substances taken. Hence liquids which are insoluble in each other (for example, water and chloride of carbon) present a pressure equal to the sum of their individual pressures, and therefore such a mixture boils at a lower temperature than the more volatile liquid (Magnus, Regnault).

⁵¹ If, in the example of common salt, the fall of pressure is divided by the pressure of water, a figure is obtained which is nearly 105 times less than the magnitude of the fall of temperature of formation of ice. This correlation was theoretically deduced by Goldberg, on the basis of the mechanical theory of heat, and has been experimentally confirmed for many solutions. But here again I must refer the reader to works on physical chemistry, because it is impossible to go into all the theoretical and practical details of the subject here.

⁵² Fritzsche showed that solutions of certain colouring matters yield colourless ice, clearly proving that the water alone without any intermixture of the substance dissolved passes into a solid state, although the possibility of the admixture in certain other cases cannot be denied.

fresh water,^{52a} and also the fact that by freezing, just as by evaporation, a solution is obtained which is richer in salts than before. In cold countries this is taken advantage of for obtaining from sea water a liquor, which is then evaporated for the extraction of salt.

On the removal of part of the water from a solution (by evaporation or the separation of ice), a saturated solution should be obtained, and the solid substance dissolved should then separate out. Solutions saturated at a certain temperature should also deposit a corresponding portion of the substance dissolved if they be reduced, by cooling,⁵³ to a temperature at which the water can no longer hold in solution the quantity of the substance originally present. If this separation, by cooling a saturated solution or by evaporation, takes place slowly, **crystals** of the substance dissolved are in many cases formed; and this is the method by which crystals of soluble salts are usually obtained. Certain solids very easily separate out from their solutions in perfectly formed crystals, which may attain very large dimensions. Such are nickel sulphate, alum, sodium carbonate, chrome-alum, copper sulphate, potassium ferricyanide, and a whole series of other salts. The most remarkable circumstance in this is that many solids in separating out from an aqueous solution retain a portion of water, forming crystallised solid substances which contain water. Water which is thus retained is called **water of crystallisation**. Alum, copper sulphate, Glauber's salt, and magnesium sulphate contain such water, but neither sal-ammoniac, common salt, nitre, potassium chlorate, silver nitrate, nor sugar contains water of crystallisation in its crystals. One and the same substance may separate out from a solution with or without water of crystallisation, according to the temperature at which the crystals are formed. Thus common salt when crystallised from its solution in

^{52a} If the ice be gradually formed in a continuous mass. But if it occurs as frozen fragments, it will enclose a portion of the salt water.

⁵³ As the solubility of certain substances (for example, coniine, cerium sulphate, &c.) decreases with a rise of temperature (between certain limits—see, for example, note 24), these substances separate from their saturated solutions, not on cooling, but on heating. Thus a solution of manganese sulphate, saturated at 70°, becomes cloudy on further heating. The observation of the point at which a substance separates from its solution with a change of temperature gives an easy means of determining the coefficient of solubility, and this was taken advantage of by Prof. Alexéeff for determining the solubility of many substances. The phenomenon and method of observation are here essentially the same as in the determination of the temperature of formation of ice. If a solution of a substance which separates out on heating be taken (for example, sulphate of calcium or manganese), then on a certain fall of temperature ice will separate out from it, and on a certain rise of temperature the salt will separate out. From this example, and from general considerations, it is clear that the separation of a dissolved substance from a solution presents a certain analogy to the separation of ice from a solution. In both cases a heterogeneous system of a solid and a liquid is formed from a homogeneous (liquid) system.

water at the ordinary or at a higher temperature does not contain water of crystallisation. But if it separates from solution at a low temperature, namely, below -10° , then 100 parts of the crystals contain 38 parts of water. Crystals of the same substance which separate out at different temperatures may contain different amounts of water of crystallisation. This proves to us that a solid dissolved in water may form various compounds with it, differing in their properties and composition, and capable of appearing in a separate solid form like many ordinary definite compounds. This is indicated by the numerous properties and phenomena connected with solutions, and gives reason for thinking that there exist in solutions themselves either such compounds of the dissolved substance with the solvent or compounds similar to them, only in a liquid and partly decomposed form. Even the **colour of solutions** may often confirm this opinion. Copper sulphate forms crystals having a blue colour and containing water of crystallisation. If the water of crystallisation be removed by heating the crystals to redness, a colourless anhydrous substance—a white powder—is obtained. From this it may be seen that the blue colour belongs to the compound of the copper salt with water. Solutions of copper sulphate are all blue, and consequently they contain a compound similar to the compound formed by the salt with its water of crystallisation. Crystals of cobalt chloride when dissolved in an anhydrous liquid—like alcohol, for instance—give a blue solution; but when they are dissolved in water a red solution is obtained. Crystals from the aqueous solution, according to Professor Potilitzin, contain six times as much water ($\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$) for a given weight of the salt as the violet crystals ($\text{CoCl}_2 \cdot \text{H}_2\text{O}$) formed by the evaporation of an alcoholic solution.

Further light on the nature of solutions is given by supersaturated solutions, by the so-called cryohydrates, by solutions of certain acids having constant boiling-points, and by the properties of compounds containing water of crystallisation, to the consideration of which we now turn.

Supersaturated solutions exhibit the following phenomena:—On cooling a saturated solution of certain salts,⁵⁴ the excess of the solid

⁵⁴ Salts which separate out with water of crystallisation and form several crystallohydrates yield supersaturated solutions with the greatest facility, and the phenomenon is much more common than was previously imagined. The first data were given in the eighteenth century by Loewitz in St. Petersburg. Numerous researches have proved that supersaturated solutions do not differ from ordinary solutions in any of their essential properties. The variations in specific gravity, vapour pressure, formation of ice, &c., take place according to the ordinary laws, and their formation depends on the absence of solid particles (of the solid phase), about which crystallisation readily takes place (as has been partially explained in note 24).

may, under certain conditions, remain in solution and not separate out. A great number of substances, and more especially sodium sulphate, Na_2SO_4 , or Glauber's salt, readily form supersaturated solutions. If boiling water be saturated with this salt, and the *solution be poured off from any salt remaining undissolved*, and be kept boiling while the vessel containing it is well closed either with a plug of cotton wool, or by fusing it in the flame, or if the solution be covered with a layer of oil, it will be found that this saturated solution does not deposit any Glauber's salt whatever on cooling down to the ordinary or even to a much lower temperature; without, however, the above precautions, the salt separates out on cooling in the form of crystals of the composition $\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$ —that is, containing 180 parts of water for every 142 parts of anhydrous salt. The supersaturated solution may be moved about or shaken inside the vessel holding it, and no crystallisation will take place; the salt remains in the solution in as large an amount as at a higher temperature. If the vessel holding the supersaturated solution is opened, and a crystal of Glauber's salt thrown in, crystallisation suddenly takes place.⁵⁵ A considerable rise in temperature is noticed during this rapid separation of crystals, and this is due to the fact that the salt, previously in a liquid state, passes into a solid one. This bears some resemblance to the fact that, under certain circumstances, water may be cooled below 0° (even to -10°) if it be left at rest, and then evolves heat in suddenly crystallising. Although from this point of view there is a resemblance, yet in reality the phenomenon of supersaturated solutions is much more complicated. Thus, on cooling, a saturated solution of Glauber's salt deposits crystals of the composition $\text{Na}_2\text{SO}_4, 7\text{H}_2\text{O}$,⁵⁶ and not $\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$. The

⁵⁵ Inasmuch as air, as has been shown by direct experiment, contains, although in very small quantities, minute crystals of salts, and among them sodium sulphate, air can bring about the crystallisation of a supersaturated solution of sodium sulphate in an open vessel, but it has no effect on saturated solutions of certain other salts, for example, lead acetate. According to the observations of de Boisbaudran, Gernez, and others, isomorphous salts (analogous in composition) are capable of inducing crystallisation. Thus, a supersaturated solution of nickel sulphate crystallises by contact with crystals of other sulphates analogous with it, such as those of magnesium, cobalt, copper, and manganese. The crystallisation of a supersaturated solution, set up by the contact of a minute crystal, starts from it in rays with a definite velocity, and it is seen that the crystals as they form propagate the crystallisation in definite directions. This phenomenon recalls the evolution of organisms from germs. An attraction of similar molecules ensues, and they dispose themselves in definite similar forms.

⁵⁶ At the present time a view is very generally accepted, which regards supersaturated solutions as homogeneous systems, which pass into heterogeneous systems (composed of a liquid and a solid substance) in a manner exactly resembling the passage of water, cooled below its freezing-point, into ice and water, or the passage of crystals of rhombic sulphur into monoclinic crystals, and of the monoclinic crystals into rhombic. Although many phenomena of supersaturation are thus clearly understood, yet the spontaneous

crystals containing $7\text{H}_2\text{O}$ are distinguished for their instability : if they stand in contact not only with crystals of $\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$, but with many other substances, they immediately become opaque, forming a mixture of the anhydrous and deca-hydrated salts. It is evident that between water and a soluble substance there may be established various kinds of more or less stable equilibrium, of which solutions form a particular case.⁵⁷

formation of the unstable hepta-hydrated salt, in the place of the more stable deca-hydrated salt, indicates that the phenomenon is essentially a complex one, and is most probably determined by the fact that chemical forces act between the water and the dissolved substance, tending to the formation of compounds of the two in different proportions and with different distribution of parts (structure). Stcherbacheff asserts, on the basis of his researches, that a solution of the deca-hydrated salt gives, on evaporation without the aid of heat, the deca-hydrated salt, whilst after heating above 33° it forms a supersaturated solution and the hepta-hydrated salt. But in order that this view should be accepted, indications must be found distinguishing solutions (which are, according to this view, isomeric) containing the hepta-hydrated salt from those containing the deca-hydrated salt, and all efforts in this direction (the study of the properties of the solutions) have given negative results. As some crystallohydrates of salts (alums, sugar of lead, calcium chloride) melt directly, without depositing anything, whilst others (like $\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$) are broken up, it may be that the latter are in a state of equilibrium which does not persist at a temperature higher than the melting-point. It may here be observed that, on melting crystals of the deca-hydrated salt, there is formed, besides the solid anhydrous salt, a saturated solution giving the hepta-hydrated salt, so that this passage from the deca- to the hepta-hydrated salt, and the reverse, take place with the formation of the anhydrous (or, it may be, mono-hydrated) salt.

Moreover, supersaturation (Potilitzin, 1889) only takes place with those substances which are capable of giving several modifications or several crystallohydrates, i.e., supersaturated solutions deposit, besides the stable normal crystallohydrate, hydrates containing less water and also the anhydrous salt. Sulphate of nickel solution at 15° – 20° deposits rhombic crystals containing $7\text{H}_2\text{O}$, at 30° – 43° cubical crystals with $6\text{H}_2\text{O}$, at 50° – 70° monoclinic crystals, also containing $6\text{H}_2\text{O}$. The ability to deposit slightly hydrated or anhydrous salts by the introduction of a crystal into the solution is common to all supersaturated solutions. If a salt forms a supersaturated solution, then one would expect, according to this view, that it should exist in the form of several hydrates or in several modifications. Thus Potilitzin concluded that strontium chlorate, which readily gives supersaturated solutions, should be capable of forming several hydrates, besides the anhydrous salt known ; and he succeeded in discovering the existence of two hydrates, $\text{Sr}(\text{ClO}_3)_2, 3\text{H}_2\text{O}$ and apparently $\text{Sr}(\text{ClO}_3)_2, 8\text{H}_2\text{O}$. Further, three modifications of the common anhydrous salt were obtained, differing from each other in crystalline form. It seems to me that the following fact throws most light on the nature of supersaturated solutions ; if crystals of two forms be simultaneously thrown into a supersaturated solution (for instance, of Na_2CO_3 , note 24) capable of depositing either of them, then only the less soluble form (solid phase) will crystallise out, whilst the more soluble form will pass into solution.

⁵⁷ **Emulsions**, such as milk, are composed of a solution of glutinous or similar substances, or of oily liquids suspended in a liquid in the form of drops, which are clearly visible under a microscope, and form an example of a mechanical formation resembling solution. But the difference from solutions is here evident. There are, however, solutions which approach very near to emulsions in the facility with which the dissolved substance separates from them. It has long been known, for example, that a particular kind of Prussian blue, $\text{KFe}_2(\text{CN})_6$, dissolves in pure water, but, on the addition of the smallest quantity of any one of a number of salts, it coagulates and becomes quite insoluble. If

Solutions of salts, on cooling below 0° , deposit ice or crystals (which frequently contain water of crystallisation) of the salt dissolved, and on reaching a certain degree of concentration they solidify in their entire mass. These solidified masses are termed *cryohydrates*. My researches on solutions of common salt (1868) showed that its solution solidifies when it reaches a composition $\text{NaCl} + 10\text{H}_2\text{O}$ (180 parts of water per 58.5 parts of salt), which takes place at about -23° . The solidified solution melts at the same temperature, and both the portion melted and the remainder preserve the above composition. Guthrie (1874–1876) prepared the cryohydrates of many salts, and he showed that certain of them are formed like the above at comparatively low temperatures, whilst others (for instance, those of corrosive sublimate, potassium chlorate and various colloids, and also the alums) are formed on a slight cooling—to -2° or even before.⁵⁸ In the case of common

copper sulphide (CuS), cadmium sulphide (CdS), arsenious sulphide (As_2S_3) (the experiments with these substances proceed with great ease, and the solution obtained is comparatively stable), or one of many other metallic sulphides be obtained by a method of double decomposition (by precipitating salts of these metals by hydrogen sulphide), and be then carefully washed (by allowing the precipitate to settle, pouring off the liquid, and again adding hydrogen sulphide solution), then, as was shown by Schulze, Spring, Prost, and others, the previously insoluble sulphides pass into transparent (for mercury, lead, and silver, reddish brown; for copper and iron, greenish brown; for cadmium and indium, yellow; and for zinc, colourless) solutions, which may be preserved (the weaker they are, the longer they keep), and even boiled, but which, nevertheless, in time coagulate—that is, separate in an insoluble form, and then sometimes become crystalline and quite incapable of redissolving. Graham and others observed the power shown by colloids (see note 18) of forming similar **hydrosols or solutions of gelatinous colloids**, and, in describing alumina and silica, we shall again have occasion to speak of such solutions.

In the existing state of our knowledge concerning solution, such solutions may be regarded as a transition between emulsions and ordinary solutions.

⁵⁸ Offer (1880) concludes, from his researches on cryohydrates, that they are simple mixtures of ice and salts, having a constant melting-point, just as there are alloys having a constant point of fusion, and solutions of liquids with a constant boiling-point (see note 60). This does not, however, explain in what form a salt is contained, for instance, in the cryohydrate $\text{NaCl} + 10\text{H}_2\text{O}$. At temperatures above -10° common salt separates out in anhydrous crystals, and at temperatures near -10° , in combination with water of crystallisation, as $\text{NaCl} + 2\text{H}_2\text{O}$; so that it is very improbable that at still lower temperatures it would separate without water. If the possibility of the solidified cryohydrate containing $\text{NaCl} + 2\text{H}_2\text{O}$ and ice be admitted, then it is not clear why one of these substances does not melt before the other. If alcohol extracts water from the solid mass leaving the salt behind, this does not prove the presence of ice, because alcohol also takes up water from the crystals of many hydrated substances (for instance, from $\text{NaCl} + 2\text{H}_2\text{O}$) at about their melting-points. Besides which, a simple observation on the cryohydrate, $\text{NaCl} + 10\text{H}_2\text{O}$, shows that with the most careful cooling it does not, on the addition of ice, deposit ice, if, as should be the case on solidification, ice were formed intermixed with the salt.

I may add with regard to cryohydrates, that many of the solutions of acids solidify completely on prolonged cooling (for example, $\text{H}_2\text{SO}_4, \text{H}_2\text{O}$), and then form perfectly definite compounds. From solutions of sulphuric acid (see Chapter XX.), for instance, Pickering obtained a hydrate, $\text{H}_2\text{SO}_4, 4\text{H}_2\text{O}$ at -25° . Hydrochloric, nitric, and other

salt the cryohydrate with 10 molecules of water, and in the case of sodium nitrate that ⁵⁹ with 7 molecules of water (i.e., 126 parts of water per 85 of salt), should be accepted as established substances, capable of passing from a solid to a liquid state, and conversely; and therefore *it may be thought* that in cryohydrates we have solutions which are not only undecomposable by cold, but also have a definite composition representing a fresh case of definite equilibrium between the solvent and the dissolved substance.

The formation of definite compounds in the process of solution becomes evident from the marked decrease of vapour pressure, or from the rise of the temperature of ebullition which occurs in the solution of certain volatile liquids and gases in water. As an example, we may take hydriodic acid, HI, a gas which liquefies, giving a liquid boiling at -34° . A solution of it containing 57 per cent. of hydriodic acid is distinguished by the fact that, if it is heated, the hydriodic acid and water volatilise together in the proportions in which they occur in the solution, so that such a solution may be distilled unchanged. The solution boils at a higher temperature than water, namely, at 127° . Some of the physical properties of the gas and water have in this case

acids also give similar crystalline hydrates, melting at low temperatures and presenting many similarities with the cryohydrates. It is my personal opinion that there exist the most varied and diverse stages of transition between molecular-physical and chemical reactions, and even between the mechanical juxtaposition of particles and their chemical interaction, and that cryohydrates (like solutions in general) form one of these stages. I therefore expect the most fruitful scientific results, not only from the application of physical conceptions to chemistry, but also from indications of the manifestation of chemical forces in the operations of molecular phenomena of a physico-mechanical order. This would bring about reconciliation between conceptions now in discord. To his researches on the heat evolved in the formation of the alloys of sodium and potassium, Joannis (1887) recognises the alloy NaK_2 as a definite compound (melting at -12.5°), as it is the most fusible and evolves the most heat. In 1901 N. S. Kurnakoff and N. A. Pushin showed in their researches on the melting-points that the alloy NaK_2 does indeed fuse at a lower temperature than all the other alloys of sodium and potassium, but came to the conclusion that this is only an instance of a cryohydrate or eutectic point and not of a definite compound, as in the case of cryohydrates (see Chap. XIII., note 21). The conception of the cryohydrate (in the case of solutions) or eutectic (in the case of alloys) point, according to the views of Le Chatelier and others, takes the following form. Imagine a solution or alloy of simple or compound substances A in B or conversely. The addition of B to A causes the melting-point of the latter to fall by an amount increasing with the amount of B added, although the melting-point of B may be higher than that of A, just as the temperature of formation of ice in solutions falls on the addition of a salt. But the same takes place on the addition of A to B (for instance, in alloys of tin and lead), only in the first instance A separates out in the solid state, and in the second B, which predominates. Evidently there must be some proportions of A and B, at which the decrements of the melting-points will coincide, and then the solidified alloy will contain both A and B. I cannot say for certain, but I think in general (there are probably different cases) that further study of this subject will elucidate certain aspects of the theory of solutions (see Chap. XVIII.)

⁵⁹ See note 24.

already disappeared—a new substance is formed, which has its definite boiling-point. To put it more correctly, this is not the temperature of ebullition, but the temperature at which the compound formed decomposes, yielding the vapours of the products of dissociation, which, on cooling, recombine. Should a less amount of hydriodic acid than the above be dissolved in water, then, on heating such a solution, water at first distils over alone, until the solution attains the above-mentioned composition; it will then distil over unaltered. If more hydriodic acid be passed into such a solution, a fresh quantity of the gas will dissolve, but it passes off with great ease, like air from water. It must not, however, be thought that those forces which determine the formation of ordinary gaseous solutions have no part whatever in the formation of a solution having a definite boiling-point; that they do come into play is shown by the fact that such constant gaseous solutions vary in their composition under different pressures.⁶⁰ It is not, therefore, at every, but only at the ordinary, atmospheric pressure that a constant boiling solution of hydriodic acid will contain 57 per cent. of the gas. At another pressure the proportions of water and hydriodic acid will be different. Judging, however, from observations made by Roscoe, the composition varies very little for considerable variations of pressure. This variation in composition indicates directly that pressure exerts an influence on the formation of unstable chemical compounds which are

⁶⁰ For this reason (the inconstancy of the composition of constant boiling solutions with a change of pressure), the existence of definite hydrates formed by volatile substances—for instance, by hydrochloric acid and water—is frequently denied. It is generally argued as follows: If there did exist a constancy of composition, then it would be unaltered by a change of pressure. But the distillation of constant boiling hydrates is undoubtedly accompanied (judging by the vapour densities determined by Bineau), like the distillation of sal-ammoniac, sulphuric acid, &c., by a complete decomposition of the original compound—that is, these substances do not exist in a state of vapour, but their products of decomposition (hydrochloric acid and water) are gases at the temperature of volatilisation and dissolve in the volatilised and condensed liquids; but the solubility of gases in liquids depends on the pressure, and therefore the composition of constant boiling solutions may, and even ought to, vary with a change of pressure; and, further, the smaller the pressure and the lower the temperature of volatilisation, the more likely is a true compound to be obtained. Sulphuric acid, H_2SO_4 , presents an instance of an undoubted chemical compound, and yet, as we shall see in Chap. XX., it gives off sulphuric anhydride on heating and decomposes when distilled. According to the researches of Roscoe and Dittmar (1859), the constant boiling solution of hydrochloric acid proved to contain 18 per cent. of hydrochloric acid at a pressure of 3 atmospheres, 20 per cent. at 1 atmosphere, and 23 per cent. at $\frac{1}{10}$ of an atmosphere. On passing air through the solution until its composition became constant (i.e., forcing the excess of aqueous vapour or of hydrochloric acid to pass away with the air) acid was obtained containing about 20 per cent. at 100° , about 23 per cent. at 50° , and about 25 per cent. at 0° . From this it is seen that either by decreasing the pressure or by lowering the temperature of evaporation one arrives at the same limit, where the composition must be taken as $\text{HCl} + 6\text{H}_2\text{O}$, which requires 25.26 per cent. of hydrochloric acid. Fuming hydrochloric acid contains more than this.

easily dissociated (with formation of a gas), just as it influences the solution of gases, the latter being, however, influenced to a greater degree than the former.⁶¹ Hydrochloric, nitric, and other acids form **solutions having definite boiling-points**, like that of hydriodic acid. They show, further, the common property, if containing but a small proportion of water, that they **fume in air**. Strong solutions of nitric, hydrochloric, hydriodic, and similar acids are even termed 'fuming acids.' The fuming liquids contain a definite compound whose temperature of ebullition (decomposition) is higher than 100° , and contain also an excess of the volatile substance dissolved, which exhibits a capacity to combine with water and form a hydrate the vapour pressure of which is less than that of aqueous vapour. On evaporating in air, this dissolved substance meets the atmospheric moisture and forms with it a visible vapour (fumes), consisting of the above-mentioned compound. The attraction or affinity which binds, for instance, hydriodic acid to water is evinced, not only in the evolution of heat and the diminution of vapour pressure (rise of boiling-point), but also in many purely chemical relations. Thus hydriodic acid is produced from iodine and hydrogen sulphide in the presence of water; but unless water is present this reaction does not take place.⁶²

Many **compounds containing water of crystallisation** are solid substances (when melted they are already solutions—i.e., liquids); furthermore, they are capable of being formed from solutions, like ice or aqueous vapour. They may be called **crystallo-hydrates**. Inasmuch as the direct presence of ice or aqueous vapour cannot be admitted in solutions, although the presence of water may be, so also there is no basis for acknowledging the presence in solutions of crystallo-hydrates, although they are obtained from solutions as such.⁶³ It is evident that

⁶¹ The essence of the matter may be thus represented. A gaseous or easily volatile substance, A , forms with a certain quantity of water, nH_2O , a definite complex compound, A, nH_2O , which is stable up to a temperature t° , higher than 100° . At this temperature it is decomposed into two substances, A and H_2O . Both boil below t° at the ordinary pressure, and therefore at t° they distil over and recombine in the receiver. But if a part of the substance A, nH_2O is decomposed or volatilised, there still remains in the vessel a portion of the undecomposed liquid which can partially dissolve one of the products of decomposition, and that in quantity varying with the pressure and temperature, so that the constant boiling-point solution will have a slightly different composition at different pressures.

⁶² For solutions of hydrochloric acid in water there are still greater differences in reaction. For instance, strong solutions decompose antimony sulphide (forming hydrogen sulphide, H_2S), and precipitate common salt from its solutions, whilst weak solutions do not act in this way.

⁶³ Supersaturated solutions give an excellent proof of this point. Thus a solution of copper sulphate generally crystallises in penta-hydrated crystals, $CuSO_4 + 5H_2O$, and a saturated solution gives such crystals when it is brought into contact with the minutest possible crystal of the same kind. But, according to the observations of Lecoq de

such substances present one of the many forms of equilibrium between water and a substance dissolved in it. This form, however, reminds one, in all respects, of solutions—that is, aqueous compounds which are more or less easily decomposed, with separation of water and the formation of a less aqueous or an anhydrous compound. In fact, there are not a few crystals containing water which lose a part of this water at the ordinary temperature. Such, for instance, are the crystals of soda, or sodium carbonate, which, when separated from an aqueous solution at the ordinary temperature, are quite transparent; but when left exposed to air, they lose a portion of their water, becoming opaque, and in the process lose their crystalline appearance, although preserving their original form. This process of the separation of water at the ordinary temperature is termed the **efflorescence** of crystals. Efflorescence takes place more rapidly under the receiver of an air-pump, and especially at a gentle heat. This breaking-up of a crystal is dissociation at the ordinary temperature. Solutions are decomposed in exactly the same manner.⁶⁴ The pressure of the aqueous vapour given off from crystallo-hydrates is naturally, as with solutions, less than the vapour pressure of water itself ⁶⁵ at the same temperature, and therefore many

Boisbaudran, if a crystal of ferrous sulphate (an isomorphous salt; see note 55), $\text{FeSO}_4 + 7\text{H}_2\text{O}$, be placed in a saturated solution of copper sulphate, then crystals of hepta-hydrated salt, $\text{CuSO}_4 + 7\text{H}_2\text{O}$, will be obtained. It is evident that neither the penta- nor the hepta-hydrated salt is contained as such in the solution. The solution presents its own particular liquid form of equilibrium (see note 24).

⁶⁴ Efflorescence, like evaporation, always proceeds from the surface. In the interior of crystals which have effloresced there is usually found a non-effloresced mass, so that the majority of effloresced crystals of washing soda show, in their fracture, a transparent nucleus coated by an effloresced, opaque, powdery mass. It is a remarkable circumstance that efflorescence proceeds in a perfectly regular and uniform manner, so that the angles and planes of similar crystallographic character effloresce simultaneously, and in this respect the crystalline form determines on which parts of crystals efflorescence starts, and the order in which it continues. In solutions, evaporation also proceeds from the surface, and the first crystals which appear when the required degree of saturation is reached are also formed at the surface. After falling to the bottom the crystals naturally continue to grow (see Chapter X., note 12).

⁶⁵ According to Lescœur (1883), at 100° a concentrated solution of barium hydroxide, BaH_2O_2 , on first depositing crystals (with $1\text{H}_2\text{O}$), has a pressure of about 630 mm. (instead of 760 mm., the pressure of water), which decreases (because the solution evaporates) to 45 mm., when all the water is expelled and only the crystals, $\text{BaH}_2\text{O}_2 + \text{H}_2\text{O}$ left; the latter then also lose water (dissociate, effloresce at 100°), leaving the hydroxide, BaH_2O_2 , which at 100° is perfectly undecomposable; that is, does not part with water. At 73° (the pressure of water is then 265 mm.) a solution containing $33\text{H}_2\text{O}$, on crystallising, has a pressure of 230 mm. and the crystals $\text{BaH}_2\text{O}_2 + 8\text{H}_2\text{O}$, which separate out, have a pressure of 160 mm., and on losing water give $\text{BaH}_2\text{O}_2 + \text{H}_2\text{O}$. This substance does not decompose at 73° , and therefore its pressure = 0. In those crystallo-hydrates which effloresce at the ordinary temperature, the pressure of dissociation approximates closely to that of the aqueous vapour, as was shown by Lescœur (1891). To this category of compounds belong $\text{B}_2\text{O}_3, (3+x)\text{H}_2\text{O}$; $\text{C}_2\text{O}_4\text{H}_2, (2+x)\text{H}_2\text{O}$; $\text{BaO}, (9+x)\text{H}_2\text{O}$, and $\text{SrO}, (9+x)\text{H}_2\text{O}$. And a still greater pressure is possessed

anhydrous salts which are capable of combining with water absorb aqueous vapour from moist air; that is, they act like a cold body, on which steam condenses. It is on this that the desiccation of gases is based, and it must further be remarked in this respect that certain substances—for instance, potassium carbonate (K_2CO_3) and calcium chloride ($CaCl_2$)—not only absorb the water necessary for the formation of a solid crystalline compound, but also give solutions, or **deliquesce**, as it is termed, in moist air. Many crystals do not effloresce in the least at the ordinary temperature; for example, copper sulphate, which may be preserved for an indefinite length of time without efflorescing (because its vapour pressure is less than that of the moisture in the air), but if it be placed under the receiver of an air-pump, and efflorescence be once started, it goes on at the ordinary temperature. The temperature at which the complete separation of water from crystals takes place varies considerably, not only for different substances, but also for different portions of the contained water of any one substance. Very often the temperature at which dissociation begins is very much higher than the boiling-point of water. Thus, for example, copper sulphate, which contains 36 per cent. of water, gives up 28·8 per cent. at 100° , and the remainder, namely, 7·2 per cent., only at 240° . Alum, out of the 45·5 per cent. of water which it contains, gives up 18·9 per cent. at 100° , a further 17·7 per cent. at 120° , 7·7 per cent. at 180° , and 1 per cent. at 280° ; it only loses the remainder (1 per cent.) at its temperature of decomposition. These examples clearly show that the taking-up of water of crystallisation is accompanied by a rather profound, although, in comparison with instances which we shall consider later, still inconsiderable, change of its properties. In certain cases the water of crystallisation is only given off when the solid form of the substance is destroyed, i.e., when the crystals melt on heating. The crystals are then said **to melt in their water of crystallisation**. Further, after the separation of the water, a solid substance remains behind, so that by further heating of the molten mass it acquires a solid form. This is seen most clearly in

by $Na_2SO_4 \cdot 10H_2O$; $Na_2CO_3 \cdot 10H_2O$, and $MgSO_4 \cdot (7+x)H_2O$. Müller-Erzbach (1884) determines the pressure (with reference to liquid water) by placing tubes of the same length containing water and the substances experimented with in a desiccator, the rate of loss of water giving the relative pressure. Thus, at the ordinary temperature, crystals of sodium phosphate, $Na_2HPO_4 \cdot 12H_2O$, present a pressure of 0·7 compared with that of water, until they lose $5H_2O$, then 0·4 until they lose $5H_2O$ more, and on losing the last portions of water the pressure falls to 0·04 compared with that of water. It is clear that the different molecules of water are held by unequal forces. Of the five molecules of water in copper sulphate the first two are comparatively easily separated, even at the ordinary temperature (but only after several days in a desiccator, according to Latchinoff); the next two are more difficultly separated, and the last equivalent is retained even at 100° . This is another indication of the capacity of $CuSO_4$ to form three hydrates, $CuSO_4 \cdot 5H_2O$, $CuSO_4 \cdot 3H_2O$, and $CuSO_4 \cdot H_2O$. The

crystals of sugar of lead or lead acetate, which melt in their water of crystallisation at a temperature of 56.25° , and in so doing begin to lose water. On reaching a temperature of 100° the sugar of lead solidifies, having lost all its water; and then, at a temperature of 280° , the anhydrous and solidified salt again melts.^{65a}

It is most important to recognise, in respect to the water of crystallisation, that its ratio to the quantity of the substance with which it is combined is always constant. However often we may prepare copper sulphate, we shall always find 36.07 per cent. of water in its crystals, and these crystals always lose four-fifths of their water at 100° , while one-fifth of the whole amount of the contained water remains in the crystals at 100° , and is only expelled from them at a temperature of about 240° . What has been said about copper sulphate crystals applies also to all other crystals containing water of crystallisation. It is impossible in any of these cases to increase the relative proportion either of the salt or of the water without changing the homogeneity of the substance. If once a portion of the water is lost—for instance, if once efflorescence takes place—there is obtained not a homogeneous substance, but a mixture consisting of a substance deprived of water and one which has not yet lost water, i.e., decomposition has already commenced. This constant ratio is an example of the fact that in chemical compounds the proportions of the component parts are quite definite; that is, it is an example of the so-called **definite chemical compounds**. These may be distinguished from solutions, and from all other so-called indefinite chemical compounds, in that at least one, and sometimes both, of the component parts may be added in large quantity to an indefinite chemical compound without destroying the homogeneity, as in the case of solutions; whilst it is impossible to add to a definite chemical compound any one of its component parts without destroying the homogeneity of the entire mass. Definite chemical compounds only decompose on a certain rise in temperature; on lowering the temperature they do not, at least in but few cases, yield their components, as do solutions, which form ice or compounds containing water

researches of Andreae on the pressure of dissociation of hydrated copper sulphate showed (1891) the existence of three regions, characterised at a given temperature by constant pressures: (1) between 3 and 5, (2) between 1 and 3, and lastly (3) between 0 and 1 molecule of water, again confirming the existence of three hydrates of this salt having the above compositions.

^{65a} Sodium acetate ($\text{C}_2\text{H}_3\text{O}_2\text{Na}, 3\text{H}_2\text{O}$) melts at 58° , but resolidifies only on contact with a crystal, otherwise it may remain liquid even at 0° , and may be used for obtaining a constant temperature. According to Jeannel, the latent heat of fusion is about 28 calories, and according to Pickering the heat of solution is 35 calories. When melted, this salt boils at 123° , that is, the pressure of the vapour given off at that temperature equals the atmospheric pressure.

of crystallisation. This leads to the assumption that solutions contain water as water,⁶⁶ although it may sometimes be in very small quantity. So that solutions which are capable of solidifying completely (for instance, crystallo-hydrates capable of melting), such as the compound of $84\frac{1}{2}$ parts of sulphuric acid, H_2SO_4 , with $15\frac{1}{2}$ parts of water, H_2O , or $\text{H}_2\text{SO}_4\cdot\text{H}_2\text{O}$ (or H_4SO_5), appear as true definite chemical compounds. If, then, we imagine such a definite compound in a liquid state, and admit that in this state it partially decomposes, with the separation of water—not as ice or vapour (for then the system would be heterogeneous, containing substances in different physical states), but in a liquid form, when the system will be homogeneous—we shall form an idea of a solution as an unstable, dissociating fluid state of equilibrium between water and the substance dissolved.^{66a} Moreover, it should be remarked that, judging by experiment, many substances give with water not one but several *different* compounds,⁶⁷ as is seen in the capacity of one substance to form with water many different **crystallo-hydrates**, or compounds with water of crystallisation, showing diverse and independent

⁶⁶ Such a phenomenon frequently presents itself in purely chemical actions. For instance, let a liquid substance *A* give, with another liquid substance *B*, under certain experimental conditions, only a minute quantity of a solid or gaseous substance *C*. This small quantity will separate out (pass away from the sphere of action, as Berthollet expressed it), and the remaining masses of *A* and *B* will again give *C*; consequently under these conditions action will go on to the end. Such, it seems to me, is the action in solutions when they yield ice or vapour indicating the presence of water.

^{66a} A difficulty in understanding solutions is here met with in the fact that it is necessary to admit the interpenetration (entire uniform intermixture) of two liquids, water and the liquid compound. But if gases and vapours of all kinds intermix in all proportions by virtue of the mobility of their particles, of their elasticity, and of the radical similarity of their structure, there is no reason why these properties should be denied to liquids, as much in them is akin to gases; and if liquids resemble each other, the intermixture or interpenetration of their particles is also admissible, more especially as particles of different substances are found mixed together in the crystals of similar (isomorphous) substances.

⁶⁷ Certain substances on combining are capable of forming together only one compound, whilst others yield several, and these of the most varied degrees of stability. The compounds of water are instances of this kind. In solutions the existence of several different definite compounds must be acknowledged, but many of these have not yet been obtained in a free state, and it may be that they cannot be obtained in any other than a liquid form—that is, dissolved—just as there are many undoubted definite compounds which only exist in one physical state. Such instances occur among the hydrates. The compound $\text{CO}_2 + 8\text{H}_2\text{O}$ (see note 31), according to Wroblewski, only occurs in a solid form. Hydrates like $\text{H}_2\text{S} + 12\text{H}_2\text{O}$ (De Forcrand and Villard), $\text{HBr} + \text{H}_2\text{O}$ (Roozeboom), are recognised only by a decrease of pressure and are very transient substances, incapable of stable existence in a free state. Even sulphuric acid, H_2SO_4 , itself, which is undoubtedly a definite compound, fumes in a liquid form, giving off the anhydride, SO_3 , and this exhibits a very unstable equilibrium. The crystallo-hydrates of chlorine, $\text{Cl}_2 + 8\text{H}_2\text{O}$, of hydrogen sulphide, $\text{H}_2\text{S} + 12\text{H}_2\text{O}$ (formed at 0° , and completely decomposed at $+1^\circ$, when 1 vol. of water only dissolves 4 vols. of hydrogen sulphide, while at 0.1° it dissolves about 100 vols.), and of many other gases, are instances of hydrates which are very unstable.

properties. From these considerations, *solutions* ⁶⁸ *may be regarded as definite, unstable liquid chemical compounds in a state of dissociation.* ⁶⁹

Regarding solutions from this point of view, they come under the head of those definite compounds with which chemistry is mainly concerned. ⁷⁰

⁶⁸ Of such a kind are also other indefinite chemical compounds, for example, metallic alloys. These are solid substances or solidified solutions of metals. They also contain definite compounds, and may contain an excess of one of the metals. According to the experiments of Laurie (1888), the alloys of zinc with copper behave, in respect to their electromotive force in galvanic batteries, just like zinc, if the proportion of zinc does not exceed a certain percentage—that is, so long as a definite compound is not formed—for in that case particles of free zinc are present; but if a copper plate be taken, and only one-thousandth part of its area be covered by zinc, then the zinc alone will act in a galvanic battery.

⁶⁹ According to the above supposition, the condition of solutions in the sense of the kinetic hypothesis of matter (that is, on the supposition of an internal motion of molecules and atoms) may be represented in the following form:—In a homogeneous liquid—for instance, water—the molecules occur in a certain state of equilibrium, which, although mobile, is stable. When a substance A dissolves in water, its molecules form, with several molecules of water, systems, A, nH_2O , which are so unstable that when surrounded by molecules of water they decompose and re-form, so that A passes from one group of water molecules to another, and the molecules of water which were at one moment in harmonious motion with A in the form of the system A, nH_2O , in the next instant may have already succeeded in getting free. The addition of water or of molecules of A may either only alter the number of free molecules, which in their turn enter into systems A, nH_2O , or it may introduce conditions for the possibility of building up new systems A, mH_2O , where m is either greater or less than n . If the relation of the molecules in the solution were the same as in the system A, mH_2O , then the addition of fresh molecules of water or of A would be followed by the formation of new molecules A, nH_2O . The relative quantity, stability, and composition of these systems or definite compounds will vary in one or another solution. I adopted this view of solutions in 1887 (Pickering subsequently putting forward a similar view) after a most intimate study of the variation of their specific gravities, to which my book, cited in note 19, is devoted. Substances A , which give solutions, are distinguished by the fact that they can form such unstable systems, A, nH_2O , but besides these they may give other much more stable systems, A, n_1H_2O . Thus ethylene, C_2H_4 , in dissolving in water probably forms a system, C_2H_4, nH_2O , which easily splits up into C_2H_4 and H_2O , but it gives also the system alcohol, C_2H_4, H_2O or C_2H_6O , which is comparatively stable. Further, oxygen can dissolve in water, and it can also combine with it, forming peroxide of hydrogen. Turpentine, $C_{10}H_{16}$, does not dissolve in water, but it combines with it, giving a comparatively stable hydrate. In other words, the chemical structure of hydrates or of the definite compounds contained in solutions, is distinguished, not only by its peculiar characters, but also by a diversity of stability.

⁷⁰ The above representation of solutions and other indefinite compounds, considering them as a particular state of definite compounds, excludes the independent existence of indefinite compounds; in this way, that unity of chemical conception is obtained which cannot be arrived at by admitting the physico-mechanical conception of indefinite compounds. The gradual transition from typical solutions (such as those of gases in water and weak saline solutions) to sulphuric acid, and from it and its definite but yet unstable and liquid compounds, to clearly defined compounds, such as salts and their crystallo-hydrates, is so imperceptible that in denying that solutions belong to the number of definite but dissociating compounds we risk denying the definiteness of the atomic composition of such substances as sulphuric acid or molten crystallo-hydrates. I repeat, however, that

We saw above that copper sulphate loses four-fifths of its water at 100° and the remainder at 240° . This means that there are two definite compounds of water with the anhydrous salt. Washing soda or carbonate of sodium, Na_2CO_3 , separates out from its solutions at the ordinary temperature as crystals, $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$, containing 62.9 per cent. of water by weight. When a solution of the same salt deposits crystals at a low temperature, about -20° , these crystals contain 71.8 parts of water to 28.2 of the anhydrous salt. Further, the crystals are obtained together with ice, and are left behind when the latter melts. If ordinary soda, with 62.9 per cent. of water, be cautiously melted in its own water of crystallisation, there remains a salt, in a solid state, containing only 14.5 per cent. of water, and a liquid is obtained which at 34° deposits crystals which contain 46 per cent. of water and do not effloresce in the air. Lastly, if a supersaturated solution of soda be prepared at temperatures below 8° , it deposits crystals containing 54.3 per cent. of water. Hence as many as five compounds of anhydrous soda with water are known, and they are dissimilar in their properties and crystalline forms, and even in their solubilities. There is apparently no relation between the above quantities of water and salt, but this is only because in each case the amounts of water and anhydrous salt were given in percentages; if the amounts of water be calculated for one and the same quantity of anhydrous salt, great regularity will be observed in the proportions of the component parts in all these compounds. It appears that for 106 parts of anhydrous salt there are, in the crystals separated out at -20° , 270 parts of water; in the crystals obtained at 15° , 180 parts of water; in those obtained from a supersaturated solution, 126 parts; in the crystals which separate out at 34° , 90 parts; and in the crystals with the smallest amount of water, 18 parts. On comparing these quantities of water it will readily be seen that they are very simply related to each other, for they are all divisible by 18, and are in the ratio 15 : 10 : 7 : 5 : 1. Naturally, direct experiment, however carefully it be conducted, is hampered with errors; but taking these unavoidable experimental errors into consideration, it will be seen that for a given quantity of the anhydrous salt there occur, in its various compounds with water, quantities of water which are in very simple multiple proportion. This is observed in, for the present the theory of solutions cannot be considered as firmly established. The above opinion concerning them is nothing more than an hypothesis. By submitting solutions to the Daltonic conception of atomism, I hope that we may not only attain to a general harmonious chemical doctrine, but also that new motives for investigation and research will appear in the problem of solutions, which must either confirm the proposed theory or replace it by another, fuller and truer; and I, for my part, cannot consider this to be the case with any of the other present doctrines of solutions (note 49).

and is common to, all definite chemical compounds. This rule is called **the law of multiple proportions**. It was discovered by Dalton, and will be evolved in further detail subsequently in this work. For the present we will only state that the law of definite composition enables the composition of substances to be expressed by formulæ, and the law of multiple proportions permits the application of whole numbers as coefficients of the symbols of the elements in these formulæ. Thus the formula $\text{Na}_2\text{CO}_3, 10\text{H}_2\text{O}$ shows directly that in this crystallo-hydrate there are 180 parts of water to 106 parts by weight of the anhydrous salt, because the formula of soda, Na_2CO_3 , corresponds with a weight of 106, and the formula of water to 18 parts by weight, which are here taken ten times.

In the above examples of the combinations of water, we saw the gradually increasing intensity of the bond between water and a substance with which it forms a homogeneous compound. There is a series of such compounds with water, in which the latter is held with very great force, and is only given up at a very high temperature, and indeed, in some cases, cannot be separated by any degree of heat without completely decomposing the substance. In these compounds there is generally no outward sign whatever that they contain water. A perfectly new substance is formed from an anhydrous substance and water, in which sometimes the properties of neither one nor the other component are observable. In the majority of cases a considerable amount of heat is evolved in the formation of such compounds with water. Sometimes this evolution is so intense that a red heat is produced and light emitted. After this it is hardly to be wondered at that stable compounds are formed by such combinations. Their decomposition requires much heat; a large amount of work is necessary to separate them into their component parts. All such compounds are definite, and, as a rule, quite distinctly definite. Such definite compounds with water are called **hydrates**. The water contained in these compounds is often called **water of constitution**, i.e., water which enters into the structure or composition of the given substance. By this it is desired to express that in other cases the molecules of water are, as it were, separate from the molecules of the substance with which it is combined. It is supposed that, in the formation of hydrates, this water, even in the smallest particles, forms one complete whole with the anhydrous substance. Many examples of the formation of such hydrates might be cited. The most familiar example in practice is the hydrate of lime, or so-called 'slaked' lime. Lime is prepared by burning limestone, by which the carbonic anhydride is expelled from it and there remains a white stony mass, which is dense, compact, and somewhat tenacious. Lime is

usually sold in this form, which bears the name of 'quick' or 'unslaked' lime. If water be poured over such lime, a considerable rise in temperature is remarked either directly or after a certain time. The whole mass becomes hot, part of the water is evaporated, the stony mass in absorbing water crumbles into powder, and if the water be taken in sufficient quantity, and the lime be pure and well burnt, not a particle of the original stony mass is left—it all crumbles into powder. If the water be in excess, then naturally a portion of it remains and forms a solution. This process is called 'slaking' lime. Slaked lime is used in practice mixed with sand as mortar. Slaked lime is a definite hydrate of lime. If it is dried at 100° , it retains 24.3 per cent. of water. This water can only be expelled at a temperature above 400° , and then quicklime is obtained again. The heat evolved in the combination of lime with water is so intense that it can set fire to wood, sulphur, gunpowder, &c. Even on mixing lime with ice, the temperature rises to 100° . If lime is moistened with a small quantity of water in the dark, a luminous effect is observed. The reaction which takes place is as follows: $\text{CaO} + \text{H}_2\text{O} = \text{CaH}_2\text{O}_2$. But, nevertheless, water may still be separated from this hydrate.⁷¹ If phosphorus be burnt in dry air, a white substance called 'phosphoric anhydride' is obtained. This combines with water with such energy that the experiment must be conducted with great caution. A red heat is produced in the formation of the compound, and it is impossible to separate the water from the resultant hydrate at any temperature. The hydrate formed by phosphoric anhydride is a substance which is totally undecomposable into its original component parts by the action of heat. Almost as energetic a combination occurs when sulphuric anhydride, SO_3 , combines with water, forming its hydrate, sulphuric acid, H_2SO_4 . In both cases definite compounds are produced, but the latter substance, as a liquid, and capable of decomposition by heat, forms an evident link with solutions. If 80 parts of sulphuric anhydride combine with 18 parts of water, this water cannot be separated from the anhydride, even at a temperature of 300° . It is only by the addition of phosphoric anhydride, or by a series of chemical transformations, that water can be separated from its combination with sulphuric anhydride. This compound is oil of vitriol, or sulphuric acid. If a larger proportion of water be taken, it will combine with the H_2SO_4 ; for instance, if 36

⁷¹ In combining with water, one part by weight of lime evolves 245 units of heat. A high temperature is obtained, because the specific heat of the resulting product is small. Sodium oxide, Na_2O , in reacting on water, H_2O , and forming caustic soda (sodium hydroxide), NaHO , evolves 552 units of heat for each part by weight of sodium oxide, and the resulting hydrate decomposes entirely on ignition, without the separation of water.

parts of water per 80 parts of sulphuric anhydride be taken, a compound is formed which crystallises in the cold, and melts at $+8^{\circ}$, whilst oil of vitriol does not solidify even at -30° . If still more water be taken, the oil of vitriol will dissolve in the remaining quantity of water. An evolution of heat takes place, not only on the addition of the water of constitution, but in a less degree on further additions of water;⁷² and therefore there is no distinct boundary, but only a gradual transition, between those chemical phenomena which are expressed in the formation of solutions and those which take place in the formation of the most stable hydrates.⁷³

⁷² The diagram given in note 28 shows the evolution of heat on mixing sulphuric acid, or the mono-hydrate (H_2SO_4 , i.e., $\text{SO}_3 + \text{H}_2\text{O}$), with different quantities of water per 100 vols. of the resultant solution. Every 98 grams of sulphuric acid (H_2SO_4) evolve, on the addition of 18 grams of water, 6,379 units of heat; with twice or three times the quantity of water 9,418 and 11,137 units of heat, and with an infinitely large quantity of water 17,860 units of heat, according to the determinations of Thomsen. The latter also showed that when H_2SO_4 is formed from SO_3 (=80) and H_2O (=18), 21,308 units of heat are evolved for every 98 parts by weight of the resultant sulphuric acid.

⁷³ Thus for different hydrates the stability with which the water is held is very dissimilar. Certain hydrates hold water very loosely, and in combining with it evolve little heat. From other hydrates the water cannot be separated by any degree of heat, even if they are formed from anhydrides (i.e., anhydrous substances) and water with but little evolution of heat; for instance, acetic anhydride in combining with water evolves an inconsiderable amount of heat, but the water cannot afterwards be expelled. If the hydrate (acetic acid) formed by this combination be strongly heated, it either volatilises without change, or decomposes into new substances, but it does not again yield the original substances, namely, the anhydride and water, at least in a liquid form. Here is an instance which gives the reason for calling the water entering into the composition of the hydrate 'water of constitution.' Such, for example, is the water entering into the so-called caustic soda or sodium hydroxide (see note 71). But there are hydrates which easily part with their water; yet this water cannot be considered as water of crystallisation, not only because sometimes such hydrates have no crystalline form, but also because in perfectly analogous cases very stable hydrates are formed, capable of particular kinds of chemical reactions, as we shall subsequently learn. Such, for example, is the unstable hydrated oxide of copper, which is not formed from water and oxide of copper, but which is obtained just like far more stable hydrates, for example, the hydrated oxide of barium, BaH_2O_2 , or $\text{BaO} + \text{H}_2\text{O}$, by the double decomposition of the solution of salts with alkalies. In a word, there is no distinct boundary either between the water of hydrates and of crystallisation, or between solution and hydration.

It must be observed that, in separating from an aqueous solution, many substances, without having a crystalline form, hold water in the same unstable state as in crystals; but this water cannot be termed 'water of crystallisation' if the substance which separates out has no crystalline form. The hydrates of alumina and silica are examples of such unstable hydrates. If these substances are separated from an aqueous solution by a chemical process, they always contain water. The formation of a new chemical compound containing water is here particularly evident, for alumina and silica in an anhydrous state have chemical properties differing from those they show when combined with water, and do not combine directly with it. The entire series of colloids on separating from water form with it similar compounds, which have the aspect of solid gelatinous substances. Water is held in considerable quantity in solidified glue or boiled albumin. It cannot be expelled from them by pressure; hence in this case there has ensued some kind of combination of the substance with water. This water is, however, easily separated

We have thus considered many aspects and degrees of combination of various substances with water, or instances of the **compounds of water**, when it and other substances form new homogeneous substances, which in this case will evidently be complex, i.e., made up of different substances; and although they are homogeneous, yet it must be admitted that there exist in them those component parts which entered into their composition, inasmuch as these parts may be again obtained from them. It must not be imagined that water really exists in hydrate of lime, any more than that ice or steam exists in water. When we say that water occurs in the composition of a certain hydrate, we only wish to point out that there are chemical transformations in which it is possible to obtain that hydrate by means of water, and other transformations in which this water may be separated out from the hydrate. This is all simply expressed by saying that water enters *into the composition* of this hydrate. And the study of the composition of compounds, that is, the expression of their transformations, forms one of the chief problems of chemistry, when our study is limited to the elements, or simple substances.

on drying; but not the whole of it, as a portion is retained, and this portion is considered to belong to the hydrate, although in this case it is very difficult, if not impossible, to obtain definite compounds. The absence of any distinct boundary lines between solutions, crystallo-hydrates, and ordinary hydrates above referred to is very clearly seen in such examples.

CHAPTER II

THE COMPOSITION OF WATER ; HYDROGEN

THE question now arises, Is not **water** itself a **compound substance**? Can it not be formed by the mutual reaction of some component parts? Can it not be broken up into its component parts? There cannot be the least doubt that if it does split up, and if it is a compound, then it is a **definite** one characterised by the stability of the union between those component parts from which it is formed. From the fact alone that water passes into all physical states as a homogeneous whole, without in the least varying chemically in its properties and without splitting up into its component parts (neither solutions nor many hydrates can be distilled—they are split up), we must conclude, that if water is a compound, then it is a stable and definite chemical compound capable of entering as a whole into many other combinations. As with all other great discoveries in the province of chemistry, it is to the end of the eighteenth century that we are indebted for the important discovery that water is not a simple substance, but that, like a number of other compound substances, it is composed of two separate substances. This was proved by two of the methods by which the compound nature of bodies may be directly determined: by analysis and by synthesis, that is, by the decomposition of water into, and by the formation of water from, its component parts. In 1781 Cavendish first obtained water by burning hydrogen in oxygen, both of which gases were already known to him. He concluded from this that water was composed of two substances. But he did not make more accurate experiments, which would have shown the relative quantities of the component parts in water, and which would have determined its complex nature with certainty. Although his experiments were the first, and although the conclusion he drew from them was a true one, yet such novel ideas as the complex nature of water are not easily recognised so long as there is no series of researches which completely and indubitably proves the truth of such conclusions. The fundamental experiments which really proved the complexity of water by the method

of synthesis, and its formation from other substances, were made in 1789 by Monge, Lavoisier, Fourcroy, and Vauquelin. They obtained four ounces of water by burning hydrogen, and found that 100 parts of water contain 15 parts of hydrogen and 85 parts of oxygen. It was also proved that the weight of water formed was equal to the sum of the weights of the component parts entering into its composition; consequently water contains all the matter entering into oxygen and hydrogen, and no other. The compound nature of water was proved in this manner by a method of synthesis. But we will turn to its analysis, i.e., to its decomposition into its component parts. The analysis may be more or less complete. Either both component parts may be obtained in a separate state, or else only one is separated and the other converted into a new compound in which its amount may be determined by weighing. This will be a reaction of substitution such as is often taken advantage of in analysis. The first analysis of water was conducted in this way by Lavoisier and Meusnier in 1784. The apparatus they employed consisted of a glass retort containing water previously purified, of which the weight had been determined. The neck of the retort was inserted into a porcelain tube, placed inside an oven, and heated to a red heat by means of charcoal. Iron filings, which decompose water at a red heat, were placed inside this tube, the end of which was connected with a worm, for the purpose of condensing any water which might pass through the tube undecomposed. This condensed water was collected in a separate flask. The gas formed by the decomposition was collected over water in a bell jar. The aqueous vapour in passing over the red-hot iron was decomposed, and a gas was formed from it whose weight could be determined from its volume and its known density. Besides the water which passed through the tube unaltered a certain quantity of water disappeared in the experiment, and this quantity, in the experiments of Lavoisier and Meusnier, was equal to the weight of gas collected in the bell jar plus the increase in weight of the iron filings. Hence the water was decomposed into a gas, which was collected in the bell jar, and a substance, which combined with the iron, and is consequently composed of these two component parts. This was the first analysis of water ever made; but here only one (and not both) of the gaseous components of water was collected separately. Both the component parts of water can, however, be simultaneously obtained in a free state. For this purpose the decomposition is brought about by a galvanic current or by heat, as we shall learn directly.¹

¹ The first experiments on the synthesis and decomposition of water did not afford, however, an entirely convincing proof that water was composed of hydrogen and oxygen

Water is a bad conductor of electricity, that is, pure water is incapable of transmitting a feeble current; but if any salt or acid be dissolved in it, its conductivity increases, and **on the passage of a current** through acidified water **it is decomposed** into its component parts. A little sulphuric acid is generally added to the water. By immersing platinum plates (electrodes) in this water (platinum is chosen because it is not attacked by acids, which act chemically on many other metals) and connecting them with a galvanic battery it will be observed that bubbles of gas appear on these plates. The gas which separates is called **detonating gas**,² because on ignition it very readily explodes.³ What takes place is as follows. The water, by the action of the current, is decomposed into two gases. The mixture of these gases forms detonating gas, and when this is brought into contact with an incandescent substance—for instance, a lighted taper—the gases recombine, forming water, the combination being accompanied by a great evolution of heat, so that the vapour of the water formed expands considerably and very rapidly, and as a consequence an explosion takes place—that is, sound and increase of pressure, and atmospheric disturbance, as in the explosion of gunpowder.

In order to discover what gases are obtained by the decomposition of water, the gases which are given off at the two electrodes must be collected separately. For this purpose a V-shaped tube is taken, one end being open and the other fused up. A platinum wire, terminating inside the tube in a plate, is fused into the closed end, which is entirely

alone. Davy, who investigated the decomposition of water by the galvanic current, thought for a long time that, besides these gases, an acid and alkali were also obtained. He was only convinced of the fact that water contains nothing but hydrogen and oxygen by a long series of researches, which showed him that the appearance of an acid and alkali in the decomposition of water proceeds from the presence of impurities (especially ammonium nitrate) in the water. A final comprehension of the composition of water is obtained from the accurate determination of the quantities of the component parts which enter into its composition. It will be seen from this how many data are necessary for proving the composition of a substance—that is, of the transformations of which it is capable. What has been said of water refers to all other compounds; the investigation of each one, the entire proof of its composition, can only be obtained by the accumulation of a large mass of data referring to it.

² This gas is collected in a voltameter.

³ In order to observe this explosion without the slightest danger, it is best to proceed in the following manner. Some soapy water which easily forms soap bubbles is prepared and poured into an iron trough. In this water the end of a gas-conducting tube is immersed. This tube is connected with any suitable apparatus in which detonating gas is evolved. In this way soap bubbles full of this gas are formed. If the apparatus in which the gas is produced be then removed (otherwise the explosion might travel into the interior of the apparatus), and a lighted taper be brought to the soap bubbles, a very sharp explosion will take place. The bubbles should be small to avoid any danger; ten, each about the size of a pea, suffice to give a sharp report like a pistol-shot.

filled with water⁴ acidified with sulphuric acid, and another platinum wire, terminating in a plate, is immersed in the open end. If a current from a galvanic battery be now passed through the wires, an evolution of gases will be observed, that obtained in the open branch passing into the air, while that in the closed branch accumulates above the water. As this latter gas accumulates it displaces the water, which continues to descend in the closed and ascend in the open branch of the tube. When the water in this way reaches the top of the open end, the passage of the current is stopped, and the gas evolved from one of the electrodes only is obtained in the apparatus. By this means it is easy to prove that a distinct gas appears at each electrode. If the closed end be the cathode, i.e., be connected with the negative pole of the battery (the zinc), then the gas collected in the apparatus is capable of

FIG. 18.—Decomposition of water by the galvanic current.

burning. This may be demonstrated by the following experiment. The bent tube is taken from the stand, its open end stopped up with the thumb and the tube inclined in such a manner that the gas passes from the closed into the open end. It will then be found, on applying a lighted lamp or taper, that the gas burns. This combustible gas, which collects at the cathode or negative electrode, is **hydrogen**. If the same experiment be carried on with a current passing in the opposite direction—that is, if the closed end be joined up with the positive pole, (i.e., with the carbon, copper, or platinum)—then the gas which is evolved from it does not itself burn, but it supports combustion very vigorously, so that a smouldering taper placed in it immediately bursts into flame. This gas, which is collected at the anode or positive pole, is

⁴ In order to fill the tube with water it is turned up, so that the closed end points downwards and the open end upwards, water acidified with sulphuric acid being then poured into it.

oxygen, which is obtained, as we saw before (in the Introduction,, from mercury oxide, and is contained in air.

Thus, in the decomposition of water, oxygen appears at the positive pole and hydrogen at the negative pole ^{4a}; so that detonating gas will be a mixture of both. Hydrogen burns in air from the fact that in doing so it forms water with the oxygen of the air. Detonating gas explodes owing to the hydrogen burning in the oxygen mixed with it. It is very easy to measure the relative quantities of one and the other

FIG. 19.—Decomposition of water by the galvanic current, for determining the relation between the volumes of hydrogen and oxygen.

gas which are evolved in the decomposition of water. For this purpose a funnel is taken whose orifice is closed by a cork through which pass two platinum wires connected with a battery. Acidified water is poured into the funnel and a glass cylinder full of water is placed over the end of each wire (fig. 19). On passing a current, hydrogen and oxygen collect in these cylinders, and it will easily be seen that two volumes of hydrogen are evolved for every one volume of oxygen. This signifies that in decomposing, water gives two volumes of hydrogen and one volume of oxygen.

Water is also decomposed into its component parts by **the action of heat**. At the melting-point of silver (950°), and in its presence, water is decomposed and the oxygen absorbed by the molten silver, which dissolves it so long as it is liquid. But directly the silver solidifies the oxygen is expelled from it. This experiment is, however, not entirely convincing; it might be thought that in this case the

^{4a} Owing to the gradual but steady progress made during the last quarter of the nineteenth century in the production of an electric current from the dynamo and its transmission over considerable distances, the electrolytic decomposition of many compound bodies has acquired great importance, and the use of the electric current is making its way into many chemical manufactures. Hence Prof. D. A. Lachinoff's proposal to obtain hydrogen and oxygen (both of which have many applications) by means of electrolysis (of either a 10 to 15 per cent. solution of caustic soda or a 15 per cent. solution of sulphuric acid) may find a practical application, at all events at some future time. Owing to their simplicity, electrolytic methods of decomposition have a great future; but as yet, so long as the production of an electric current remains so costly, their application is limited. And for this reason, although certain of these methods are mentioned in this work, they are not specially considered, the more so since a profitable and proper use of the electric current for chemical purposes requires special electro-technical knowledge which beginners cannot be assumed to have, and therefore an exposition of the principles of electro-technology as applied to the production of chemical transformations, although referred to in places, does not come within the scope of the present work.

decomposition of the water did not proceed from the action of heat, but from the action of the silver on water—that silver decomposes water, taking up the oxygen. If steam be passed through a red-hot tube, the interior of which is at a temperature of $1,000^{\circ}$, a portion⁵ of the water decomposes into its component parts, forming detonating gas. But on passing into the cooler portions of the apparatus this detonating gas again forms water, since the hydrogen and oxygen obtained combine at a lower temperature.⁶ The problem of showing the decomposability of water at high temperatures is apparently unsolvable. It was considered as such before Henri Sainte-Claire Deville (in the fifties) introduced into chemistry the conception of dissociation; that is, a change of chemical state resembling evaporation (if decomposition be likened to boiling), and before he had demonstrated the decomposability of water by the action of heat in an experiment which will presently be described. In order to demonstrate clearly the **dissociation** of water, or its decomposability by heat, at a temperature approaching that at which it is formed, it was necessary to separate the hydrogen from the oxygen at a high temperature without allowing

⁵ As water is formed by the combination of oxygen and hydrogen, with a considerable evolution of heat, and as it can also be decomposed, this reaction is a reversible one (see Introduction), and consequently at a high temperature the decomposition of water cannot be complete—it is limited by the opposite reaction. Strictly speaking, it is not known how much water is decomposed at a given temperature, although many efforts (by Bunsen and others) have been made in various directions to solve this question. Our small knowledge of the coefficient of expansion, and of the specific heat of gases at such high temperatures, renders all calculations (from observations of the pressure on explosion) of doubtful value.

⁶ Grove, in 1847, observed that a platinum wire fused in the oxy-hydrogen flame—that is, having acquired the temperature of the formation of water—forms at its end a molten drop which in falling into water evolves detonating gas, that is, decomposes the water. It therefore follows that water decomposes at the temperature of its formation. At that time this formed a scientific paradox, which we shall unravel only with the development of the conceptions of dissociation, introduced into science by Henri Sainte-Claire Deville in 1857. These conceptions form an important epoch in science, and their development is one of the problems of modern chemistry. The essence of the matter is that, at high temperatures, water exists, but also decomposes, just as a volatile liquid, at a certain temperature, exists both as a liquid and as a vapour. Similarly as a volatile liquid saturates a space, attaining its maximum pressure, so also the products of dissociation have their maximum pressure; and when once that is attained decomposition ceases, just as evaporation does. Under like conditions, if the vapour be allowed to escape (and therefore its partial pressure be diminished) evaporation will recommence; so also if the products of decomposition be removed decomposition again proceeds. These simple conceptions of dissociation introduce infinitely varied consequences into the mechanism of chemical reactions, and we shall therefore have occasion to return to them very often. We may add that Grove also concluded that water is decomposed at a white heat from the fact that he obtained detonating gas by passing steam through a tube containing a wire heated strongly by an electric current, and that by passing steam over molten oxide of lead he obtained, on the one hand, minium (= oxide of lead plus oxygen), and, on the other, metallic lead, formed by the action of the hydrogen

the mixture to cool. To do this, Deville took advantage of the difference between the densities of hydrogen and oxygen.

A wide porcelain tube *p* (fig. 20) is placed in a furnace, which can be raised to a high temperature (it should be heated with small pieces of good coke). In this tube there is inserted a second tube, *t*, of smaller diameter, made of unglazed earthenware, and therefore porous. The ends of the tube are luted to the wide tube, and two tubes, *c* and *c'*, are inserted into the ends, as shown in the drawing. With this arrangement it is possible for a gas to pass into the annular space between the walls of the two tubes, whence it can be collected. Steam from a retort or flask is passed through the tube *d* into the inner porous tube *t*. This steam on entering the red-hot space is decomposed into hydrogen and oxygen. The densities of these gases are very different, hydrogen being sixteen times lighter than oxygen.

FIG. 20.—Decomposition of water by the action of heat, and the separation of the hydrogen formed by its diffusion through a porous tube.

Light gases, as we saw above, penetrate through porous surfaces very much more rapidly than denser ones, and therefore the hydrogen passes through the pores of the tube into the annular space very much more rapidly than the oxygen (about four times quicker, judging by the results of experiment). The hydrogen which separates out into the annular space can only be collected when this space does not contain any oxygen. If any air remains in this space, then the hydrogen which passes out will combine with its oxygen and form water. For this reason a gas incapable of supporting combustion—for instance, nitrogen or carbonic anhydride—is previously passed into the annular space. Thus the carbonic anhydride is passed through the tube *c*, and the hydrogen, separated from the steam, is collected through the tube *c'*, and will be partly mixed with carbonic anhydride. A certain portion of the carbonic anhydride will penetrate through the pores of the

unglazed tube into the interior of the tube T. The oxygen will remain in this tube, and the volume of the remaining oxygen will be half that of the hydrogen which separates out from the annular space.^{6a}

The decomposition of water is effected much more easily by a method of substitution, advantage being taken of the affinity of substances for either the oxygen or the hydrogen of water. If a substance be added to water, which takes up the oxygen, that is, which replaces the hydrogen, we shall then obtain the latter gas from the water. Thus with sodium, water gives hydrogen, whilst with chlorine, which takes up the hydrogen, oxygen is obtained.

Hydrogen is evolved from water by many metals, which are capable of forming oxides in air; that is, which are capable of burning or combining with oxygen. The capacity of metals for combining with oxygen, and therefore for decomposing water, or for the evolution of hydrogen, is very varied.⁷ Among metals potassium and sodium

^{6a} Part of the oxygen will also penetrate through the pores of the tube, but, as was said before, in much smaller quantity than the hydrogen; and as the density of oxygen is sixteen times greater than that of hydrogen, the volume of oxygen which passes through the porous walls will be four times less than that of the hydrogen (the quantities of gases passing through porous walls being inversely proportional to the square roots of their densities). The oxygen which separates out into the annular space will combine, when the temperature falls a certain amount, with the hydrogen; but as each volume of oxygen only requires two volumes of hydrogen, whilst four volumes of hydrogen will pass through the porous walls for every volume of oxygen that passes, part of the hydrogen will remain free, and can be collected from the annular space. A corresponding quantity of oxygen remaining from the decomposition of the water can be collected from the inner tube.

⁷ In order to demonstrate the differences between the affinities of oxygen for different elements, it suffices to compare the amounts of heats evolved in their combination with 16 parts by weight of oxygen; in the case of sodium (when Na_2O is formed, or 46 parts of Na combine with 16 parts of oxygen, according to Beketoff) 100,000 calories (or kilogram units of heat) are evolved, for hydrogen (when water, H_2O , is formed) 69,000 calories, for magnesium (MgO is formed) about 140, for aluminium ($\frac{1}{3}\text{Al}_2\text{O}_3$ is formed) about 130, for iron (when the oxide FeO is formed) 69,000, or (if the oxide Fe_2O_3 is formed) 64,000 calories, for zinc (forming ZnO) 86,000 calories, for lead (when PbO is formed) 51,000 calories, for copper (when CuO is formed) 38,000 calories, and for mercury (HgO being formed) 31,000 calories.

These figures cannot correspond directly with the magnitudes of the affinities, for the physical and mechanical side of the matter is very different in the different cases. Hydrogen is a gas, and, in combining with oxygen, gives a liquid; consequently it changes its physical state, and in doing so evolves heat. But zinc and copper are solids, and, in combining with oxygen, give solid oxides. The oxygen, previously a gas, now passes into a solid or liquid state, and so must also give up its store of heat in forming oxides. Therefore the figures expressing the heat of combination cannot depend only upon the affinities, i.e., only on the loss of internal energy previously in the elements. Nevertheless the figures above cited correspond, in a certain degree, with the order in which the elements stand in respect to their affinity for oxygen, as may be seen from the fact that mercury oxide, which evolves the least heat (among the above examples), is the least stable and is easily decomposed, giving up its oxygen; whilst sodium, the formation of whose oxide is accompanied by the greatest evolution of heat, is able to decompose all

exhibit considerable energy in this respect. The first occurs in potash, the second in soda. They are both lighter than water, soft, and readily change in air. By bringing one or the other of them into contact with water at the ordinary temperature⁸ a quantity of hydrogen, corresponding with the amount of the metal taken, may be directly obtained. One gram of hydrogen, occupying a volume of 11.16 litres at 0° and 760 mm., is evolved for every 39 grams of potassium or 23 grams of sodium taken. The phenomenon may be observed in the following

the other oxides, taking up their oxygen. In order to generalise the connection between affinity and the evolution and absorption of heat, which is evident in its main features, and was firmly established by the researches of Favre and Silberman (about 1840), and then of Thomsen (in Denmark) and Berthelot (in France), many investigators, especially the one last mentioned, established the *law of maximum work*. This states that only those chemical reactions take place of their own accord in which the greatest amount of chemical (latent, potential) energy is transformed into heat. But, in the first place, we are not able, judging from what has been said above, to distinguish that heat which corresponds with purely chemical action from the sum total of the heat observed in a reaction (in the calorimeter); in the second place, there are evidently endothermal reactions which proceed under the same circumstances as exothermal ones (carbon burns in the vapour of sulphur with absorption of heat, whilst in oxygen it evolves heat); and, in the third place, there are reversible reactions, which when taking place in one direction evolve heat, and when taking place in the opposite direction, absorb it; and, therefore, the principle of maximum work in its elementary form is not supported by science. But the subject continues to be developed, and will probably lead to a general law, such as thermal chemistry does not at present possess. And now thermochemical data clearly show that the chemical affinity of sodium for oxygen is greater than that of hydrogen, whilst mercury and copper have less affinities for oxygen than hydrogen has. Hence sodium easily decomposes water, which neither mercury nor copper can do. If aluminium does not decompose water directly, it is only because the oxide Al_2O_3 is insoluble in water, and a coating of the hydrogen formed prevents the reaction (Ditte). This and many other instances show that the course of chemical reactions is determined, not only by the properties and energy of the reacting substances, but also by the nature of those produced.

⁸ If a piece of metallic sodium be thrown into water, it floats on it (owing to its lightness), keeps in a state of continual motion (owing to the evolution of hydrogen on all sides), and immediately decomposes the water, evolving hydrogen, which can be ignited. This experiment may, however, lead to an explosion should the sodium stick to the walls of the vessel, and begin to act on the limited mass of water immediately adjacent to it (probably in this case the NaHO and Na yield Na_2O , which acts on the water, evolving much heat and rapidly forming steam), and the experiment should therefore be cautiously performed. The decomposition of water by sodium may be demonstrated better, and with greater safety, in the following manner. Into a glass cylinder filled with mercury, and immersed in a mercury bath, water is first introduced, and owing to its lightness rises to the top, and then a piece of sodium wrapped in paper is introduced into the cylinder by means of forceps. The metal rises through the mercury to the surface of the water, on which it remains, and evolves hydrogen, which collects in the cylinder and may be tested after the experiment has been completed. The safest method of making this experiment is, however, as follows. The sodium (cleaned from the naphtha in which it is kept) is either wrapped in fine copper gauze and held by forceps or else held in forceps to the end of which a small copper cage is attached, and is then held under water. The evolution of hydrogen goes on quietly, and the gas may be collected in a bell jar and then lighted.

way. A solution of sodium in mercury—or ‘sodium amalgam,’ as it is generally called—is poured into a vessel containing water, where, owing to its weight, it sinks to the bottom; the sodium held in the mercury then acts on the water like pure sodium, liberating hydrogen. The mercury does not act here, and the same amount of it as was taken for dissolving the sodium is obtained in the residue. The hydrogen is evolved gradually in the form of bubbles, which pass through the liquid.

Beyond the hydrogen evolved and a solid substance which remains in solution (and may be obtained by evaporating the resultant liquid) no other products are here obtained. Consequently from the two substances (water and sodium) taken the same number of new substances (hydrogen and the substance dissolved in water, namely, caustic soda) have been obtained, from which we may conclude that the reaction which here takes place is one of double decomposition or of substitution. The resultant solid is nothing else than the so-called caustic soda (sodium hydroxide), which is made up of sodium, oxygen, and half of the hydrogen contained in the water. The substitution, therefore, takes place between the hydrogen and the sodium, half of the hydrogen in the water being replaced by the sodium and evolved in a free state. Hence the reaction which takes place here may be expressed by the equation: $\text{H}_2\text{O} + \text{Na} = \text{NaHO} + \text{H}$; the meaning of this is clear from what has already been said.⁹

⁹ This reaction is vigorously exothermal, i.e., it is accompanied by the evolution of heat. If a sufficient quantity of water be taken, the whole of the sodium hydroxide, NaHO, formed is dissolved, and about 42,500 kilogram units of heat are evolved per 23 grams of sodium taken. As 40 grams of sodium hydroxide are produced, and they in dissolving, judging from direct experiment, evolve about 10,000 calories, the reaction would evolve about 32,500 calories, supposing no excess of water to be present and no solution to be formed. We shall afterwards learn that hydrogen contains, in its smallest isolable particles, H_2 and not H , so that the reaction should be written thus, $2\text{Na} + 2\text{H}_2\text{O} = \text{H}_2 + 2\text{NaHO}$, and it then corresponds with an evolution of heat of + 65,000 calories. And as N. N. Beketoff showed that Na_2O , or anhydrous oxide of sodium, combines with water, forming the hydrate, or sodium hydroxide (caustic soda), 2NaHO , with the evolution of about 35,500 calories, the reaction $2\text{Na} + \text{H}_2\text{O} = \text{H}_2 + \text{Na}_2\text{O}$ corresponds to 29,500 calories. This quantity of heat is less than that which is evolved by the oxide in combining with water and forming caustic soda, and therefore it is not to be wondered at that the hydrate, NaHO, is always formed and not the anhydrous substance Na_2O . That such a conclusion, agreeing with the facts, is inevitable is also seen from the fact that, according to Beketoff, the anhydrous sodium oxide, Na_2O , acts directly on hydrogen, with separation of sodium, $\text{Na}_2\text{O} + \text{H} = \text{NaHO} + \text{Na}$. This reaction is accompanied by an evolution of heat equal to about 3,000 calories, because $\text{Na}_2\text{O} + \text{H}_2\text{O}$ gives, as we saw, 35,500 calories and $\text{Na} + \text{H}_2\text{O}$ evolves 32,500 calories. However, an opposite reaction also takes place— $\text{NaHO} + \text{Na} = \text{Na}_2\text{O} + \text{H}$ (both with the aid of heat)—in which of course heat is absorbed. In this we see an example of calorimetric calculations and the limited application of the law of maximum work to the general phenomena of reversible reactions, to which the case just considered belongs.

Sodium and potassium act on water at the ordinary temperature. Other heavier metals only act on it at higher temperatures, and even then not so rapidly or vigorously. Thus magnesium and calcium only liberate hydrogen from water at its boiling-point, and zinc and iron only at a red heat; whilst a whole series of heavy metals, such as copper, lead, mercury, silver, gold, and platinum, do not in the least decompose water at any temperature, and do not replace its hydrogen.

From this it is clear that hydrogen may be obtained by the decomposition of steam by the action of iron (or zinc) at a high temperature. The experiment is conducted in the following manner. Pieces of iron (filings, nails, &c.) are placed in a porcelain tube, which is then subjected to a strong heat and steam passed through it. The steam, coming into contact with the iron, gives up its oxygen to it, the hydrogen being thus set free and passing out at the other end of the tube, together with undecomposed steam. This method, which is historically of great importance,¹⁰ is practically inconvenient, as it requires a rather high temperature. Further, this reaction, as a reversible one (a red-hot mass of iron decomposes a current of steam, forming oxide and hydrogen; and a mass of oxide of iron, heated to redness in a stream of hydrogen, forms iron and steam), does not proceed in virtue of the comparatively small difference between the affinities of oxygen for iron (or zinc) and for hydrogen, but only because the hydrogen escapes, as it is formed, by virtue of its elasticity.¹¹ If the oxygen compounds—that is, the oxides—which are obtained

¹⁰ The composition of water, as we saw above, was determined by passing steam over red-hot iron. The same method was formerly used for making hydrogen for filling balloons. An oxide having the composition Fe_3O_4 is formed in the reaction, which is hence expressed by the equation, $3\text{Fe} + 4\text{H}_2\text{O} = \text{Fe}_3\text{O}_4 + 8\text{H}$.

¹¹ The reaction between iron and water (notes 7 and 10) is reversible. By heating the oxide in a current of hydrogen, water and iron are obtained. From this it follows, from the principle of chemical equilibria, that if iron and hydrogen be taken, and also oxygen in such quantity that it is insufficient for combination with both substances, then it will divide itself between the two: part of it will combine with the iron and the other part with the hydrogen, but a portion of both of these will remain in an uncombined state.

Therefore, if iron and water be placed in a closed space, decomposition of the water will proceed on heating to the temperature at which the reaction, $3\text{Fe} + 4\text{H}_2\text{O} = \text{Fe}_3\text{O}_4 + 8\text{H}$, commences; it does not go on to the end but ceases, because the conditions for the reverse reaction are attained, and a state of equilibrium will ensue after the decomposition of a certain quantity of water. Here, again, the reversibility is connected with the small heat effect, and again both reactions (direct and reverse) proceed at a red heat. But if, in the above-described reaction, the hydrogen escapes as it is evolved, then its partial pressure does not increase with its formation, and therefore all the iron can be oxidised by the water. In this we see the influence of mass to which we shall have occasion to return later. With copper and lead there will be no decomposition, either at the ordinary or at a high temperature, because the affinities of these metals for oxygen are much less than that of hydrogen.

from the iron or zinc be able to pass into solution, then the affinity acting during solution is added, and the reaction may become non-reversible and proceed with comparatively much greater facility.¹² As the oxides of iron and zinc, by themselves insoluble in water, are capable of combining with (have an affinity for) acid oxides (as we shall afterwards fully consider), and form saline and soluble substances with acids or hydrates having acid properties, these metals are able by the action of such acid hydrates, or of their aqueous solutions,¹³ to liberate hydrogen with great ease at the ordinary temperature ; that is, they act on solutions of acids just as sodium acts on water.¹⁴ Sulphuric acid, H_2SO_4 , is usually chosen for this purpose ; the hydrogen is displaced from it by many metals with much greater facility than directly from water, and such a displacement is accompanied by the evolution of a large amount of heat.¹⁵ When the hydrogen in sulphuric acid

¹² In general, if reversible as well as non-reversible reactions can take place between substances acting on each other, then, judging by our present knowledge, the non-reversible reactions take place in the majority of cases, which obliges one to acknowledge the action, in this case, of comparatively strong affinities. The reaction, $\text{Zn} + \text{H}_2\text{SO}_4 = \text{H}_2 + \text{ZnSO}_4$, which takes place in solutions at the ordinary temperature, is scarcely reversible under these conditions, but at a certain high temperature, it becomes reversible, because then zinc sulphate and sulphuric acid decompose, and the action must take place between the water and zinc. From the preceding proposition results proceed which are in some cases verified by experiment. If the action of zinc or iron on a solution of sulphuric acid is a non-reversible reaction, we may by its means obtain hydrogen in a very compressed state, and compressed hydrogen will not act on solutions of sulphates of the above-named metals. This was actually verified as far as it was possible, in the experiments, to keep up the compression or pressure of the hydrogen. Those metals which do not evolve hydrogen with acids, on the contrary, should, at least with increase of pressure, be displaced by hydrogen. And in fact Brunner showed that gaseous hydrogen displaces platinum and palladium from the aqueous solutions of their chlorine compounds, but not gold, and Beketoff succeeded in showing that silver and mercury, under a considerable pressure, are separated from the solutions of certain of their compounds by means of hydrogen. Reaction commences under a pressure of only six atmospheres if a weak solution of silver sulphate be taken ; with a stronger solution a much greater pressure is, however, required for the separation of the silver.

¹³ For the same reason, many metals in acting on solutions of the alkalies displace hydrogen. Aluminium acts particularly well in this respect, because its oxide gives a soluble compound with alkalies. For the same reason tin, in acting on hydrochloric acid, evolves hydrogen, and silicon does the same with hydrofluoric acid.

¹⁴ It is acknowledged that zinc itself acts on water, even at the ordinary temperature, but that the action is confined to small masses and only proceeds at the surface. In reality, zinc, in the form of a very fine powder, or so-called 'zinc dust,' is capable of decomposing water with the formation of oxide (hydrated) and hydrogen. The oxide formed acts on sulphuric acid, water then dissolves the salt produced, and the action continues because one of the products of the action of water on zinc, namely, the zinc oxide, is removed from the surface. One might naturally imagine that the reaction does not proceed directly between the metal and the water, but between the metal and the acid ; but such a simple representation, which we shall notice later, hides the mechanism of the reaction, and does not permit of its actual complexity being seen.

¹⁵ According to Thomsen, the reaction between zinc and a very weak solution of sulphuric acid evolves about 38,000 calories (zinc sulphate being formed) per 65 parts

is replaced by a metal, a substance is obtained which is called a salt of sulphuric acid or a sulphate. Thus, by the action of zinc on sulphuric acid, hydrogen and zinc sulphate, ZnSO_4 ,^{15a} are obtained. The latter is a solid substance, soluble in water. In order that the action of the metal on the acid should go on regularly, and to the end, it is necessary that the acid should be diluted with water, which dissolves the salt as it is formed; otherwise the salt in a solid state covers the metal and prevents the acid from attacking it. Usually the acid is diluted with from three to five times its volume of water, and the metal is covered with this solution. In order that the metal may act rapidly on the acid it should present a large surface, so that a maximum amount of the reacting substances may come into contact in a given time. For this

FIG. 21.—Apparatus for the preparation of hydrogen from zinc and sulphuric acid.

purpose the zinc is used as strips of sheet zinc, or in the granulated form (that is, zinc which has been poured from a height, in a molten state, into water). The iron should be in the form of wire, nails, filings, or cuttings.

by weight of zinc; and 56 parts by weight of iron—which combine, like 65 parts of zinc, with 16 parts by weight of oxygen—evolve about 25,000 calories forming ferrous sulphate, FeSO_4). Paracelsus observed the action of metals on acids in the seventeenth century; but it was not until the eighteenth century that Lémery determined that the gas evolved in this action is a particular one which differs from air and is capable of burning. Even Boyle confused it with air. Cavendish determined the chief properties of the gas discovered by Paracelsus. At first it was called ‘inflammable air:’ later, when it was recognised that in burning it gives water, it was called hydrogen, a word derived from the Greek terms for water and generator.

^{15a} If, when the sulphuric acid is poured over the zinc, the evolution of the hydrogen proceed too slowly, it may be greatly accelerated by adding a small quantity of a solution of copper sulphate or platinum chloride to the acid. The reason of this is explained in Chap. XVI., note 10a.

The usual method of obtaining hydrogen is as follows. A certain quantity of granulated zinc is put into a double-necked, or Woulfe's, bottle. Into one neck a funnel is placed, reaching to the bottom of the bottle, so that the liquid poured in may prevent the hydrogen from escaping through it. The gas escapes through a special gas-conducting tube, which is firmly fixed, by a cork, into the other neck, and ends in a water-bath (fig. 21), under the orifice of a glass cylinder full of water.¹⁶ If sulphuric acid be now poured into the Woulfe's bottle it will

¹⁶ As laboratory experiments with gases require special methods of manipulation, we will describe certain of them here. When in laboratory practice an intermittent supply of hydrogen (or other gas which is evolved without the aid of heat) is required, the apparatus represented in fig. 22 is the most convenient. It consists of two bottles, having at the bottom orifices, in which corks with tubes are placed, and these tubes are connected by an indiarubber tube (sometimes furnished with a spring clamp). Zinc is placed in

FIG. 22.—A very convenient apparatus for the preparation of gases obtained without heat. It may also replace an aspirator or gasometer.

one bottle and dilute sulphuric acid in the other. The neck of the former is closed by a cork fitted with a gas-conducting tube with a stopcock. If the two bottles be connected with each other, and the stopcock be opened, the acid will flow to the zinc and evolve hydrogen. If the stopcock be closed, the hydrogen will force out the acid from the bottle containing the zinc, and the action will cease. Or the vessel containing the acid may be placed at a lower level than that containing the zinc, when all the liquid will flow into it; and in order to start the action the acid vessel may be placed on a higher level than the other, when the acid will flow to the zinc. It can also be employed for collecting gases (as an aspirator or gasometer).

An *aspirator* (for collecting and delivering gas) usually consists of a vessel furnished with a stopcock at the bottom. A stout cork, through which a glass tube passes, is fixed into the neck of this vessel. If the vessel be filled up with water to the cork, and the bottom stopcock opened, the water will run out and draw gas in. For this purpose the glass tube is connected with the apparatus from which it is desired to pump out or exhaust the gas.

The aspirator represented in fig. 23 may be recommended for its continuous action. It consists of a tube, *d*, which widens out at the top, the lower part being long and narrow. In the expanded upper portion, *c*, two tubes are sealed: one, *e*, is for drawing in the gas, whilst the other, *b*, is connected with the water supply, *w*. The amount of water supplied through the tube *b* must be less than the amount which can be carried off by the tube *d*.

soon be seen that bubbles of a gas are evolved, which is hydrogen. The first part of the gas evolved should not be collected, as it is mixed

Owing to this the water in the tube *d* will flow through it in cylindrical portions alternating with cylindrical gas bubbles, which will be thus carried away. The gas which is drawn through may be collected from the end of the tube *d*; but this form of pump is usually employed where the air or gas aspirated is not to be collected. If the tube *d* is of considerable length, say 40 ft. or more, a very fair vacuum will be produced, the amount

FIG. 23.—Continuous aspirator. The tube *d* should be more than 32 feet long.

being shown by the gauge *g*: it is often used for filtering under reduced pressure, as shown in the figure. If the water be replaced by mercury, and the length of the tube *d* be greater than 760 mm., the aspirator may be employed as an air-pump, and all the air may be exhausted from a limited space; for instance, by connecting *g* with a hollow sphere.

Gasholders are often used for collecting and holding gases. They are made of glass, copper, or tin plate. The usual form is shown in fig. 24. The lower vessel *B* is made hermetically tight—i.e., impervious to gases—and is filled with water. A funnel is attached to this vessel (by several supports). The vessel *B* communicates with the

with the air originally in the apparatus. This precaution should be taken in the preparation of all gases. Time must be allowed for the gas evolved to displace all the air from the apparatus, otherwise in testing the combustibility of the hydrogen an explosion may occur owing to the formation of detonating gas (the mixture of the oxygen of the air with the hydrogen).¹⁷

bottom of the funnel by a stopcock *b* and a tube *a*, reaching to the bottom of the vessel *B*. If water be poured into the funnel, and the stopcocks *a* and *b* be opened, the water will run through *a*, and the air escape from the vessel *B* by *b*. A glass tube *f* runs up the side of the vessel *B*, with which it communicates at the top and bottom, and shows the amount of water and gas the gasholder contains. In order to fill the gasholder with a gas, it is first filled with water, the cocks *a*, *b*, and *e* are closed, the nut *d* unscrewed, and the end of the tube conducting the gas from the apparatus in which it is generated is passed into *d*. As the gas fills the gasholder the water runs out at *d*. If the pressure of a gas be not greater than the atmospheric pressure, and it be required to collect it in the gasholder, then the stopcock *e* is put into communication with the space containing the gas. Then, having opened the orifice *d*, the gasholder acts like an aspirator; the gas will pass through *e*, and the water run out at *d*. If the cocks be closed, the gas collected in the gasholder may be easily preserved and transported. If it be desired to transfer this gas into another vessel, a gas-conducting tube is attached to *e*, the cock *a* opened, *b* and *d* closed, and the gas will then pass out at *e*, its pressure in the apparatus being greater than the atmospheric pressure, owing to the pressure of the water poured into the funnel. If it be required to fill a cylinder or flask with the gas, it is filled with water and inverted in the funnel, and the stopcocks *b* and *a* opened. Then water will run through *a*, and the gas will escape from the gasholder into the cylinder through *b*.

¹⁷ When it is required to prepare hydrogen in large quantities for filling balloons, copper vessels or wooden casks lined with lead are employed: they are filled with scrap iron over which dilute sulphuric acid is poured. The hydrogen generated from a number of casks is carried through lead pipes into special casks containing water (in order to cool the gas) and lime (in order to remove acid fumes). To avoid loss of gas all the joints are made hermetically tight with cement or tar. In order to fill his gigantic balloon (of 25,000 cubic metres capacity), Giffard, in 1878, constructed a complicated apparatus for giving a continuous supply of hydrogen, in which a mixture of sulphuric acid and water was run continuously into vessels containing iron, and from which the solution of iron sulphate formed was continually drawn off. When coal gas, extracted from coal, is employed for filling balloons, it should be as light, or as rich in hydrogen, as possible. For this reason, only the last portions of the gas coming from the retorts are collected,

FIG. 24.—Gasholder.

Besides being contained in water, hydrogen is also present in many other substances,¹⁸ and may be obtained from them. As examples of this it may be mentioned: (1) that a mixture of formate of sodium, CHNaO_2 , and caustic soda, NaHO , when heated to redness, forms sodium carbonate, Na_2CO_3 , and hydrogen, H_2 ; ¹⁹ (2) that a number of organic substances are decomposed at a red heat, forming hydrogen, among other gases; and thus it is that hydrogen is contained in ordinary coal gas; (3) charcoal liberates hydrogen from steam at a high temperature,²⁰ but the reaction which here takes place is distinguished by its complexity, and will therefore be considered later; (4) that a certain amount of hydrogen is formed, together with other gases, in the process of decay (change under the influence of micro-organisms) of certain organic substances (for instance, of plants under water).

Gaseous hydrogen is rarely met with in nature. It has been found in the gases of volcanoes (and fumaroles), in small cavities in crystals of rock salt (under pressure and mixed with other gases), and it even occurs in small quantities in the atmosphere, according to the careful and, besides this, it is then sometimes passed through red-hot vessels, in order to decompose the hydrocarbons as much as possible. Charcoal is deposited in these vessels, and hydrogen remains as gas. Coal gas may be yet further enriched in hydrogen, and consequently rendered lighter, by passing it over an ignited mixture of charcoal and lime.

L. Mond (London) proposes to manufacture hydrogen on a large scale from water gas (see *infra*, and Chapters VIII. and IX.), which contains a mixture of oxide of carbon (CO) and hydrogen, and is produced by the action of steam upon incandescent coke ($\text{C} + \text{H}_2\text{O} = \text{CO} + \text{H}_2$). He destroys the oxide of carbon by converting it into carbon and carbonic anhydride, $2\text{CO} = \text{C} + \text{CO}_2$, which is easily done by means of incandescent finely divided metallic nickel; the carbon then remains with the nickel, from which it may be removed by burning it in air, and the nickel can then be used over again (see Chapter IX., note 24a). The CO_2 formed is removed from the hydrogen by passing it through milk of lime. This process should apparently give hydrogen on a large scale more economically than any of the methods hitherto proposed. Hydrogen is formed in many other ways. We shall meet many reactions which are accompanied by the formation of hydrogen gas. The methods here mentioned are the most convenient and easily adopted.

¹⁸ Of the metals, only a very few combine with hydrogen (for example, palladium and sodium), and give substances which are easily decomposed, and some metals, especially platinum and iron, absorb this gas (see Occlusion, note 37). Of the non-metals, the halogens (fluorine, chlorine, bromine, and iodine) most easily form hydrogen compounds: of these the hydrogen compound of chlorine, and still more that of fluorine, are stable, whilst those of bromine and iodine are easily decomposed, especially the latter. The other non-metals—for instance, sulphur, carbon, and phosphorus—give hydrogen compounds of varying composition and properties, but they are all less stable than water.

¹⁹ This reaction, expressed by the equation, $\text{CNaHO}_2 + \text{NaHO} = \text{CNa}_2\text{O}_3 + \text{H}_2$, may be effected in a glass vessel, like the decomposition of copper carbonate or mercury oxide (see Introduction): it is non-reversible, and takes place without the presence of water, and therefore Pictet (see later) made use of it to obtain hydrogen under great pressure.

²⁰ The reaction between charcoal and superheated steam is a double one—that is, there may be formed either carbonic oxide, CO (according to the equation, $\text{H}_2\text{O} + \text{C} = \text{H}_2 + \text{CO}$), or carbonic anhydride, CO_2 (according to the equation $2\text{H}_2\text{O} + \text{C} = 2\text{H}_2 + \text{CO}_2$), and the resulting mixture is called *water-gas*, but of this we shall speak in Chapter IX.

researches of Armand Gautier (1900). The spectroscope has proved that hydrogen is also undoubtedly present in the atmospheres of the sun and many of the stars (Chap. XIII.).

The properties of hydrogen.—Hydrogen presents us with an example of a gas which at first sight does not differ from air. It is not surprising, therefore, that Paracelsus, having discovered that an aëriiform substance is obtained by the action of metals on sulphuric acid, did not determine exactly its difference from air.^{20a} In fact, hydrogen, like air, is colourless, and has no smell;²¹ but a more intimate acquaintance with its properties proves it to be entirely different from air. The first sign which distinguishes hydrogen from air is its combustibility. This property is so easily observed that it is the one to which recourse is usually had in order to recognise if hydrogen is evolved in a reaction, although there are many other combustible gases. But before speaking of the combustibility and other chemical properties of hydrogen, we will first describe the physical properties of this gas, as we did in the case of water. It is easy to show that it is one of the lightest gases.²²

^{20a} Considering the immense velocity of the hydrogen molecules—about 1,800 metres a second (see Chapter I., note 34)—they may, perhaps, travel away from the terrestrial atmosphere into space. The absence of any considerable quantity of hydrogen in the atmosphere of the earth is also probably due to its being converted into water by electrical discharges, &c., in the presence of an excess of oxygen.

²¹ Hydrogen obtained by the action of zinc or iron on sulphuric acid generally smells of hydrogen sulphide (like rotten eggs), which it contains in admixture. As a rule, such hydrogen is not so pure as that obtained by the action of an electric current or of sodium on water. The impurity of the hydrogen depends on the impurities contained in the zinc, or iron, and sulphuric acid, and on secondary reactions which take place simultaneously with the main reaction. Impure hydrogen may be freed from the impurities it contains: some of them—namely, those having acid properties—are absorbed by caustic soda, and may therefore be removed by passing the gas through a solution of this substance; another series of impurities is absorbed by a solution of mercuric chloride; and, lastly, a third series is absorbed by a solution of potassium permanganate. If absolutely **pure hydrogen** be required, it is sometimes obtained by the decomposition of water (previously boiled to expel all air, and mixed with pure sulphuric acid) by the galvanic current. Only the gas evolved at the negative electrode is collected. Or else an apparatus like that which gives detonating gas is used, the positive electrode, however, being immersed under mercury containing zinc in solution. The oxygen which is evolved at this electrode then combines immediately, at the moment of its evolution, with the zinc, and this compound dissolves in the sulphuric acid and forms zinc sulphate, which remains in solution, so that the hydrogen generated will be free from oxygen. Quite pure hydrogen (and oxygen) is obtained by decomposing a solution of caustic baryta by electricity. Caustic soda gives hydrogen containing some carbonic anhydride, and sulphuric acid also does not give perfectly pure gases. (Becker, 1902.)

²² An inverted beaker is attached to one arm of the beam of a tolerably sensitive balance, and its weight counterpoised by weights in the pan attached to the other arm. If the beaker be then filled with hydrogen it rises, owing to the air being replaced by hydrogen. At the ordinary temperature of a room, a litre of air weighs about 1·2 gram, and on replacing the air by hydrogen a decrease in weight of about 1 gram per litre is obtained. Moist hydrogen is heavier than dry—for aqueous vapour is nine times heavier than hydrogen. In filling balloons it is usually calculated (as it is impossible to have

If passed into the bottom of a flask full of air, hydrogen will not remain in it, but, owing to its lightness, rapidly escapes and mixes with the atmosphere. If, however, a cylinder whose orifice is turned downwards be filled with hydrogen, it will not escape, or, more correctly, it will only slowly mix with the atmosphere. This may be demonstrated by the fact that a lighted taper sets fire to the hydrogen at the orifice of the cylinder, and is itself extinguished inside the cylinder. Hence hydrogen, being itself combustible, does not support combustion. The great lightness of hydrogen is taken advantage of for balloons. Ordinary coal gas, which is often also used for the same purpose, is only about twice as light as air, whilst hydrogen is fourteen times lighter than air. A very simple experiment with soap bubbles illustrates very well the application of hydrogen to the filling of balloons. Charles, of Paris, showed the lightness of hydrogen in this way, and constructed a balloon filled with hydrogen almost simultaneously with Montgolfier. One litre of pure and dry hydrogen ²³ at 0° and 760 mm. pressure weighs 0.08995 gram; that is, hydrogen is almost 14½ times lighter than air. It is the lightest of all gases. The small density of hydrogen determines many remarkable properties which it shows; thus hydrogen passes exceedingly rapidly through fine orifices, its molecules (Chap.

perfectly dry hydrogen or to obtain it quite free from air) that the lifting force due to the difference between the weights of equal volumes of hydrogen and air is equal to 1 kilogram (=1,000 grams) per cubic metre (=1,000 litres).

²³ The density of hydrogen in relation to the air has been repeatedly determined. The first determination, made by Lavoisier, was not very exact. Taking the density of air as unity, he obtained 0.0769 for that of hydrogen; that is, this gas is thirteen times lighter than air. More accurate determinations are due to Thomsen, who obtained the figure 0.0693; Berzelius and Dulong, who obtained 0.0688; and Dumas and Boussingault, who obtained 0.06945. Regnault, and more recently Le Duc, took two spheres of considerable volume, having equal capacities and displacing equal volumes of air (thus avoiding the necessity of any correction for weighing them in air). Both spheres were attached to the scale pans of a balance. One was sealed up, and the other weighed first empty and then full of hydrogen. Thus, knowing the weight of the hydrogen filling the sphere, and the capacity of the sphere, it was easy to find the weight of a litre of hydrogen; and, knowing the weight of a litre of air at the same temperature and pressure, it was easy to calculate the density of hydrogen. Regnault found the average density of hydrogen to be 0.06926; Le Duc, 0.06948. In 1892 and 1895 Rayleigh, Morley, and Thomsen made fresh determinations, and obtained results very nearly equal to the above. The mean of their results is equal to 0.06956, and this latter figure must now be looked upon as near the truth. Hydrogen is therefore 14.4 times lighter than air. In other words a litre of hydrogen at 0°, under the normal pressure of 760 mm., at the sea level and latitude 45°, weighs 0.08995 gram, or at t° , and under the pressure H , at latitude 45°, the weight of a litre of hydrogen is equal to

$$0.08995 \frac{H}{760} \times \frac{1}{1 + 0.00367t} \text{ grams.}$$

In this book we shall always refer the density of gases to that of hydrogen, as it is the lightest of all gases and vapours under the same conditions.

I.) being endowed with the greatest velocity.²⁴ At pressures somewhat higher than that of the atmosphere, all other gases exhibit a greater compressibility and coefficient of expansion than they should, according to the laws of Mariotte and Gay-Lussac; whilst hydrogen, on the contrary, is compressed to a less degree than it should be from the law of Mariotte,²⁵ and with a rise of pressure it expands slightly

²⁴ If a cracked flask be filled with hydrogen, and its neck immersed under water or mercury, the liquid will rise up into the flask, owing to the hydrogen passing out through the cracks about 3·8 times quicker than the air is able to pass through these cracks into the flask. The same phenomenon may be better observed if, instead of a flask, a tube be employed whose end is closed by a porous substance, such as graphite, unglazed earthenware, or a gypsum plate.

²⁵ According to Boyle and Mariotte's law, for a given gas at a constant temperature the volume decreases by as many times as the pressure increases; that is, the product of the volume v and the pressure p for a given gas is a constant quantity: $pv = C$, which does not vary with a change of pressure. This equation does very nearly and exactly express the observed relation between the volume and pressure, but only within comparatively small variations of pressure. If these variations be in any degree considerable, the quantity pv proves to be dependent on the pressure, and it either increases or diminishes with an increase of pressure. In the former case the compressibility is less than it should be according to Mariotte's law—in the latter case it is greater. We will call the first case a positive discrepancy (because then $d(pv)/d(p)$ is greater than zero), and the second case a negative discrepancy (because then $d(pv)/d(p)$ is less than zero). Determinations made by myself (in the seventies), M. L. Kirpicheff, and V. A. Hemilian showed that all known gases at low pressures—i.e., when considerably rarefied—present positive discrepancies. On the other hand, it appears from the researches of Cailletet, Natterer, and Amagat that all gases under great pressures (when the volume obtained is 500–1,000 times less than under the atmospheric pressure) also present positive discrepancies. Thus under a pressure of 2,700 atmospheres air is compressed, not 2,700 but only 800 times, and hydrogen 1,000 times. Hence the positive kind of discrepancy is, so to speak, normal to gases. And this is easily intelligible. If a gas followed Mariotte's law, or if it were compressed to a greater extent than is shown by this law, then under great pressures it would attain a density greater than that of solid and liquid substances, which is in itself improbable and even impossible by reason of the fact that solid and liquid substances are themselves but little compressible. For instance, a cubic centimetre of oxygen at 0° and under the atmospheric pressure weighs about 0·0014 gram, and at a pressure of 3,000 atmospheres (this pressure is attained in gums) it would, if it followed Mariotte's law, weigh 4·2 grams—that is, would be about four times heavier than water—and at a pressure of 10,000 atmospheres it would be heavier than mercury. Besides this, positive discrepancies are probable because the molecules of a gas themselves must occupy a certain volume. Considering that Mariotte's law, strictly speaking, applies only to the intermolecular space, we can understand the necessity of positive discrepancies. If we designate the volume of the molecules of a gas by b (like van der Waals, see Chapter I., note 34), then it must be expected that $p(v - b) = C$. Hence $pv = C + bp$, which expresses a positive discrepancy. Supposing that for hydrogen, $pv = 1,000$, at a pressure of one metre of mercury, we obtain b , according to the results of Regnault's, Amagat's, and Natterer's experiments, as approximately 0·7 to 0·9.

Thus the increase of pv with increase of pressure must be considered as the normal law of the compressibility of gases. Hydrogen presents such a positive compressibility at all pressures, for it presents positive discrepancies, according to Regnault, at all pressures slightly above the atmospheric pressure. Hence hydrogen is, so to speak, a model gas. No other gas behaves so simply with a change of pressure. All other gases at pressures from 1 to 30 atmospheres present negative discrepancies; that is, they are

less than at the atmospheric pressure.²⁶ However, hydrogen, like air and many other gases which are permanent at the ordinary temperature,

then compressed to a greater degree than should follow from Mariotte's law, as was shown by the determinations of Regnault, which were verified when repeated by myself and Boguzsky. Thus, for example, on changing the pressure from 4 to 20 metres of mercury—that is, on increasing the pressure five times—the volume of hydrogen only decreased 4.93 times, and that of air 5.06 times.

The positive discrepancies from the law at low pressures are of particular interest, and, according to the above-mentioned determinations made by myself, Kirpicheff, and Hemilian, and verified (by two methods) by K. D. Kraevitch and Ramsay (London, 1894), they are common to all gases (even to those which are easily compressed into a liquid state, such as carbonic and sulphurous anhydrides). These discrepancies coincide with a very high rarefaction of the gas, where it is near a condition of maximum dispersion of its molecules, and perhaps presents a passage towards the substance termed 'luminiferous ether' which fills up interplanetary and interstellar space. If we suppose that gases are rarefiable only to a definite limit, after having attained which they (like solids) hardly alter in volume with a decrease of pressure, then on the one hand the passage of the atmosphere at its upper limits into a homogeneous ethereal medium becomes comprehensible, and on the other hand it would be expected that gases would, in a state of high rarefaction, present positive discrepancies from Boyle and Mariotte's law. Our present acquaintance with this province of highly rarefied gases is very limited (because direct measurements are exceedingly difficult to make, and are hampered by possible errors of experiment, which may be considerable), and its further development promises to elucidate much in respect to natural phenomena. To the three states of matter (solid, liquid, and gaseous) perhaps a fourth may yet be added, the ethereal or ultra-gaseous (as Crookes proposed), by which is understood matter in its highest possible state of rarefaction.

²⁶ The law of Gay-Lussac states that all gases in all conditions present one coefficient of expansion, 0.00367; that is, when heated from 0° to 100° they expand like air, 1,000 volumes of a gas at 0° occupying 1,367 volumes at 100°. Regnault, about 1850, showed that Gay-Lussac's law is not entirely correct, and that different gases, and also one and the same gas at different pressures, have not quite the same coefficients of expansion. Thus the expansion of air between 0° and 100° is 0.367 under the ordinary pressure of one atmosphere, but at three atmospheres it is 0.371, whilst that of carbonic anhydride is 0.37. Regnault, however, did not directly determine the change of volume between 0° and 100°, but measured the variation of pressure with the change of temperature. But since gases do not entirely follow Mariotte's law, the change of volume cannot be directly judged by the variation of pressure. The investigations carried on by myself and Kayander, about 1870, showed the variation of volume on heating from 0° to 100° under a really constant pressure. These investigations confirmed Regnault's conclusion, that Gay-Lussac's law is not absolutely accurate, and further showed (1) that the expansion per unit volume from 0° to 100° under a pressure of one atmosphere is for air 0.368, for hydrogen 0.367, for carbonic anhydride 0.373, for hydrogen bromide 0.386, &c.; (2) that for gases which are more compressible than should follow from Mariotte's law, the expansion by heat increases with the pressure—for example, for air at a pressure of three and a half atmospheres, it equals 0.371, for carbonic anhydride, at one atmosphere 0.373, at three atmospheres 0.389, and at eight atmospheres 0.413; (3) that for gases which are less compressible than should follow from Mariotte's law, the expansion by heat decreases with an increase of pressure—for example, for hydrogen at one atmosphere 0.367, at eight atmospheres 0.369, for air at a quarter of an atmosphere 0.370, at one atmosphere 0.368; and hydrogen like *air* (and other gases) is less compressed at low pressures than should follow from Mariotte's law (see note 25). Hence, hydrogen, starting from zero and rising to the highest pressures, exhibits a gradually, although only slightly, varying coefficient of expansion, whilst for air and other gases at the atmospheric and higher pressures the coefficient of expansion increases with the

does not pass into a liquid state even under the greatest possible pressures,²⁷ but is compressed into a lesser volume than would follow

increase of pressure, so long as their compressibility is greater than should follow from Mariotte's law. But when at considerable pressures this kind of discrepancy passes into the normal (see note 25), then the coefficient of expansion of all gases decreases with an increase of pressure, as is seen from the researches of Amagat. The difference between the two coefficients of expansion, for a constant pressure and for a constant volume, is explained by these relations. Thus, for example, for air at a pressure of one atmosphere the true coefficient of expansion (the volume varying at constant pressure) = 0.00368 (according to Mendeléeff and Kayander) and the variation of pressure (at a constant volume, according to Regnault) = 0.00367.

²⁷ Permanent gases are those which cannot be liquefied by an increase of pressure alone. With rise of temperature, all gases and vapours become permanent gases. As we shall afterwards learn, carbonic anhydride becomes a permanent gas at temperatures above 31°, and at lower temperatures it has a maximum pressure, and may be liquefied by pressure alone.

The liquefaction of gases, accomplished by Faraday (see Ammonia, Chapter VI.) and others, in the first half of the last century, showed that a number of substances are capable, like water, of assuming all three physical states, and that there is no essential difference between vapours and gases, the only distinction being that the boiling-points (or the temperatures at which the pressure = 760 mm.) of liquids lie above the ordinary temperature, and those of liquefied gases below, and that consequently a gas is superheated vapour, or vapour heated above the boiling-point, or removed from saturation and rarefied, having a lower pressure than that maximum which is proper to a given temperature and substance. We will here cite the **maximum pressures** of certain liquids and gases **at various temperatures**, because they may be taken advantage of for obtaining constant temperatures by changing the pressures at which boiling or the formation of saturated vapours takes place. The temperatures (according to the air thermometer) are placed on the left, and the pressures in millimetres of mercury (at 0°) on the right-hand side. Carbon bisulphide, CS₂; 0°, 127.9; 10°, 198.5; 20°, 298.1; 30°, 431.6; 40°, 617.5; 50°, 857.1. Aniline, C₆H₇N; 150°, 283.7; 160°, 387.0; 170°, 515.6; 108°, 677.2; 185°, 771.5. Mercury, Hg; 300°, 246.8; 310°, 304.9; 320°, 373.7; 330°, 454.4; 340°, 548.6; 350°, 658.0; 359°, 770.9. Sulphur, S; 395°, 300; 423°, 500; 443°, 700; 452°, 800; 459°, 900. These figures were obtained by Ramsay and Young. We may add the following boiling-points under a pressure of 760 mm. (according to the air thermometer, Callendar and Griffiths, 1891: aniline, 184°, 13; naphthalene, 217°, 94; benzophenone, 305°, 82; mercury, 356°, 76; sulphur, 444°, 53. And melting-points: tin, 231°, 68; bismuth, 269°, 22; lead, 327°, 69; and zinc, 417°, 57. These data may also be used for obtaining a constant temperature and for verifying thermometers. The pressures of liquefied gases are expressed *in atmospheres*. Sulphurous anhydride, SO₂: - 30°, 0.4; - 20°, 0.6; - 10°, 1; 0°, 1.5; + 10°, 2.3; 20°, 3.2; 30°, 5.3. Ammonia, NH₃: - 40°, 0.7; - 30°, 1.1; - 20°, 1.8; - 10°, 2.8; 0°, 4.2; + 10°, 6.0; 20°, 8.4. Carbonic anhydride, CO₂: - 115°, 0.033; - 80°, 1; - 70°, 2.1; - 60°, 3.9; - 50°, 6.8; - 40°, 10; - 20°, 23; 0°, 35; + 10°, 46; 20°, 58. Nitrous oxide, N₂O: - 125°, 0.033; - 92°, 1; - 80°, 1.9; - 50°, 7.6; - 20°, 23.1; 0°, 36.1; + 20°, 55.3. Ethylene, C₂H₄: - 140°, 0.033; - 130°, 0.1; - 103°, 1; - 40°, 13; - 1°, 42. Air: - 191°, 1; - 158°, 14; - 140°, 39. Nitrogen: N₂: - 203°, 0.085; - 193°, 1; - 160°, 14; - 146°, 32. The methods of liquefying gases (by pressure and cold) will be described under ammonia, nitrous oxide, sulphurous anhydride, and in later footnotes. We will now turn our attention to the fact that the evaporation of volatile liquids, under various, and especially under low, pressures, gives an easy means for obtaining **low temperatures**. Thus, liquefied carbonic anhydride, under the ordinary pressure, reduces the temperature to - 80°, and when it evaporates in a rarefied atmosphere (under an air-pump) at 25 mm. (= 0.033 atmosphere) the temperature, judging by the above-cited figures, falls to - 115° (Dewar). Even the evaporation of

from Mariotte's law.²⁸ From this it may be concluded that the critical temperature (absolute boiling-point) of hydrogen, and of gases resembling it,²⁹ lies very much below the ordinary temperature; that is, that

liquids of common occurrence, under low pressures easily attainable with an air-pump, may produce low temperatures, which may be again taken advantage of for obtaining still more volatile liquids. Water boiling in a vacuum becomes cold, and under a pressure of less than 4.5 mm. it freezes, because its pressure at 0° is 4.5 mm. A sufficiently low temperature may be obtained by forcing fine streams of air through common ether, carbon bisulphide, CS₂, or methyl chloride, CH₃Cl, and other similar volatile liquids. In the adjoining table are given, for certain gases, (1) the number of atmospheres necessary for their liquefaction at 15°, and (2) the boiling-points of the resultant liquids under a pressure of 760 mm.

	C ₂ H ₂	C ₂ H ₄	N ₂ O	CO ₂	H ₂ S	AsH ₃	NH ₃	HCl	CH ₃ Cl	C ₂ N ₂	SO ₂
(1)	39	56	45	50	10	8	7	25	4	4	3
(2)	-75°	-104°	-90°	-79°	-74°	-58°	-34°	-84°	-24°	-21°	-10°

²⁸ Natterer's determinations (1851-1854), together with Amagat's results (1880-1888), show that the compressibility of hydrogen, under high pressures, may be expressed by the following figures:—

p	=	1	100	1000	2500
v	=	1	0.0107	0.0019	0.0013
pv	=	1	1.07	1.9	3.25
s	=	0.11	10.3	58	85

where p is the pressure in metres of mercury, v the volume (that under a pressure of 1 metre being taken as 1), and s the weight in grams of a litre of hydrogen at 20°. If hydrogen followed Mariotte's law, then under a pressure of 2,500 metres one litre would contain not 85, but about 265 grams. It is evident from the above figures, that as the pressure increases, the weight of a litre of the gas approaches a limit which is doubtless the density of the gas when liquefied, and therefore the weight of a litre of liquid hydrogen would be near 100 grams (density about 0.1, which is less than that of all other liquids) at 20°, if liquid hydrogen could exist at that temperature.

²⁹ Cagniard de Latour, on heating ether in a closed tube to about 190°, observed that at this temperature the liquid is transformed into vapour occupying the original volume—that is, having the same density as the liquid. The further investigations made by Drion and by myself showed that every liquid has such an **absolute boiling-point**, above which it cannot exist as a liquid, and is transformed into a dense gas. In order to grasp the true signification of this absolute boiling temperature, it must be remembered that the liquid state is characterised by a cohesion of the particles which does not exist in vapours and gases. The cohesion of liquids is expressed in their capillary phenomena (drop formation, rise in capillary tubes, &c.), and the product of the density of a liquid into the height to which it rises in a capillary tube (of a definite diameter) may serve as the measure of the magnitude of cohesion. Thus, in a tube of 1 mm. diameter, water at 15° rises (the height being corrected for the meniscus) 14.8 mm., and ether at t° to a height $(5.35 - 0.028 t)$ mm. The cohesion of a liquid is lessened by heating, and therefore the capillary heights are also diminished. It has been shown by experiment that this decrement is proportional to the temperature, and hence by the aid of capillary observations we are able to form an idea that at a certain temperature the cohesion may vanish. For ether, according to the above formula, this would occur at 191°. If the cohesion disappears from a liquid it becomes a gas, for cohesion is the only point of difference between these two states. A liquid in evaporating and overcoming the force of cohesion, absorbs heat. Therefore the absolute boiling-point was defined by me (1861) as that temperature at which: (a) a liquid cannot exist as a liquid, but forms a gas which cannot pass into a liquid state under any pressure whatever; (b) its cohesion is zero; and (c) the latent heat of evaporation = 0.

the **liquefaction** of this gas is only possible at low temperatures, and under great pressures.³⁰ This conclusion was verified (1877) by the experiments of Pictet and Cailletet.³¹ They compressed gases at a very

This definition was but little known until Andrews (1869) explained the matter from another aspect by starting from gases. He discovered that carbonic anhydride cannot be liquefied by any degree of compression at temperatures above 31° , whilst at lower temperatures it can be liquefied. He called this temperature the *critical temperature*. It is evident that it is the same as the absolute boiling-point. We shall afterwards designate it by *tc*. At low temperatures a gas which is subjected to a pressure greater than its maximum pressure is transformed into a liquid, which, in evaporating, gives a saturated vapour possessing this maximum pressure; whilst at temperatures above *tc*, the pressure to which the gas is subjected may increase indefinitely. However, under these conditions the volume of the gas does not change indefinitely but approaches a definite limit (see notes 25 and 28)—that is, it resembles in this respect a liquid or a solid which is altered but little in volume by pressure. The volume which a liquid or gas occupies at *tc* is termed the **critical volume**, and corresponds with the **critical pressure**, which we will designate by *pc* and express in atmospheres. It is evident from what has been said that the discrepancies from Mariotte and Boyle's law, the absolute boiling-point, the density in the liquid and compressed gaseous states, and the properties of liquids, must all be intimately connected together. We shall consider these relations in one of the following notes. At present we will supplement the above observations by the values of *tc* and *pc* for certain liquids and gases which have been investigated in this respect—

<i>tc</i>		<i>pc</i>	<i>tc</i>		<i>pc</i>
H ₂	— 240°	15	CH ₃ COOH	+ 322°	57
N ₂	— 146°	33	H ₂ S	+ 108°	92

Young and Guy (1891) showed that *tc* and *pc* clearly depend upon the composition and molecular weight.

³⁰ I came to this conclusion in 1870 (*Ann. Phys. Chem.* **141**, 623).

³¹ **Pictet**, in his researches, effected the direct liquefaction of many gases, which up to that time had not been liquefied. He employed the apparatus used for the manufacture of ice on a large scale, employing the vaporisation of liquid sulphurous anhydride, which may be liquefied by pressure alone. This anhydride is a gas which is transformed into a liquid at the ordinary temperature under a pressure of several atmospheres (see note 27), and boils at -10° at the ordinary atmospheric pressure. The liquid, like all others, boils at a lower temperature under a diminished pressure, and by continually pumping out the gas which comes off by means of a powerful air-pump its boiling-point falls as low as -75° . Consequently if, on the one hand, liquid sulphurous anhydride be forced into a vessel, and on the other hand the gas be pumped from the same vessel by powerful air-pumps, the temperature falls to -75° . If a second vessel is placed inside this one, then another gas may be easily liquefied in it at the low temperature

low temperature, and then allowed them to expand, either by directly decreasing the pressure or by allowing them to escape into the air, by which means the temperature fell still lower, and then, just as steam produced, if the latter is less than its critical temperature. Pictet in this manner easily liquefied carbonic anhydride, CO_2 (at -60° under a pressure of from four to six atmospheres). This gas is more refractory to liquefaction than sulphurous anhydride, but for this reason it gives on evaporating a still lower temperature than can be attained by the evaporation of sulphurous anhydride. A temperature of -80° may be obtained by the evaporation of liquid carbonic anhydride at a pressure of 760 mm., and in an atmosphere rarefied by a powerful pump the temperature falls to -140° . By employing such low temperatures it was possible, with the aid of pressure, to liquefy the majority of the other gases, but not hydrogen. It is evident that special pumps which are capable of rarefying gases are necessary to reduce the pressure in the chambers in which the sulphurous and carbonic anhydrides boil; and that, in order to recondense the resultant gases into liquids, special force pumps are required for pumping the liquid anhydrides into the refrigerating chamber. Thus, in Pictet's apparatus (fig. 25), the

FIG. 25.—General arrangement of the apparatus employed by Pictet for liquefying gases.

carbonic anhydride was liquefied by the aid of the pumps E A F, which compressed the gas (at a pressure of 4–6 atmospheres) and forced it into the tube K, vigorously cooled by being surrounded with boiling liquid sulphurous anhydride, which was condensed in the tube C by the pump B, and rarefied by the pump A. The liquefied carbonic anhydride flowed down the tube K into the tube H, in which it was subjected to a low pressure by the pump E, and thus gave a very low temperature of about -140° . The pump E carried off the vapour of the carbonic anhydride, and conducted it to the pump F, by which it was again liquefied. The carbonic anhydride thus made an entire circuit—that is, it passed from a rarefied vapour of small pressure and low temperature into a compressed and cooled gas, which was transformed into a liquid, which again vaporised and produced a low temperature.

Inside the wide inclined tube H, where the carbonic acid evaporated, was placed a

when rapidly rarefied³² deposits liquid water in the form of a fog, hydrogen in expanding forms a fog, thus indicating its passage into

second and narrow tube, M, containing hydrogen, which was generated in the vessel L by heating a mixture of sodium formate and caustic soda ($\text{CHO}_2\text{Na} + \text{NaHO} = \text{Na}_2\text{CO}_3 + \text{H}_2$). This vessel and the tube M were made of thick copper, and could withstand great pressures. They were, moreover, hermetically connected together and closed up. Thus the gas evolved had no outlet, accumulated in a limited space, and its pressure increased in proportion to the amount of it evolved. This pressure was recorded on a metallic manometer, R, attached to the end of the tube M. As the hydrogen in this tube was submitted to a very low temperature and a powerful pressure, all the necessary conditions were present for its liquefaction. When the temperature had fallen to -140° and the manometer R indicated a pressure of 600 atmospheres in the tube M, this pressure did not apparently rise with a further evolution of hydrogen in the vessel L. Pictet regarded this as an indication that the pressure of the vapour of the hydrogen had attained a maximum corresponding with -140° , and that consequently all the excess of the gas was condensed to a liquid. As a matter of fact Pictet could not possibly have obtained liquid hydrogen, for -140° was far too high a temperature, considering that the critical point of hydrogen lies at about -240° ; but he obtained oxygen, nitrogen, and many other gases in a liquid state, and this was a great novelty in those days.

³² At the same time (1879) as Pictet was working on the liquefaction of gases in Switzerland, **Cailletet**, in Paris, was occupied with the same subject, and his results, although not so convincing as Pictet's, still showed that the majority of gases, previously unliquefied, were capable of passing into a liquid state. Cailletet subjected gases to a pressure of several hundred atmospheres in narrow thick-walled glass tubes (fig. 26) and then cooled the compressed gas as far as possible by surrounding it with a freezing mixture; a cock was then rapidly opened for the outlet of mercury from the tube containing the gas, which consequently rapidly and vigorously expanded. This rapid expansion of the gas would produce great cold, just as the rapid compression of a gas evolves heat and causes a rise in temperature. This cold was produced at the expense of the gas itself, for in rapidly expanding its particles were not able to absorb heat from the walls of the tube, and in cooling a portion of the expanding gas was transformed into liquid. This was seen from the formation of cloud-like drops like a fog which rendered the gas opaque. Thus Cailletet proved the possibility of the liquefaction of gases, but he did not isolate the liquids.

The methods of Pictet and Cailletet were afterwards improved by Olszewski, Wroblewski, Dewar, and others. In order to obtain a still lower temperature they employed, instead of carbonic acid gas, liquid ethylene (C_2H_4) or nitrogen and oxygen, whose evaporation at low pressures produces a much lower temperature (as low as -200°). They also improved on the methods of determining such low temperatures without, however, essentially altering the principle.

The most instructive results have been obtained in recent years by Professor Dewar in the Royal Institution of London, which is glorified by the names of Davy, Faraday, and Tyndall. Dewar, by working with large quantities and powerful pumps, obtained many kilograms of oxygen and air (the boiling-point under the atmospheric pressure = -190°) in a liquid state, and kept them in this state for a length of time by means of open glass vessels (constructed as seen in the drawing)

FIG. 26.—Cailletet's apparatus for liquefying gases.

a liquid state. But the first of these experimenters was unable to preserve this liquid, even for a short time, to determine its properties,

with double walls (silvered inside to reflect the rays of heat) having a vacuum between them, which prevented the rapid transference of heat, and so gave the possibility of

FIG. 27.—Dewar's vacuum-jacketed vessel for liquefied gases.

maintaining very low temperatures inside the vessel for a long period of time. The liquefied oxygen or air can be poured from one vessel into another and used for any investigations. Thus, in June 1894, Professor Dewar showed that at the low temperature produced by liquid oxygen many substances become phosphorescent (self-luminous; for instance, oxygen on passing into a vacuum) and fluoresce (emit light after being illuminated; for instance, paraffin, glue, &c.) much more powerfully than at the ordinary temperature; also that solids then greatly alter in their mechanical properties, &c. The liquid gas poured into the above vessel only remains as such at the ordinary temperature, because it preserves its own low temperature (with air, for instance, this is -191° under the corresponding pressure) and does not evaporate to any extent, because that would require the absorption of heat (so-called latent) which penetrates with difficulty

and but slowly through the double walls, just as the heat of a warm room passes with difficulty through a double window. It was the employment of such vessels with double (and even treble) walls which enabled Dewar (1898) not only to obtain liquid hydrogen

FIG. 28.—Dewar's apparatus for liquefying hydrogen.

but to keep it as such for a sufficient length of time to determine its properties and even its transition into a solid state. A scheme of the apparatus, used by Dewar for this purpose, is given in the accompanying drawings. *A* is a metallic reservoir con-

notwithstanding the employment of a temperature of -200° and a pressure of 200 atmospheres,³³ although by these means the gases of the atmosphere may be easily liquefied. This is due to the fact that the absolute boiling-point of hydrogen lies lower than that of all other known gases, a fact which also depends on the extreme lightness of hydrogen.³⁴

taining hydrogen under a pressure of 180–200 atmospheres, *B* and *C* are double-walled vessels, with a vacuum between the walls, in which liquid carbonic anhydride and air are evaporated under a diminished pressure and cool the hydrogen passing through the spiral tube to -203° . In the third double-walled vessel, *D*, the refrigerated and liquefied hydrogen expands on opening the cock *F*, which causes its temperature to fall yet further, and it is then obtained as a colourless liquid whose chief properties are given in the text.

³³ The investigations of S. Wroblewski in Cracow clearly show that Pictet could not have obtained liquid hydrogen in the interior of his apparatus, and that if he did obtain it, it could only have been at the moment of its exit due to the fall in temperature following its sudden expansion, as hydrogen is not liquefied by any pressure at -140° because its critical temperature (absolute boiling-point) lies much lower—at about -240° . However, on expansion a fog is formed and a liquid state attained, but the liquid does not separate.

³⁴ After the idea of the absolute temperature of ebullition (*tc*, note 29) had been worked out (about 1870), and its connection with the deviations from Mariotte's law had become evident, and especially after the liquefaction of permanent gases, general attention was turned to the development of the fundamental conceptions of the gaseous and liquid states of matter. Some investigators directed their energies to the further study of vapours (for instance, Ramsay and Young), gases (Amagat), and liquids (Zaencheffsky, Nadeschdin, and others), especially to liquids near the critical temperature and pressure; others (Konovaloff and De Heen) endeavoured to discover the relation between liquids under ordinary conditions (far removed from the critical temperature and pressure) and gases; whilst a third class of investigators (van der Waals, Clausius, and others), starting from the generally accepted principles of the mechanical theory of heat and the kinetic theory of gases, and assuming in gases the existence of those forces which certainly act in liquids, deduced the connection between the properties of one and the other. It would be out of place in an elementary handbook (see Physical Chemistry) like the present to enunciate the whole mass of conclusions arrived at by this method; but it is well to give an idea of the results of van der Waals's considerations, for they explain the gradual uninterrupted passage from a liquid into a gaseous state in the simplest manner, and, although the deduction cannot be considered as complete and decisive (see note 25), nevertheless it penetrates so deeply into the essence of the matter that its signification is not only reflected in a great number of physical investigations, but also in the province of chemistry, where instances of the passage of substances from a gaseous to a liquid state (and conversely) are so common, and where the very processes of dissociation, decomposition, and combination must be identified with a change of physical state of the participating substances, which has been elaborated by Gibbs, Liveing, and others.

For a *given quantity* (weight, mass) of a *definite substance*, its state is expressed by three variables—volume *v*, pressure (elasticity, tension) *p*, and temperature *t*.

FIG. 29.—Dewar's apparatus for solidifying hydrogen. The inner vacuum vessel, *B*, contains liquid hydrogen, and the outer one liquid air. By pumping gas out of both of these vessels, the temperature of the hydrogen falls to -256° , when it solidifies.

Dewar, who obtained and investigated liquid hydrogen in 1898, showed that the critical temperature of this gas lies at about -240° ,

Although the compressibility—[i.e., $d(v)/d(p)$ —of liquids is small, still it is clearly expressed, and varies not only with the nature of the liquids, but also with their pressure and temperature (the compressibility of liquids at a low temperature is very considerable; for instance, for hydrogen 0.024, nitrogen 0.0056, and oxygen 0.0046). Although, according to Mariotte's law, with small variations of pressure, gases are uniformly compressed, nevertheless the dependence of their volume v on t and p is very complex. This also applies to the coefficient of expansion [$=d(v)/d(t)$, or $d(p)/d(t)$], which also varies with t and p , both for gases (see note 26) and for liquids (at tc it is very considerable, and often exceeds that of gases, 0.00367). Hence, the **equation of condition** must include three variables, v , p , and t . For a so-called perfect (ideal) gas or for inconsiderable variations of density, the elementary expression, $pv = R(273 + t)$ should be accepted, where R is a constant varying with the mass and nature of a gas. In its simplest form the equation may be expressed thus:

$$pv = RT :$$

where T denotes what is termed the absolute temperature, or the ordinary temperature $+273$, that is, $T = t + 273$.

Starting from the supposition of the existence of an attraction or internal pressure (expressed by a) proportional to the square of the density (or inversely proportional to the square of the volume) and of the existence of a real volume or diminished length of path (expressed by b) for each gaseous molecule, **van der Waals** gives for gases the following complex **equation** of condition:—

$$\left(p + \frac{a}{v^2}\right)(v - b) = 1 + 0.00367t,$$

if at 0° and under a pressure $p = 1$ (for example, under the atmospheric pressure), the volume (for instance, a litre) of a gas or vapour be taken as 1, and v and b be therefore expressed by the same units as p and a . The above equation **expresses the deviations** from the laws both of Mariotte and Gay-Lussac. Thus, for hydrogen a must be taken as infinitely small, and $b = 0.0009$, judging by the data for 1,000 and 2,500 metres pressure (note 28). For other permanent gases these deviations may be expressed by giving definite magnitudes of a and b (although van der Waals's formula is not applicable in the case of very small pressures) with sufficient accuracy for present requirements. It is evident that van der Waals's equation can also express the variation of the coefficients of expansion of gases with change either of pressure or of the method of determination (note 26). Besides this, van der Waals's formula shows that the absolute boiling-point $(tc) = 273 \left(\frac{8a}{27b} - 1 \right)$. This is found from the fact that all three possible volumes (the three roots of van der Waals's cubic equation) are then similar and equal, i.e. $(vc) = 3b$. The pressure in this case is given by $(pc) = \frac{a}{27b^2}$. These ratios between the constants a and b and the conditions of the critical state, i.e. (tc) and (pc) , give the possibility of determining one pair of these magnitudes from the others. Thus for ether (note 29), $(tc) = 193^{\circ}$, $(tp) = 40$; hence $a = 0.0307$, $b = 0.00533$, and $(vc) = 0.016$. That mass of ether which at a pressure of one atmosphere at 0° occupies one volume—for instance, a litre—occupies, according to the above-mentioned condition, this critical volume. And as the density of the vapour of ether compared with that of hydrogen is 37, and a litre of hydrogen at 0° and under the atmospheric pressure weighs 0.0896 gram, then a litre of ether vapour weighs 3.32 grams; therefore in a critical state (at 193° and 40 atmospheres) 3.32 grams occupy 0.016 litre, or 16 c.c.; so that 1 gram occupies a volume of about 5 c.c., and the weight of 1 c.c. of ether will then be 0.21. According to the investigations of Ramsay and Young (1887), the critical volume of ether is approximately such at about the absolute boiling-point; but the compressibility of the liquid is so great that the slightest change of pressure or temperature has a considerable effect on the volume.

i.e., at a temperature difficult to attain even by evaporating other liquefied gases under diminished pressure. Dewar succeeded in liquefying hydrogen by cooling it to -220° (which he obtained in liquid oxygen under diminished pressure) under a pressure of 200 atmospheres, and then making it expand rapidly (by letting it flow from an orifice in the vessel holding it) when its temperature fell to -252° , at which temperature liquid hydrogen boils under the ordinary pressure (about 760 mm.) Liquid hydrogen then occurs as a colourless liquid, a litre of which weighs about 0.086 gram at its melting-point, -256° (it is thus the lightest liquid known), and which freezes (on lowering the

But the investigations of the above savants gave another indirect demonstration of the truth of van der Waals's equation. They also found for ether that the isochords, or the lines of equal volumes (if both t and p vary), are generally straight lines, which is a direct result of van der Waals's formula.

When, in 1883, I demonstrated that the specific gravity of liquids decreases *approximately* in proportion to the rise of temperature [$S = S_0 - Kt$ or $S_t = S_0 (1 - kt)$], where k is the modulus of expansion, which varies with the nature of the liquid, then, in general, not only does a connection arise between gases and liquids with respect to a change of volume, but also it would appear possible, by applying van der Waals's formula, to judge, from the phenomena of the expansion of liquids, as to their transition into vapour, and to connect together all the principal properties of liquids, which up to this time had not been considered to be in direct dependence. Thus Thorpe and Rücker found that $2(tc) + 273 = 1/k$, where k is the *modulus* of expansion in the above-mentioned formula. For example, the expansion of ether is expressed with sufficient accuracy from 0° to 100° by the equation: $S_t = 0.736 (1 - 0.00154t)$, or $V_t = 1/(1 - 0.00154t)$, where 0.00154 is the modulus of expansion, so that $(tc) = 188^{\circ}$, direct observation giving 194° . For silicon tetrachloride, SiCl_4 , the modulus equals 0.00136, whence $(tc) = 231^{\circ}$, the experimental value being 230° . On the other hand, D. P. Konovaloff, admitting that the external pressure, p , in liquids is insignificant when compared with the internal (a in van der Waals's formula), and that the work in the expansion of liquids is proportional to their temperature (as in gases), deduced directly from van der Waals's equation, the above-mentioned formula for the expansion of liquids, and also the magnitudes of the latent heat of evaporation, of the cohesion, and of the compressibility. In this way van der Waals's formula embraces the gaseous, critical, and **liquid states** of substances, and shows the connection between them. On this account, although van der Waals's formula cannot be considered as perfectly general and accurate, yet it is not only very much more exact than $pv = RT$, but it is also more comprehensive, because it applies both to gases and liquids. Further research will naturally give a closer proximity to truth, and will show the connection between composition and the constants (a and b); but this form of the equation of state marks great scientific progress.

Clausius (in 1880), taking into consideration the variability of a in van der Waals's formula with the temperature, gave the following equation of condition:—

$$\left(p + \frac{a}{T(v+c)^2}\right)(v-b) = RT.$$

Sarrau (1882) applied this formula to Amagat's data for hydrogen, and found $a = 0.0551$, $c = -0.00043$, $b = 0.00089$, and therefore calculated its absolute boiling-point to be -174° , and $(pc) = 99$ atmospheres. But as similar calculations for oxygen (-105°), nitrogen (-124°), and marsh gas (-76°) gave tc higher than it really is, the absolute boiling-point of hydrogen must lie below -174° , and as a matter of fact it is about -240° . Further details on the subjects here touched upon must be sought in physical chemistry.

pressure and temperature) into colourless crystals, melting at about -256° .

Although a substance which passes with great difficulty into a liquid or solid state by the action of physico-mechanical forces, hydrogen loses its gaseous state (that is, its elasticity, or the physical energy of its molecules, or their rapid progressive motion) with comparative ease under the influence of chemical attraction,³⁵ as is seen, not only from the fact that hydrogen and oxygen (two permanent gases) form liquid water, but also from many phenomena of the absorption of hydrogen.

Hydrogen is vigorously absorbed by certain solids; for example, by charcoal and by spongy platinum. If a piece of freshly ignited charcoal be introduced into a cylinder full of hydrogen standing in a mercury bath, the charcoal will absorb as much as twice its volume of hydrogen. Spongy platinum condenses still more hydrogen. But **palladium**, a grey metal which is found with platinum, **absorbs** more **hydrogen** than any other metal. Graham showed that, when heated to a red heat and cooled in an atmosphere of hydrogen, palladium retains as much as 600 volumes of the gas. When once absorbed, the hydrogen is retained at the ordinary temperature, and is only given up at a red heat.³⁶ This capacity of certain metals for the absorption of hydrogen explains the property of hydrogen of passing through metallic tubes made, for instance, of iron or platinum.³⁷ This property is termed

³⁵ This and a number of similar cases clearly show how great are internal chemical forces compared with physical and mechanical forces.

³⁶ The property of palladium of absorbing hydrogen, and of increasing in volume in so doing, may be easily demonstrated by taking a sheet of palladium, varnished on one side, and using it as a cathode. The hydrogen which is evolved by the action of the current is retained by the unvarnished surface, as a consequence of which the sheet curls up. By attaching a pointer (for instance, a quill) to the end of the sheet, this bending effect is rendered strikingly evident, and on reversing the current (when oxygen will be evolved and will combine with the absorbed hydrogen, forming water) it may be shown that on losing the hydrogen the palladium regains its original form.

³⁷ Deville discovered that iron and platinum become pervious to hydrogen at a red heat. He speaks of this in the following terms:—‘The permeability of such homogeneous substances as platinum and iron is quite different from the passage of gases through such non-compact substances as clay and graphite. The permeability of metals depends on their expansion, brought about by heat, and proves that metals and alloys have a certain porosity.’ However, Graham proved that it is only hydrogen which is capable of passing through the above-named metals in this manner. Oxygen, nitrogen, ammonia, and many other gases only pass through in extremely minute quantities. Graham showed that at a red heat about 500 c.c. of hydrogen per minute pass through a surface of one square metre of platinum 1.1 mm. thick, but that with other gases the amount transmitted is hardly perceptible. Indiarubber has the same capacity for allowing the transference of hydrogen through its substance (see Chapter III.), and at the ordinary temperature one square metre, 0.014 mm. thick, transmits about 127 c.c. of hydrogen per minute. In the experiment on the decomposition of water by heat in porous tubes the clay tube may be exchanged for a platinum one with advantage. Graham showed that by placing a platinum tube containing hydrogen under these conditions, and surrounding

occlusion, and is very similar to solution: it is based on the capacity of metals of forming with hydrogen unstable, easily dissociating compounds,³⁸ similar to those which salts form with water. Some of these direct compounds of hydrogen with metals have been isolated by Winkler, Moissan, and others (see Chaps. XII., XIV. &c.).

At the ordinary temperature hydrogen enters very rarely and feebly into chemical reaction. The capacity of gaseous **hydrogen** for reaction becomes evident only under a change of circumstances—by compression, heating, or the action of light, or at the moment of its evolution. However, even under these circumstances it **combines** directly with only a very few of the elements. Hydrogen combines directly with oxygen, sulphur, fluorine, carbon, potassium, and certain other elements, but not with the majority of the metals, nor with nitrogen, phosphorus, &c. Compounds of hydrogen with certain elements on which it does not act directly are, however, known, and are obtained by reactions of decomposition, or of double decomposition, of other hydrogen compounds. The property possessed by hydrogen of combining with oxygen at a red heat determines its combustibility. We have already seen that hydrogen easily takes fire, and that it then burns with a pale—that is, non-luminous—flame.³⁹ Hydrogen does not combine with the oxygen of the atmosphere at the ordinary temperature; but this combination takes place at a red heat,⁴⁰ and is accompanied by the evolution of

it by a tube containing air, the transference of the hydrogen may be observed by the decrease of pressure in the platinum tube. In one hour almost all the hydrogen (97 per cent.) had passed from the tube, without being replaced by air. It is evident that the occlusion and passage of hydrogen through metals capable of occluding it are not only intimately connected together, but are dependent on the capacity of metals to form compounds of various degrees of stability with hydrogen-like solutions.

³⁸ It appeared on further investigation that palladium gives a definite compound, Pd_2H (see Chapter XXIII.), with hydrogen; but what was most instructive was the investigation of sodium hydride, Na_2H .

Molten iron absorbs hydrogen, but in solidifying it expels it. The solution of hydrogen by metals is to a certain degree based on its affinity for metals, and must be likened to the solution of metals in mercury and to the formation of alloys. In its chemical properties hydrogen, as we shall see later, has much of a metallic character. The metallic properties of hydrogen are also evinced in the fact that it is a good conductor of heat, which is not the case with other gases (Magnus).

³⁹ If it be desired to obtain a perfectly colourless hydrogen flame, the gas must issue from a platinum nozzle, as the glass end of a gas-conducting tube imparts a yellow tint to the flame, owing to the presence of sodium in the glass.

⁴⁰ Let us imagine that a stream of hydrogen passes along a tube, and let us mentally divide this stream into several parts, consecutively passing out from the orifice of the tube. The first part is lighted—that is, brought to a state of incandescence, in which state it combines with the oxygen of the atmosphere. A considerable amount of heat is evolved in the combination. The heat evolved then ignites the second part of hydrogen coming from the tube, and, therefore, when once ignited, the hydrogen continues to burn, if there is a continual supply of it, and if the atmosphere in which it burns is unlimited and contains oxygen.

much heat. The product of this combination is water—that is, a compound of oxygen and hydrogen. This is the **synthesis of water**, and we have already noticed its analysis or decomposition into its component parts. The synthesis of water may be very easily observed if a cold glass bell jar be placed over a burning hydrogen flame, or, better still, if the hydrogen flame be lighted in the tube of a condenser. The water will condense in drops, as it is formed, on the walls of the condenser and trickle down.⁴¹

Light does not aid the combination of hydrogen and oxygen, so that a mixture of these two gases does not change when exposed to the action of light; but an electric spark acts just like a flame, and this is taken advantage of for inflaming a mixture of oxygen and hydrogen, or detonating gas, inside a vessel, as will be explained in the following chapters. As hydrogen (and oxygen also) is condensed by spongy platinum, with rise of temperature, and as platinum acts by contact (Introduction), therefore hydrogen also combines with oxygen, under the influence of platinum, as was shown by Döbereiner. If spongy platinum is thrown into a mixture of hydrogen and oxygen, an explosion takes place; and if a mixture of the gases be passed over spongy platinum, combination will also ensue, and the platinum become red-hot.⁴² Hydrogen exhibits

⁴¹ The combustibility of hydrogen may be shown by the direct decomposition of water by sodium. If a pellet of sodium is thrown into a vessel containing water, it floats on the water and evolves hydrogen, which may be lighted. The presence of sodium imparts a yellow tint to the flame. If potassium be taken, the hydrogen bursts into flame spontaneously, because sufficient heat is evolved in the reaction to ignite the hydrogen. The flame is coloured violet by the potassium. If sodium be thrown, not on to water, but on to an acid, it will evolve more heat, and the hydrogen will then also burst into flame. These experiments must be carried on with caution, as, sometimes towards the end, a mass of sodium oxide (note 8) is produced, and flies about. It is therefore best to cover the vessel in which the experiment is carried on.

⁴² This property of spongy platinum is made use of in the so-called hydrogen cigar-lighter. It consists of a glass cylinder or beaker, inside which there is a small lead stand (which is not acted on by sulphuric acid), on which a piece of zinc is laid. This zinc is covered by a bell, which is open at the bottom and furnished with a cock at the top. Sulphuric acid is poured into the space between the bell and the sides of the outer glass cylinder, and will thus compress the gas in the bell. If the cock of the cylinder be opened the gas will escape by it, and will be replaced by the acid, which, coming into contact with the zinc, evolves hydrogen, and this will escape through the cock. If the cock be closed, then the hydrogen evolved will increase the pressure of the gas in the bell, and thus again force the acid into the space between the bell and the walls of the outer cylinder. Thus the action of the acid on the zinc may be stopped or started at will by opening or shutting the cock, and consequently a stream of hydrogen may be turned on at any time. Now, if a piece of spongy platinum be placed in this stream, the hydrogen will take fire, because the spongy platinum becomes hot in condensing the hydrogen and inflames it. The considerable rise in temperature of the platinum depends, among other things, on the fact that the hydrogen condensed in its pores comes into contact with previously absorbed and condensed atmospheric oxygen, with which hydrogen combines with great facility in this form. In this manner the hydrogen cigar-lighter gives a stream of burning hydrogen when the cock is open. In order that it should work

its greatest affinity for direct reaction, with fluorine and chlorine, forming hydrofluoric, HF, and hydrochloric acids, HCl, which will be considered more fully in Chapter XI.

Although gaseous hydrogen does not act directly ⁴³ on many substances, yet in a **nascent state** reaction often takes place. Thus, for instance, water on which sodium amalgam is acting contains hydrogen in a nascent state. The hydrogen is here evolved from a liquid, and at the first moment of its formation must be in a condensed state.⁴⁴ In this condition it is capable of reacting on substances on which it does not act in a gaseous state. Reactions of substitution or **displacement of metals by hydrogen** at the moment of its formation are particularly numerous.⁴⁵

regularly it is necessary that the spongy platinum should be quite clean, and it is best enveloped in a thin sheet of platinum foil, which protects it from dust. In any case, after some time it will be necessary to clean the platinum, and this may be easily done by boiling it in nitric acid, which does not dissolve the platinum, but frees it from all dirt. This imperfection has given rise to several other forms, in which an electric spark is made to pass in front of the orifice from which the hydrogen escapes. This is arranged in such a manner that the zinc of a galvanic element is immersed when the cock is turned, or a small coil giving a spark is put into circuit on turning the hydrogen on.

⁴³ Under conditions similar to those in which hydrogen combines with oxygen it is also capable of combining with chlorine. A mixture of hydrogen and chlorine explodes on the passage of an electric spark through it, or on contact with an incandescent substance, or in the presence of spongy platinum; but, besides this, the action of light alone is enough to bring about the combination of hydrogen and chlorine. If a mixture of equal volumes of hydrogen and chlorine is exposed to the action of sunlight, complete combination rapidly ensues, accompanied by a report. Hydrogen does not combine directly with carbon, either at the ordinary temperature or under the action of heat and pressure. But if an electric current be passed through carbon electrodes at a short distance from each other (as in the electric light or voltaic arc), so as to form an electric arc in which the particles of carbon are carried from one pole to the other, then, in the intense heat to which the carbon is subjected in this case, it is capable of combining with hydrogen. A gas of peculiar smell called acetylene, C_2H_2 , is thus formed from carbon and hydrogen.

⁴⁴ There is another explanation of the facility with which hydrogen reacts in a nascent state. We shall afterwards learn that the molecule of hydrogen contains two atoms, H_2 , but there are elements the molecules of which contain only one atom—for instance, mercury. Therefore every reaction of gaseous hydrogen must be accompanied by the disruption of that bond which exists between the atoms forming a molecule. At the moment of evolution, however, it is supposed that free atoms exist, and in this condition, according to the hypothesis, act energetically. This hypothesis is not based upon facts, and the idea that hydrogen is condensed at the moment of its evolution is more natural, and is in accordance with the fact (note 12) that compressed hydrogen displaces palladium and silver (Brunner, Beketoff)—that is, acts as at the moment of its liberation. It is impossible at present to form any idea of the properties of the isolated atoms (ions) of hydrogen, for certain of the elements whose molecules contain one atom are chemically very active (for instance, Na) while others (such as argon) are perfectly inert.

⁴⁵ When, for instance, an acid and zinc are added to a salt of silver, the silver is reduced; but this may be explained as a reaction of the zinc, and not of the hydrogen at the moment of its formation. There are, however, examples to which this explanation is entirely inapplicable; thus, for instance, hydrogen, at the moment of its liberation,

Metals, as we shall afterwards see, are in many cases able to replace each other; they also, and in some cases still more easily, replace and are replaced by hydrogen. We have already seen examples of this in the formation of hydrogen from water, sulphuric acid, &c. In all these cases the metal sodium, iron, or zinc displaces the hydrogen which occurs in these compounds. Hydrogen may be displaced by metals from many of its compounds in exactly the same manner as it is displaced from water; thus, for example, hydrochloric acid, which is formed directly by the combination of hydrogen with chlorine, gives hydrogen by the action of a great many metals, just as sulphuric acid does. Potassium and sodium also displace hydrogen from its compounds with nitrogen; it is only from its compounds with carbon that hydrogen is not displaced by metals. Hydrogen, in its turn, is able to replace metals: this is accomplished most easily on heating, and with those metals which do not themselves displace hydrogen. If hydrogen be passed over the compounds of many metals with oxygen maintained at a red heat, it takes up the oxygen from the metals and displaces them just as it is itself displaced by metals. If hydrogen is passed over the compound of oxygen with copper at a red heat, then metallic copper and water are obtained— $\text{CuO} + \text{H}_2 = \text{H}_2\text{O} + \text{Cu}$. This kind of double decomposition is called **reduction**, with reference to the metal, which is thus reduced to a metallic state from its combination with oxygen. But it must be recollected that all metals do not displace hydrogen directly from its compound with oxygen; and, conversely, hydrogen is not able to displace all metals from their compounds with oxygen, &c.; thus it does not displace potassium, calcium, or aluminium from its compounds with oxygen. If the metals be arranged in the following series: K, Na, Ca, Al . . . Fe, Zn, H . . . Cu, Pb, Ag, Au, then the first are able to take up oxygen from water—that is, displace hydrogen—whilst the last do not act thus, but are, on the contrary, reduced by hydrogen—that is, have, as is said, a less affinity for oxygen than hydrogen, whilst potassium, sodium, and calcium have more. This is also expressed by the amount of heat evolved in the act of combination with oxygen (see note 7), and is shown by the fact that potassium and sodium and other similar metals evolve heat in decomposing water; but copper, easily takes up oxygen from its compounds with nitrogen if they be in solution, and converts the nitrogen into its hydrogen compound. Here the nitrogen and hydrogen, so to speak, meet at the moment of their liberation, and in this state combine.

It is evident from this that the elastic gaseous state of hydrogen fixes the limit of its energy and prevents it from entering into those combinations of which it is capable. In the nascent state we have hydrogen which is not in a gaseous state, and its action is then much more energetic. At the moment of evolution that heat which would be latent in the gaseous hydrogen is transmitted to its molecules, and consequently they are in a state of strain, and hence capable of acting on many substances.

silver, and the like do not do this, because in combining with oxygen they evolve less heat than hydrogen does, and therefore it happens that when hydrogen reduces these metals heat is evolved. Thus, for example, if 16 grams of oxygen combine with copper, 38,000 units of heat are evolved; and when 16 grams of oxygen combine with hydrogen, forming water, 69,000 units of heat are evolved; whilst 23 grams of sodium, in combining with 16 grams of oxygen, evolve 100,000 units of heat. This example clearly shows that chemical reactions which proceed directly and unaided evolve heat. Sodium decomposes water, and hydrogen reduces copper, because they are **exothermal** reactions, or such as evolve heat; copper does not decompose water, because such a reaction would be accompanied by an absorption (or secretion) of heat, or belongs to the class of **endothermal** reactions in which heat is absorbed; and such reactions do not generally proceed directly, although they may take place with the aid of energy (electrical, thermal, &c.) borrowed from some foreign source.⁴⁶

The reduction of metals by hydrogen is taken advantage of for **determining the composition of water by weight**. Copper oxide is usually chosen for this purpose. It is heated to redness in hydrogen, and the quantity of water thus formed is determined, while the quantity of oxygen which occurs in it is found from the loss of weight of the copper oxide. The copper oxide must be weighed immediately before and after the experiment. The difference shows the weight of the oxygen which entered into the composition of the water formed. In this manner only solids have to be weighed, which is a very great gain in the accuracy of the results obtained.⁴⁷ Dulong and Berzelius (1819) were the first to determine the composition of water by this method, and they found that water contains 88·91 parts of oxygen and 11·09 of hydrogen in 100 parts by weight, or 8·008 parts of oxygen per one part of hydrogen. Dumas (1842) improved on this method,⁴⁸ and found that

⁴⁶ Several numerical data and ideas bearing on this matter are given in notes 7, 9, and 11. It must be observed that the action of iron or zinc on water is reversible. But the reaction $\text{CuO} + \text{H}_2 = \text{Cu} + \text{H}_2\text{O}$ is not reversible; the difference between the degrees of affinity is very great in this case, and, therefore, so far as is at present known, no hydrogen is liberated even in the presence of a large excess of water. If definite amounts of a metal and acid be taken and their reaction be carried on in a closed space, the evolution of hydrogen will cease when its pressure equals that at which compressed hydrogen displaces the metal. The result depends upon the nature of the metal and the strength of the solution of acid. Tammann and Nernst (1892) found that the metals stand in the following order in respect to this limiting pressure of hydrogen:—Na, Mg, Zn, Al, Cd, Fe, Ni.

⁴⁷ This determination may be carried on in an apparatus like that mentioned in note 13 of Chapter I.

⁴⁸ We will proceed to describe Dumas's method and results. For this determination, pure and dry copper oxide is necessary. In each determination Dumas took a sufficient

water contains 12.575 parts of hydrogen per 100 parts of oxygen—that is, 7.990 parts of oxygen per 1 part of hydrogen—and it is therefore

FIG. 30.—Apparatus employed by Dumas for determining the composition of water. Described in text.

quantity of copper oxide for the formation of 50 grams of water. As the oxide of copper was weighed before and after the experiment, and as the amount of oxygen contained in water was determined by the difference between these weights, it was essential that no other substance besides the oxygen forming the water should be evolved from the oxide of copper during its ignition in hydrogen. It was necessary also that the hydrogen should be perfectly pure, and free not only from traces of moisture, but from any other impurities which might dissolve in the water or combine with the copper and form some other compound with it. The bulb containing the oxide of copper (fig. 30), which was heated to redness, should be quite free from air, as otherwise the oxygen in the air might, in combining with the hydrogen passing through the vessel, form water in addition to that formed by the oxygen of the oxide of copper. The water formed should be entirely absorbed in order to accurately determine its quantity. The hydrogen was evolved in a three-necked bottle. The sulphuric acid, for acting on the zinc, is poured through funnels into the middle neck. The hydrogen evolved in the Woulfe's bottle passes through U-tubes, in which it is purified, to the bulb, where it comes into contact with the incandescent copper oxide, forms water, and reduces the oxide to metallic

copper; the water formed is condensed in the second bulb, and any passing off is absorbed in the second set of U-tubes. This is the general arrangement of the apparatus. The loss in weight of the bulb containing the copper oxide shows the

accepted that *water contains eight parts by weight of oxygen to one part by weight of hydrogen*. And as the most exact determinations

quantity of oxygen which entered into the composition of the water formed, the weight of the latter being shown by the gain in weight of the absorbing apparatus. Knowing the amount of oxygen in the water formed, we also know the quantity of hydrogen contained in it, and consequently we can determine the composition of water by weight. This is the essence of the determination. We will now turn to certain details. In one neck of the three-necked bottle a tube is placed dipping under mercury. This serves as a safety-valve to prevent the pressure inside the apparatus becoming too great owing to the rapid evolution of hydrogen. If the pressure rose to any considerable extent, the current of gases and vapours would be very rapid, and, as a consequence, the hydrogen would not be perfectly purified nor the water entirely absorbed in the tubes placed for this purpose. In the third neck of the Woulfe's bottle is a tube conducting the hydrogen to the purifying apparatus, consisting of eight U-tubes, destined for the purification and testing of the hydrogen. The hydrogen, evolved from zinc and sulphuric acid, is purified by passing it first through a tube full of pieces of glass moistened with a solution of lead nitrate and then through silver sulphate; the lead nitrate retains sulphuretted hydrogen, while arseniuretted hydrogen is retained by the silver sulphate tube. Caustic potash in the next U-tube retains any acid which might come over. The two following tubes are filled with lumps of dry caustic potash in order to absorb any carbonic anhydride and moisture which the hydrogen might contain. The next two tubes, to remove the last traces of moisture, are filled with phosphoric anhydride, mixed with lumps of pumice-stone. They are immersed in a freezing mixture. The small U-tube contains hygroscopic substances, and is weighed before the experiment: it is used in order to ascertain whether the hydrogen passing through still retains any moisture. If it does not, then the weight of this tube will not vary during the whole experiment, but if the hydrogen evolved still retains moisture, the tube will increase in weight. The copper oxide is placed in the bulb, which, previous to the experiment, is dried with the copper oxide for a long time. The air is then exhausted from it in order to weigh the oxide of copper in a vacuum, and so avoid the need of a correction for weighing in air. The bulb is made of infusible glass, that it may be able to withstand a lengthy (20 hours) exposure to a red heat without changing in form. The weighed bulb is only connected with the purifying apparatus after the hydrogen has passed through for a long time, and after experiment has shown that the hydrogen passing from the purifying apparatus is pure and does not contain any air. The first U-tube contains pieces of ignited potash, and the second and third tubes, phosphoric anhydride or pumice-stone moistened with sulphuric acid. The last tube is employed for determining whether all the moisture is absorbed, and is therefore weighed separately. The glass cylinder contains sulphuric acid, through which the excess of hydrogen passes: it enables the rate at which the hydrogen is evolved to be seen, and shows whether its amount should be decreased or increased.

When the apparatus is fitted up it must be seen that all its parts are hermetically tight before commencing the experiment. When the previously weighed parts are connected together, and the whole apparatus put into communication, the bulb containing the copper oxide is heated with a spirit or other lamp, and the reduction of the copper oxide then takes place, and water is formed. When nearly all the copper oxide is reduced the lamp is removed and the apparatus allowed to cool, the current of hydrogen being kept up all the time. When cool, the drawn-out end of the bulb is fused up, and the hydrogen remaining in it exhausted, in order that the copper may be again weighed in a vacuum. The absorbing apparatus remains full of hydrogen, and would therefore present a less weight than if it were full of air, as it was before the experiment; and for this reason, having disconnected the copper oxide bulb, a current of dry air is passed through it until the gas passing from the glass cylinder is quite free from hydrogen. The condensing bulb and the two tubes next to it are then weighed in order to determine the quantity of water formed. Dumas repeated this experiment

of the composition of water in recent times (Keiser 1888, Morley 1895, Thomsen 1896, &c.) concur in showing that it contains not more than 7,945, and not less than 7,935 parts of oxygen per 1 part by weight of hydrogen, the mean of these, or 7,940 parts of oxygen per 1 part by weight of hydrogen, or, what is almost the same, 8 parts of oxygen per 1.0076 parts of hydrogen, is now adopted wherever great accuracy is required. This corresponds with 88.81 parts of oxygen and 11.19 parts of hydrogen per 100 parts of water; but as the approximate ratio 1 : 8 only differs from this in hundredth parts of 1 per cent. of the amounts of the elements, the composition of water may be approximately expressed by the above easily remembered ratio 1 : 8, or more correctly 1.008 : 8, which is adopted in this work and in most researches of the present day. By whatever method water be obtained, it will always present the same composition. Whether it be taken from nature and purified, or whether it be obtained from hydrogen by oxidation, or whether it be separated from any of its compounds, or obtained by some double decomposition, it will in every case contain 1 part by weight of hydrogen and about 8 parts of oxygen. This is because water is a definite chemical compound. Detonating gas, from which it may be formed, is a simple mixture of oxygen and hydrogen, although a mixture of the same composition as water. All the properties of both constituent gases are preserved in detonating gas. Either one or the other gas may be added to it without destroying its homogeneity. The fundamental properties of oxygen and hydrogen are not found in water, and neither of the gases can be directly combined with it. But they may be evolved from it. In the formation of water there is an evolution of heat; for the decomposition of water heat is required. All this is expressed by saying that *water is a definite chemical compound of hydrogen with oxygen*. Taking the symbol of hydrogen, H, as expressing many times. The average result was that water contains 1253.3 parts of hydrogen per 10,000 parts of oxygen. Making a correction for the amount of air contained in the sulphuric acid employed for producing the hydrogen, Dumas obtained the average figure 1251.5, the extreme values being 1247.2 and 1256.2. This proves that per 1 part of hydrogen, water contains 7.9904 parts of oxygen, with an error of not more than $\frac{1}{250}$, or 0.03, in the amount of oxygen per 1 part of hydrogen.

Erdmann and Marchand, in eight determinations, found that, per 10,000 parts of oxygen, water contains an average of 1,252 parts of hydrogen, the separate values ranging from 1258.5 to 1248.7; hence for 1 part of hydrogen there would be 7.9952 of oxygen, with an error of at most 0.05.

Keiser (1888), in America, by employing palladium hydride, and by introducing various fresh precautions for obtaining accurate results, found the composition of water to be 15.95 parts of oxygen per 2 of hydrogen.

The latest determinations of the composition of water, as also those made by Dumas, always give less than 8, and on the average from 7.93 to 7.95 of oxygen per 1 part of hydrogen, as has been mentioned in the text, and the final mean may be taken as 7.936, with a possible error of not more than 1 in the last decimal figure.

ing a unit quantity (or more exactly 1.008) by weight of this substance, and expressing 16 parts by weight of oxygen by O, we can formulate all the above statements by the chemical symbol of water, H_2O . As only definite chemical compounds are denoted by formulæ, having indicated the formula of a compound substance we express by it the entire series of properties which go to make up our conception of a definite compound, and at the same time the quantitative composition of the substance by weight. Further, as we shall see later, formulæ express the volume of the gases contained in a substance. Thus the formula of water shows that it contains two volumes of hydrogen and one volume of oxygen. Besides which, we shall find that the formula expresses the density of the vapour of a compound, and on this many properties of substances depend, and, as we shall learn, determine the quantities of the bodies entering into reactions. This vapour density we shall see determines also the quantity of a substance entering into a reaction. Thus the letters H_2O tell the chemist the entire history of the substance. This is an international language, which endows chemistry with a simplicity, clearness, stability, and trustworthiness founded on the investigation of the laws of nature.

CHAPTER III

OXYGEN AND THE CHIEF ASPECTS OF ITS SALINE COMBINATIONS

ON the earth's surface there is no other element which is so widely distributed as is oxygen in its various compounds.¹ It constitutes eight-ninths of the weight of water, which occupies the greater part of the earth's surface. Nearly all earthy substances and rocks consist of compounds of oxygen with metals and other elements. Thus, the greater part of sand is formed of silica, SiO_2 , which contains 53 per cent. of oxygen ; while clay and the earthy substances and rocks contain about 40 per cent. by weight of oxygen ; animal and vegetable substances are also very rich in oxygen. Without counting the water present in them, plants contain up to 40, and animals up to 20, per cent. by weight of oxygen. Thus, oxygen compounds predominate on the earth's surface. Besides this, a portion exists in a free state, and is contained in admixture with nitrogen in the atmosphere, forming about one-fourth of its mass, or one-fifth of its volume.

Being so widely distributed in nature, oxygen plays a very important part in it, for a number of the phenomena which take place around us are mainly dependent on it. **Animals breathe** air in order to obtain from it only the **oxygen**, which enters their respiratory organs (the lungs of human beings and animals, the gills of fishes, and the tracheæ of insects) ; they, so to say, drink in air in order to absorb the oxygen. The oxygen contained in the air (or dissolved in water) passes through the membranes of the respiratory organs into the blood, is retained in it by the blood corpuscles, is transmitted by their means to all parts of the body, aids their transformations, bringing about chemical processes in them, and extracting from them chiefly carbon, in the form of carbonic anhydride, the greater part of which passes into the blood, is dissolved by it, and is thrown off by the lungs during the absorption of the oxygen. Thus, in the process of respiration,

¹ As regards the interior of the earth, it probably contains far less oxygen compounds than the surface, judging by the accumulated evidences of the earth's origin, of meteorites, of the earth's density, &c. (see Chapter VIII., note 58, and Chapter XXII., note 2).

carbonic anhydride (and water) is given off and the oxygen of the air absorbed, by which means the blood is changed from the red venous to the dark-red arterial form. The cessation of this process causes death, because then all these chemical processes, and the consequent heat and work which the oxygen introduced into the system gives rise to, cease. For this reason suffocation and death ensue in a vacuum, or in a gas which does not contain free oxygen, i.e., which does not support combustion. If an animal is placed in an atmosphere of free oxygen, at first its movements are very active and a general invigoration is remarked, but a reaction soon sets in, and death may ensue. The oxygen of the air when it enters the lungs is diluted with four volumes of nitrogen, which is not absorbed into the system, so that the blood absorbs but a small quantity of oxygen from the air, whilst in an atmosphere of pure oxygen a large quantity of oxygen would be absorbed, and would produce a very rapid change of all parts of the organism, and destroy it. From what has been said, it will be understood that pure oxygen gas may be employed in respiration, at any rate for a limited time. When the respiratory organs suffer under certain forms of suffocation and impediment to breathing, pure oxygen is frequently had recourse to.²

The combustion of organic substances—that is, substances which make up the composition of plants and animals—proceeds in the same manner as the combustion of many inorganic substances, such as sulphur, phosphorus, iron, &c., from the combination of these substances with oxygen, as was described in the Introduction. The decomposition, rotting, and similar transformations of substances, which proceed around us, are also very often dependent on the action of the oxygen of the air, and reduce this gas from a free to a combined state. The majority of the compounds of oxygen are, like water, very stable, and

² It is evident that the partial pressure (see Chapter I.) acts in respiration. The researches of Paul Bert showed this with particular clearness. Under a pressure of one-fifth of an atmosphere, consisting of oxygen only, animals and human beings remain under the ordinary conditions of the partial pressure of oxygen, but organisms cannot support air rarefied to one-fifth, for then the partial pressure of the oxygen falls to one-twenty-fifth of an atmosphere. Even under a pressure of one-third of an atmosphere the regular life of human beings is impossible, because of the impossibility of respiration (owing to the decrease of solubility of oxygen in the blood), on account of the small partial pressure of the oxygen, and not from any mechanical effect of the decrease of pressure. Paul Bert illustrated all this by many experiments, some of which he conducted on himself. This explains, among other things, the discomfort felt in the ascent of high mountains or in balloons, when the height reached exceeds eight kilometres, and at pressures below 250 mm. It is evident that an artificial atmosphere has to be employed in the ascent to great heights, just as in submarine work. The cure by compressed and rarefied air which is practised in certain illnesses is based partly on the mechanical action of the change of pressure and partly on the alteration in the partial pressure of the respired oxygen.

do not give up their oxygen under the ordinary conditions of nature. As the above-mentioned influences are at work everywhere, it might be expected that the amount of free oxygen in the atmosphere should decrease, and that this decrease should proceed somewhat rapidly. This is, in fact, observed where combustion or respiration proceeds in a closed space. Animals suffocate in a closed space because in consuming the oxygen the air remains unfit for respiration. In the same manner combustion, after a time, ceases in a closed space, as may be proved by a very simple experiment. An ignited substance—for instance, a piece of burning sulphur—has only to be placed in a glass flask, which is then closed with a stout cork to prevent the access of the external air; combustion will proceed for a certain time, so long as the flask contains any free oxygen, but it will cease when the oxygen of the enclosed air has entirely combined with the sulphur. From what has been said, it is evident that regularity of combustion or respiration requires a constant renewal of air—that is, that the burning substance or respiring animal should have access to a fresh supply of oxygen. This is attained in dwellings by having many windows, outlets, and ventilators, and by the current of air produced by fires and stoves. As regards the air over the entire earth's surface its proportion of oxygen hardly decreases at all, because in nature there is a process going on which renews the supply of free oxygen. **Plants**, or rather their leaves, during the daytime,³ under the influence of light, absorb carbonic anhydride, CO_2 , and **evolve free oxygen**. Thus the loss of oxygen which occurs in consequence of the respiration of animals and of combustion is made good by plants. If a leaf be placed in a bell jar containing water, and carbonic anhydride (because this gas is absorbed and oxygen evolved from it by plants) be passed into the bell, and the whole apparatus placed in sunlight, then oxygen will accumulate in the bell jar. This experiment was first made by Priestley at the end of the last century. Thus the life of plants on the earth not only serves for the formation of food for animals, but also for keeping up a constant percentage of oxygen in the atmosphere. In the long period of the life of the earth an equilibrium has been attained between the processes absorbing and evolving oxygen, by which a definite quantity of free oxygen is preserved in the entire mass of the atmosphere.⁴

³ At night, without the action of light, without the absorption of that energy which is required for the decomposition of carbonic anhydride into free oxygen and carbon (which is retained by the plants), they breathe like animals, absorbing oxygen and evolving carbonic anhydride. This process also goes on side by side with the reverse process in the daytime, but it is then far feebler than that which gives oxygen.

⁴ The earth's surface has an area of about 510 million square kilometres, and the mass of the air (at a pressure of 760 mm.) on each kilometre of surface is about $10\frac{1}{3}$ thousand

Oxygen was obtained as an independent gas in 1774 by Priestley in England and in the same year by Scheele in Sweden, but its nature and great importance were only perfectly elucidated by Lavoisier.

Free oxygen may be obtained by one or another method from all the substances in which it occurs. Thus, for instance, the oxygen of many substances may be transferred into water, from which, as we have already seen, oxygen may be obtained.⁵ We will first consider the methods of extracting oxygen from air as being a substance everywhere distributed. The separation of oxygen from it is, however, hampered by many difficulties.

From air, which consists of a *mixture* of oxygen and nitrogen, the nitrogen alone cannot be removed, because it has no inclination to combine directly or readily with any substance; and although it does combine with certain substances (boron, magnesium, titanium), these substances combine simultaneously with the oxygen of the atmosphere.⁶

millions of kilograms, or about $10\frac{1}{2}$ million tons; therefore the whole weight of the atmosphere is about 5,100 million million ($= 51 \times 10^{14}$) tons. Consequently there are about 2×10^{15} tons of free oxygen in the earth's atmosphere. The innumerable series of processes which absorb a portion of this oxygen are compensated for by the plant processes. Assuming that 100 million tons of vegetable matter, containing 40 per cent. of carbon, formed from carbonic acid, are produced (and the same process proceeds in water) per year on the 100 million square kilometres of dry land (ten tons of roots, leaves, stems, &c., per hectare, or $\frac{1}{100}$ of a square kilometre), we find that the plant life of the dry land gives about 100,000 tons of oxygen, which is an insignificant fraction of the entire mass of the oxygen of the air.

⁵ The extraction of oxygen from water may be effected by two processes: either by the decomposition of water into its constituent parts by the action of a galvanic current (Chapter II.), or by means of the removal of the hydrogen from water. But, as we have seen and already know, hydrogen enters into direct combination with very few substances, and then only under special circumstances; whilst oxygen, as we shall soon learn, combines with a great many substances. Only gaseous chlorine (and, more especially, fluorine) is capable of decomposing water, taking up the hydrogen from it, without combining with the oxygen. Chlorine is soluble in water, and if an aqueous solution of chlorine, so-called chlorine water, be poured into a flask, and this be inverted in a basin containing the same chlorine water, we shall then have an apparatus by means of which oxygen may be extracted from water. At the ordinary temperature, and in the dark, chlorine does not act on water, or only acts very feebly; but under the action of direct sunlight chlorine decomposes water, with the evolution of oxygen. The chlorine then combines with the hydrogen, and gives hydrochloric acid, which dissolves in the water, and therefore free oxygen will be separated from the liquid, together with a small quantity of chlorine in admixture, which can be easily removed by passing the gas through a solution of caustic potash.

⁶ Differences in the physical properties of the two gases cannot be here taken advantage of, because they are very similar in these properties. Thus the density of oxygen is 16 times and that of nitrogen 14 times greater than the density of hydrogen, so that porous vessels cannot be employed, the difference between the times of their passage through a porous surface being too insignificant.

Graham, however, succeeded in enriching air in oxygen by passing it through india-rubber. This may be done in the following way:—A common indiarubber cushion, E (fig. 31), is taken, and its orifice hermetically connected with an air-pump, or, better

However, oxygen may be separated from air by causing it to combine with substances which may be easily decomposed by the action of heat,

still, a mercury aspirator (the Sprengel pump, designated by the letters A, C, B). When the aspirator (Chapter II., note 16) has pumped out the air, which will be seen by the mercury running out in an almost uninterrupted stream and by its standing approximately at the barometric height, then it may be clearly observed that gas passes through the

FIG. 31.—Graham's apparatus for the decomposition of air by pumping it through indiarubber.

indiarubber. This is also seen from the fact that bubbles of gas continually pass along with the mercury. A minus pressure may be constantly maintained in the cushion by pouring mercury into the funnel A, and screwing up the pinchcock C, so that the stream flowing from it is small, and then a portion of the air passing through the indiarubber will be carried down with the mercury. This air may be collected in the cylinder R. Its composition is found to be about 42 volumes of oxygen, 57 volumes of nitrogen, and 1 volume of carbonic anhydride, whilst ordinary air contains only 21 volumes of oxygen in 100 volumes. A square metre of indiarubber surface (of the ordinary thickness) passes about 45 c.c. of such air per hour. Such an experiment clearly shows that indiarubber is permeable to gases. This may, by the way, be observed in common toy balloons filled with coal-gas. They fall after a day or two, not because there are holes in them, but because air penetrates into, and the gas from, their interior, through the surface of the indiarubber of which they are made. As was shown by Mitchell and Graham, the rate of the passage of gases through indiarubber does not depend on their densities, and consequently its permeability

is not determined by orifices. It more resembles dialysis (Chap. I., note 18) and occlusion (Chap. II., note 37). Equal volumes of gases penetrate through indiarubber in periods of time related to each other as follows:—carbonic anhydride, 100; hydrogen, 247; oxygen, 532; marsh gas, 633; carbonic oxide, 1,220; nitrogen, 1,358. Hence nitrogen penetrates more slowly than oxygen, and carbonic anhydride more quickly than other gases. 2·556 volumes of oxygen and 13·585 volumes of carbonic anhydride pass through in the same time as one volume of nitrogen. By multiplying these ratios by the amounts of these gases in air, we obtain figures which are in almost the same

and in so doing give up the oxygen absorbed—that is, by making use of reversible reactions. Thus, for instance, the oxygen of the atmosphere may be made to oxidise sulphurous anhydride, SO_2 (by passing directly over ignited spongy platinum), and so form sulphuric anhydride, or sulphur trioxide, SO_3 ; and this substance (which is a solid and volatile, and therefore easily separated from the nitrogen and sulphurous anhydride), on further heating, gives oxygen and sulphurous anhydride. Caustic soda or lime extracts (absorbs) the sulphurous anhydride from this mixture, whilst the oxygen is not absorbed, and is hence isolated from the air. On a large scale in works, as we shall afterwards see, sulphurous anhydride is transformed into hydrate of sulphur trioxide, or sulphuric acid, H_2SO_4 ; if this is allowed to drop on to red-hot flagstones, water, sulphurous anhydride, and oxygen may be obtained. The oxygen is easily isolated from this mixture by passing the gases over lime. The extraction of oxygen from oxide of mercury (Priestley, Lavoisier), which is obtained from mercury and the oxygen of the atmosphere, is also a reversible reaction by which oxygen may be obtained from the atmosphere (see Introduction). So also, by passing dry air through a red-hot tube containing barium oxide, it is made to combine with the oxygen of the air. In this reaction the so-called barium peroxide, or dioxide, BaO_2 , is formed from barium oxide, BaO , and at a higher temperature the former evolves the absorbed oxygen, and leaves the barium oxide originally taken.⁷

proportion as the volumes of the gases penetrating from air through indiarubber. If the process of dialysis be repeated on the air which has already passed through indiarubber, then a mixture containing 65 per cent. by volume of oxygen is obtained. It may be thought that the cause of this phenomenon is the absorption or occlusion (see Chap. II., note 37) of gases by indiarubber and the evolution of the gas dissolved in a vacuum; and, indeed, indiarubber does absorb gases, especially carbonic anhydride. Graham called the above method of the decomposition of air *atmolysis*.

Now that *liquid air* can be produced in large quantities (Chap. V.), the difference between the boiling-points of nitrogen (about -194°) and oxygen (about -181°), i.e., the greater elasticity (vapour pressure) of the nitrogen, can be taken advantage of for isolating the oxygen of the air. If liquid air be kept in a double-walled vessel (Chap. II., note 32), the nitrogen will evaporate to a greater extent than the oxygen, and a liquid far richer in oxygen than nitrogen will be obtained in the residue. If the mixture be carefully distilled (or only partially liquefied) it may be reduced to a residue containing 80 per cent. of oxygen. And as the evaporation of such liquids produces the low temperatures needed for liquefying air, this method may serve as a cheap means for obtaining from the air a gas rich in oxygen, combustion in which would give a very high temperature which might be advantageously employed for many purposes (for lighting or metallurgy). The day may come when this mode of enriching the air in oxygen may be employed on a large scale in works, &c., and so crown the many efforts which have been made in this direction.

⁷ The preparation of oxygen by this method, which is due to **Boussingault**, is conducted in a porcelain tube, placed in a stove heated by charcoal. Barium oxide (which may be obtained by igniting barium nitrate, previously dried) is placed in the tube, through which a current of air passes. The air is previously passed through a solution of caustic potash, to remove all traces of carbonic anhydride, and is very carefully dried (for the

Oxygen is evolved with particular ease by a whole series of unstable oxygen compounds, of which we shall proceed to take a general survey, remarking that certain of these reactions, although not all, belong to the class of reversible reactions;⁸ so that in order to obtain many of these substances (for instance, potassium chlorate) rich in oxygen,

hydrate, BaH_2O_2 , does not give the peroxide). At a *dark-red heat* ($500\text{--}600^\circ$), the oxide of barium absorbs oxygen from the air, so that the gas leaving the tube consists chiefly of nitrogen. When the absorption ceases, the air will pass through the tube unchanged, which may be recognised from the fact that it supports combustion. Under these circumstances, the barium oxide is converted into peroxide and eleven parts of the oxide absorb about one part of oxygen by weight. When the absorption ceases, one end of the tube is closed, a cork with a gas-conducting tube is fixed into the other end, and the heat of the stove is increased to a *bright-red heat* (800°). At this temperature the peroxide gives up all that oxygen which it acquired at a dark-red heat,—i.e., about one part of oxygen is evolved from twelve parts of barium peroxide. After the evolution of the oxygen there remains the barium oxide which was originally taken, so that air may be again passed over it, and thus the preparation of oxygen from one and the same quantity of barium oxide may be repeated many times. Oxygen has been produced one hundred times from one mass of oxide by this method, all the necessary precautions being taken as regards the temperature of the mass and the removal of moisture and carbonic acid from the air. Unless such precautions be taken, the mass of oxide soon becomes spoilt.

As oxygen may become of considerable technical use, from its capacity for giving high temperatures and intense light in the combustion of substances, its preparation directly from air by practical methods forms a problem, whose solution many investigators are continuing to work at up to the present day (note 6). The most practical methods are those of **Tessié du Motay** and **Kassner**. The first is based on the fact that a mixture of equal weights of manganese peroxide and caustic soda at an incipient red heat (about 350°) absorbs oxygen from air, with the separation of water, according to the equation: $\text{MnO}_2 + 2\text{NaHO} + \text{O} = \text{Na}_2\text{MnO}_4 + \text{H}_2\text{O}$. If superheated steam, at a temperature of about 450° , be then passed through the mixture, the manganese peroxide and caustic soda originally taken are regenerated, and the oxygen held by them is evolved, according to the reverse equation: $\text{Na}_2\text{MnO}_4 + \text{H}_2\text{O} = \text{MnO}_2 + 2\text{NaHO} + \text{O}$. This mode of preparing oxygen may be repeated an infinite number of times. The oxygen in combining liberates water, and steam, acting on the resultant substance, evolves oxygen. Hence all that is required for the preparation of oxygen by this method is fuel and the alternate cutting off of the supplies of air and steam. In Kassner's process (1891) a mixture of oxide of lead and lime ($\text{PbO} + 2\text{CaO}$) is heated to redness in the presence of air, oxygen being thus absorbed and calcium plumbate, Ca_2PbO_4 , formed. The latter is of a chocolate colour, and on further heating evolves oxygen and gives the original mixture, $\text{PbO} + 2\text{CaO}$, so that the phenomenon is essentially the same as in Boussingault's process (with BaO), but according to Le Chatelier (1893) the dissociation pressure of the oxygen evolved from Ca_2PbO_4 is less than with BaO_2 at the same temperatures; for instance, at 940° , it is 112 mm. of mercury for the first, and for the latter 210 mm. at 720° , and 670 mm. at 790° , while for Ca_2PbO_4 this last pressure is only reached at $1,080^\circ$. However, in Kassner's process the oxygen is absorbed more rapidly, and the influence of the presence of moisture and carbonic anhydride in the air is not so marked, so that this process, like that of Tessié du Motay, deserves consideration.

⁸ Even the decomposition of manganese peroxide is reversible (under certain changes in the conditions of reaction), and it may be re-obtained from that suboxide (or its salts), which is formed in the evolution of oxygen (Chap. XI., note 6). The compounds of chromic acid containing the trioxide, CrO_3 , in evolving oxygen, give chromium oxide, Cr_2O_3 , but they re-form the salt of chromic acid when heated to redness in air with an alkali.

recourse must be had to indirect methods (see Introduction) with which we shall become acquainted in the course of this book.

1. **The compounds of oxygen** with certain metals, namely, mercury, silver, gold, and platinum, having once been obtained, retain their oxygen at the ordinary temperature, but part with it at a red heat. These compounds are solids, generally amorphous and infusible, and are easily decomposed by heat into the metal and oxygen. We have seen an example of this in the decomposition of mercury oxide. Priestley, in 1774, obtained pure oxygen for the first time by heating mercury oxide by means of a burning-glass. He showed its difference from air and its characteristic property of supporting combustion 'with remarkable vigour,' and he named it dephlogisticated air.

2. The substances called **peroxides**⁹ evolve oxygen at a greater or less heat (and also by the action of many acids). They usually contain metals combined with a large quantity of oxygen. Peroxides are the highest oxides of certain metals which generally give several compounds with oxygen. Those of the lowest degrees of oxidation, containing the least amount of oxygen, are generally substances capable of reacting easily with acids, for instance, with sulphuric acid. Such low oxides are called bases. Peroxides contain more oxygen than the bases formed by the same metals. For example, lead oxide contains 7.1 parts of oxygen in 100 parts, and is basic, but lead peroxide contains 13.3 parts of oxygen in 100 parts. **Manganese peroxide or dioxide** is a similar substance, and is a solid of a dark brown colour, which occurs in nature. It is employed for technical purposes under the name of black oxide of manganese (in German 'Braunstein,' the 'pyrolusite' of the mineralogist). Peroxides are able to evolve oxygen at a more or less elevated temperature. They do not then part with all their oxygen, but with only a portion of it, and are converted into a lower oxide or base. Thus for example, lead peroxide, on heating, gives oxygen and lead oxide. The decomposition of this peroxide proceeds tolerably easily on heating, even in a glass vessel, but manganese peroxide only evolves oxygen at a strong red heat, and therefore oxygen can only be obtained from it in iron or clay vessels. This was formerly the method for obtaining oxygen. Manganese peroxide only parts with one-third of its oxygen (according to the equation, $3\text{MnO}_2 = \text{Mn}_3\text{O}_4 + \text{O}_2$), two-thirds remaining

⁹ We shall afterwards see that it is only substances like barium peroxide (which give hydrogen peroxide) which should be counted as true peroxides, and that MnO_2 , PbO_2 , &c., should be distinguished from them (they do not give hydrogen peroxide with acids), and therefore it is best to call these dioxides. This we generally do in the context, only retaining the old nomenclature in a few instances, on account of its historical interest, and to enable our readers to refer to former treatises. Peroxide of hydrogen (Chap. IV.) easily parts with half of its oxygen, leaving water as a residue.

in the solid residue after heating. Metallic peroxides are also capable of evolving oxygen on heating with sulphuric acid. They then evolve just that amount of oxygen which is in excess of that necessary for the formation of the base, which latter reacts on the sulphuric acid forming a compound (salt) with it. Thus barium peroxide, when

FIG. 32.—Preparation of oxygen from manganese peroxide and sulphuric acid. The gas evolved is passed through a Woulfe's bottle containing caustic potash solution.

heated with sulphuric acid, forms oxygen and barium oxide, which gives a compound with sulphuric acid termed barium sulphate ($\text{BaO}_2 + \text{H}_2\text{SO}_4 = \text{BaSO}_4 + \text{H}_2\text{O} + \text{O}$).^{9a} For the purposes of experiment, powdered manganese peroxide is usually taken and mixed with strong sulphuric acid in a flask, and the apparatus set up as shown in fig. 32.

^{9a} Peroxide of barium also gives oxygen at the ordinary temperature in the presence of the solutions of many substances in a higher degree of oxidation. In this connection we may mention that Kassner (1890) proposes to obtain oxygen for laboratory purposes by mixing BaO_2 with $\text{FeK}_3(\text{CN})_6$ (red prussiate of potash, Chapter XXII.); the reaction proceeds with the evolution of oxygen on the addition of even a very small quantity of water. In order to ensure a gradual evolution of gas, the author proposes to introduce the two substances into the reaction, little by little, instead of all at once; and this may be done with the following arrangement (Gavaloffsky). Finely powdered peroxide of barium is placed in an ordinary flask and sufficient water is added to fill the flask one-third full. The cork closing the flask has three holes: (1) for the gas-conducting tube; (2) for a rod to stir the BaO_2 ; and (3) for a glass rod terminating in a perforated glass vessel containing crystals of $\text{FeK}_3(\text{CN})_6$. When it is desired to start the evolution of the oxygen, the vessel is lowered until it is immersed in the liquid in the flask, and the BaO_2 is stirred with the other rod. The reaction proceeds according to the equation, $\text{BaO}_2 + 2\text{FeK}_3(\text{CN})_6 = \text{FeK}_4(\text{CN})_6 + \text{FeK}_2\text{Ba}(\text{CN})_6 + \text{O}_2$. The double salt, $\text{FeBa}_2(\text{CN})_6$, crystallises out from the mother liquor. To understand the course of the reaction, it must be remembered that BaO_2 is of a higher degree of oxidation, and that it parts with oxygen and gives the base BaO , which enters into the complex salt $\text{FeK}_2\text{Ba}(\text{CN})_6 = \text{Fe}(\text{CN})_2 + 2\text{KCN} + \text{Ba}(\text{CN})_2$, and this latter $= \text{BaO} + 2\text{HCN} - \text{H}_2\text{O}$. Moreover, $\text{FeK}_3(\text{CN})_6$ contains the salt $\text{Fe}_2(\text{CN})_6$, which also corresponds with the higher degree of oxidation of iron, Fe_2O_3 , whilst after the reaction a salt is obtained which contains $\text{Fe}(\text{CN})_2$, and corresponds with the lower degree of oxidation, FeO , so that (in the presence of water) oxygen is set free on this side also, i.e., the reaction gives compounds of lower degrees of oxidation and oxygen.

The gas which is evolved is passed through a Woulfe's (two-necked) bottle containing a solution of caustic potash, to purify it from carbonic anhydride and chlorine, which accompany oxygen from commercial manganese peroxide, and the gas is not collected until a thin smouldering taper placed in front of the escape orifice bursts into flame, and so shows that the gas coming off is oxygen. By this method of decomposition of the manganese peroxide by sulphuric acid there is evolved, not, as on heating, one-third, but one-half of the oxygen contained in the peroxide ($\text{MnO}_2 + \text{H}_2\text{SO}_4 = \text{MnSO}_4 + \text{H}_2\text{O} + \text{O}$); that is, 50 grams of peroxide gives about $7\frac{1}{2}$ grams, or about $5\frac{1}{2}$ litres, of oxygen,¹⁰ whilst by heating only about $3\frac{1}{2}$ litres are obtained. The chemists of Lavoisier's time generally obtained oxygen by heating manganese peroxide. At the present time more convenient methods are known.

3. A third source to which recourse may be had for obtaining oxygen is afforded by **acids** and **salts** containing much oxygen, which are capable, by parting with a portion or all of their oxygen, of being converted into other more difficultly decomposable compounds (lower products of oxidation). These acids and salts (like peroxides) evolve oxygen either on heating alone, or only when in the presence of some other substance. Sulphuric acid may be taken as an example of an acid which is decomposed by the action of heat alone,¹¹ for it breaks up at a red heat into water, sulphurous anhydride, and oxygen, as was mentioned before. Priestley, in 1772, and Scheele, somewhat later, obtained oxygen by heating nitre to a red heat. The best example of the formation of oxygen by the heating of salts is given by **potassium chlorate**, or Berthollet's salt, so called after the French chemist who discovered it. Potassium chlorate is a salt composed of the elements potassium, chlorine, and oxygen: KClO_3 . It occurs as transparent colourless plates, is soluble in water, especially in hot water, and resembles common table salt in some of its reactions and physical properties; it melts on heating, and in melting begins to decompose, evolving oxygen gas. This decomposition ends in all the oxygen being evolved from the potassium chlorate, potassium chloride being left as a

¹⁰ Scheele, in 1785, discovered the method of obtaining oxygen by treating manganese peroxide with sulphuric acid.

¹¹ All acids rich in oxygen, and especially those whose elements form lower oxides, evolve oxygen either directly at the ordinary temperature (for instance, ferric acid), or on heating (nitric, manganic, chromic, chloric, and others), or, if lower basic oxides are formed from them, by heating with sulphuric acid. Thus the salts of chromic acid (for example, potassium dichromate, $\text{K}_2\text{Cr}_2\text{O}_7$) give oxygen with sulphuric acid; first potassium sulphate, K_2SO_4 , is formed, and then the chromic acid set free gives a sulphuric acid salt of the lower oxide, Cr_2O_3 . This is a convenient method for obtaining oxygen in small quantities in the laboratory.

residue, according to the equation, $\text{KClO}_3 = \text{KCl} + \text{O}_3$.¹² This decomposition proceeds at a temperature which allows of its being conducted in a glass vessel. However, in decomposing, the molten potassium chlorate swells up and boils, and gradually solidifies, so the evolution of the oxygen is not regular, and the glass vessel may crack. In order to overcome this inconvenience, the potassium chlorate is crushed and mixed with the powder of a substance which is infusible, incapable of combining with the oxygen evolved, and a good conductor of heat. Usually it is mixed with manganese peroxide.¹³ The decomposition of the potassium chlorate is then considerably facilitated, and proceeds at a lower temperature (because the entire mass is then better heated, both externally and internally) and without swelling up, so that this method is more convenient than the decomposition of the salt alone. This method for the preparation of oxygen is very convenient, and is generally employed when a small quantity of oxygen is required. Further, potassium chlorate is easily obtained pure, and evolves much oxygen: 100 grams of the salt give as much as 39 grams, or 30 litres, of oxygen. This method is so simple and easy¹⁴ that a course of practical chemistry is often commenced by the preparation of oxygen by this method, and of hydrogen by the aid of zinc and sulphuric acid, since by means of these gases many interesting and striking experiments may be performed.¹⁵

Bleaching powder, which contains calcium hypochlorite, CaCl_2O_2 , evolves oxygen when gently heated in presence of a small quantity of

¹² This reaction is not reversible, and is exothermal—that is, it does not absorb heat, but, on the contrary, evolves 9,713 calories per molecular weight of KClO_3 , equal to 122 parts of salt (according to the determination of Thomsen, who burnt hydrogen in a calorimeter either alone or with a definite quantity of potassium chlorate mixed with oxide of iron). It does not proceed at once, but first forms perchlorate, KClO_4 (see Chlorine and Potassium). It is to be remarked that potassium chloride melts at 766° , potassium chlorate at 359° , and potassium perchlorate at 610° . (Concerning the decomposition of KClO_3 , see Chapter II., note 47.)

¹³ The peroxide does not evolve oxygen in this case (the temperature is not high enough). It may be replaced by many oxides—for instance, by oxide of iron. It is necessary to take the precaution that no combustible substances (such as bits of paper, splinters, sulphur, &c.) fall into the mixture, as they might cause an explosion.

¹⁴ The decomposition of a mixture of fused and well-crushed potassium chlorate with powdered manganese peroxide proceeds at so low a temperature (the salt does not melt) that it may be effected in an ordinary glass flask. The apparatus is arranged in the same manner as in the decomposition of mercury oxide (Introduction), or as shown in the last drawing. As the reaction is exothermal, the decomposition of potassium chlorate with the formation of oxygen may probably be accomplished, under certain conditions (for example, under contact action), at very low temperatures. Substances mixed with the potassium chlorate act partially in this manner.

¹⁵ Many other salts evolve oxygen on heating, like potassium chlorate, but they only part with it either at a very high temperature (as, for instance, common nitre) or else are unsuited for use on account of their cost (potassium manganate), or evolve impure oxygen at a high temperature (zinc sulphate at a red heat gives a mixture of sulphurous anhydride and oxygen).

certain oxides, for instance, cobalt oxide, which in this case acts by contact (see Introduction). When heated by itself, a solution of bleaching powder does not evolve oxygen, but it oxidises the cobalt oxide to a higher degree of oxidation; this higher oxide of cobalt in contact with the bleaching powder decomposes into oxygen and lower oxidised products, and the resultant lower oxide of cobalt with bleaching powder again gives the higher oxide, which again gives up its oxygen, and so on.¹⁶ The calcium hypochlorite is here decomposed according to the equation, $\text{CaCl}_2\text{O}_2 = \text{CaCl}_2 + \text{O}_2$. In this manner a small quantity of cobalt oxide¹⁷ is sufficient for the decomposition of an indefinitely large quantity of bleaching powder. Bleaching powder gives oxygen with still greater facility (without the aid of heat) by the action of an aqueous solution of peroxide of hydrogen (Chap. IV.), which then evolves oxygen, $\text{CaCl}_2\text{O}_2 + \text{H}_2\text{O}_2 = \text{CaCl}_2 + \text{H}_2\text{O} + 3\text{O}$. Permanganate of potassium acts in a similar way.

The properties of oxygen.¹⁸—It is a permanent gas—that is, it cannot be liquefied by pressure at the ordinary temperature, and, further, is only liquefied with difficulty (although more easily than hydrogen) at temperatures below -120° , because this is its absolute (critical) boiling-point. As its critical pressure¹⁹ is about 50 atmospheres, it can be easily

¹⁶ Such is at present the only possible method of explaining the phenomenon of contact action. In many cases, such as the present one, it is supported by observations based on facts (see Chap. IV.) To this class of phenomena may also be referred the evolution of oxygen at the ordinary temperature from a mixture of barium peroxide and potassium manganate with water and sulphuric acid (note 9a). The essence of phenomena of this kind is purely a property of contact; the distribution of the atoms is slightly changed along the planes of contact; and if the equilibrium be unstable it is destroyed. This is more especially frequent with those substances which change exothermally—that is, for those reactions which are accompanied by an evolution of heat. The decomposition $\text{CaCl}_2\text{O}_2 = \text{CaCl}_2 + \text{O}_2$ belongs to this class, like the decomposition of potassium chlorate and peroxide of hydrogen.

¹⁷ Generally a solution of bleaching powder is alkaline (containing free lime), and, therefore, a solution of cobalt chloride is added directly to it, the oxide of cobalt required for the reaction being thus formed.

¹⁸ It must be remarked that in all the reactions above mentioned the formation of oxygen may be prevented by the admixture of substances capable of combining with it—for example, charcoal, many carbon (organic) compounds, sulphur, phosphorus, and various lower oxidation products, &c. These substances absorb the oxygen evolved, combining with it, forming a compound containing oxygen.

The oxygen obtained by any of the above-described methods is therefore rarely pure. It generally contains aqueous vapour, carbonic anhydride, and sometimes small traces of chlorine. The oxygen may be freed from these impurities by passing it through a solution of caustic potash, and by drying it. If the potassium chlorate be dry and pure, it gives almost pure oxygen. However, if the oxygen be required for respiration in cases of sickness, it should be washed by passing it through a solution of caustic alkali and through water. The best way to obtain pure oxygen directly is to take potassium perchlorate (KClO_4), which can be well purified and evolves pure oxygen on heating.

¹⁹ With regard to the absolute boiling-point, critical pressure, and the critical state in general, see Chap. II., notes 29 and 34.

liquefied under pressures greater than 50 atmospheres at temperatures below -120° . According to Dewar, the density of oxygen in a critical state is 0.65 (water=1); but, like all liquids near this point,²⁰ it varies considerably in density with a change of pressure and temperature, and at -181° its density is 1.13 under the ordinary pressure. Liquefied oxygen is an exceedingly mobile transparent liquid, with a faint blue tint^{20a} and boiling (at a pressure of 760 mm.) at -181° or -182° . Oxygen solidifies at the temperature obtained by liquid hydrogen (probably at about -250°), forming a transparent blue ice, which, at a pressure of 55 mm., gives a temperature of -258° . Oxygen, like all gases, is transparent, and, like the majority of gases, colourless. It has no smell or taste, which is evident from the fact of its being a component of air. The weight of one litre of oxygen gas at 0° and 760 mm. pressure, at latitude 45° , is 1.4290 gram (Regnault, Morley, Thomsen, and others); it is slightly denser than air, so that its density in respect to air is 1.1051, and in respect to hydrogen, 16.²¹

In its chemical properties oxygen is remarkable from the fact that it very easily—and, in a chemical sense, vigorously—reacts on a number of substances, forming oxygen compounds. However, only a few substances and mixtures of substances (for example, phosphorus, copper with ammonia, decomposing organic matter, aldehyde, pyrogallol with

²⁰ Judging from what has been said in note 34 of the last chapter, and also from the results of direct observation, it is evident that all substances in a critical state have a large coefficient of expansion, and are very compressible.

^{20a} Even a thin layer of liquid oxygen (or liquid air) gives a perfect absorption spectrum (see Chap. XIII., note 32).

²¹ As water consists of 1 volume of oxygen and 2 volumes of hydrogen, and contains about 16 parts by weight of oxygen per 2 parts by weight of hydrogen, it therefore follows directly that oxygen is nearly 16 times denser than hydrogen. Conversely, the composition of water by weight may be deduced from the densities of hydrogen and oxygen and the volumetric composition of water. This method of mutual and reciprocal correction strengthens the practical data of the exact sciences, the conclusions of which require the greatest possible exactitude and variety of corrections.

It must be observed that the specific heat of oxygen at constant pressure is 0.2175; consequently it is to the specific heat of hydrogen (3.409) as 1 is to 15.6. Hence, the specific heats are inversely proportional to the weights of equal volumes, so that equal volumes of the two gases have (nearly) equal specific heats—that is, they require an equal quantity of heat for raising their temperature by 1° . We shall afterwards consider the specific heat of different substances more fully in Chap. XIV. According to Dewar, the specific heat of liquid hydrogen (between -198° and -182°) is 0.32.

Oxygen, like the majority of difficultly liquefiable gases, is but slightly soluble in water and other liquids. The solubility is given in note 30, Chap. I. From this it is evident that water standing in air must absorb—i.e., dissolve—oxygen. This oxygen serves for the respiration of fishes. Fishes cannot exist in boiled water, because it does not contain the oxygen necessary for their respiration (see Chap. I.) I may also remark that repeated observations (Bore 1886, Baly and Ramsay 1894) on the *positive* discrepancies of oxygen from Boyle's law at low pressures show a rapid change in the law at pressures of about 0.7 mm., although the discrepancies remain positive even before and after this critical pressure.

an alkali, &c.) combine directly and rapidly with oxygen at the ordinary temperature, whilst many substances easily combine with oxygen at a red heat, and this combination often presents a rapid chemical reaction accompanied by the evolution of a large quantity of heat. Every reaction which takes place rapidly, if accompanied by so great an evolution of heat as to produce incandescence, is termed **combustion**. Thus combustion ensues when many metals are plunged into chlorine, or oxide of sodium or barium into carbonic anhydride, or when a spark falls on gunpowder. A great many substances are combustible in oxygen, and, owing to its presence, in air also. In order to start combustion it is generally necessary²² that the combustible substance should be brought to a state of incandescence. The continuation of the process does not require the aid of fresh external heat, because sufficient heat²³ is evolved to raise the temperature of further portions of the combustible substance to the required degree. Examples of this are familiar to all from every-day experience. Combustion proceeds in oxygen with greater rapidity, and is accompanied by a more powerful incandescence, than in ordinary air. This may be demonstrated by a number of very convincing experiments. If a piece of charcoal, attached to a wire and previously brought to red-heat, be plunged into a flask full of oxygen, it burns rapidly at a white heat—i.e., it combines with the oxygen, forming a gaseous product of combustion called carbonic anhydride, carbonic acid gas, or carbon dioxide, CO_2 . This is the same gas as is evolved in the act of respiration, for charcoal is one of the substances which are obtained by the decomposition of all organic substances which contain them, and in the process of respiration part of the constituents of the body, so to speak, slowly burn. If a piece of burning sulphur be placed in a small cup attached to a wire and introduced into a flask full of oxygen, then the sulphur, which burns in air with a very feeble flame, will burn in the oxygen with a violet flame, which,

FIG. 33.—Mode of burning sulphur, phosphorus, sodium, &c., in oxygen.

²² Certain substances (with which we shall afterwards become acquainted), however, ignite spontaneously in air; for example, impure phosphoretted hydrogen, silicon hydride, zinc ethyl, and pyrophorus (very finely divided iron, &c.) This signifies that the temperature of ignition is below the ordinary temperature.

²³ If so little heat is evolved that the adjacent parts are not heated to the temperature of combustion, then combustion will cease. Thus combustion may be stayed not only by stopping the access of oxygen, but also by cooling the burning body, i.e., by lowering its temperature. This is what occurs when a candle is blown out, or a fire extinguished by water.

although pale, is much larger than in air. If the sulphur be exchanged for a piece of **phosphorus**,²⁴ then, unless the phosphorus be heated, it will combine very slowly with the oxygen; but, if heated, even if in one spot only, it burns with an exceedingly brilliant white flame. In order to heat the phosphorus inside the flask, the simplest way is to bring a red-hot wire into contact with it. As regards charcoal, this cannot burn until it is brought to a state of incandescence. Sulphur

FIG. 34.—Mode of burning a steel spring in oxygen.

also will not burn under 100° , whilst phosphorus inflames at 40° . Phosphorus which has been already lighted in air cannot so well be introduced into the flask, because it burns very rapidly and with a large flame in air. If a small lump of metallic **sodium** be put into a small cup made of lime,²⁵ melted, and ignited,²⁶ it burns very feebly in air. But if burning sodium be introduced into oxygen, the combustion is invigorated and is accompanied by a brighter yellow flame. Metallic **magnesium**, which burns yet more brightly in air, continues to burn with still

greater vigour in oxygen (i.e., the temperature rises still higher), forming a white powder, which is a compound of magnesium with oxygen (magnesium oxide or magnesia). A strip of **iron** or steel does not burn in air, but an iron wire or steel spring may be easily burnt in oxygen.²⁷ The combustion of steel or iron in oxygen is not accompanied by a flame, but sparks of oxide fly in all directions from the burning portions of the iron.²⁸

²⁴ The phosphorus must be dry; it is usually kept in water, as it oxidises in air. It should be cut under water, as otherwise the freshly cut surface oxidises. It must be dried carefully and quickly by wrapping it in blotting-paper. If damp, it splutters on burning. A small piece should be taken, as otherwise the iron spoon will melt. In this and the other experiments on combustion, water should be poured over the bottom of the vessel containing the oxygen, to prevent it from cracking. The cork closing the vessel should not fit tightly, in order to allow for the expansion of the gas due to the heat of the combustion.

²⁵ An iron cup will melt with sodium in oxygen.

²⁶ In order to rapidly heat the lime crucible containing the sodium, it is heated in the flame of a blowpipe described in Chap. VIII.

²⁷ In order to burn a watch-spring, it is first tempered (made red-hot and then slowly cooled) in order to soften it, and then a piece of tinder (or paper soaked in a solution of nitre, and dried) is attached to one end. The tinder is lighted, and the spring then plunged into the oxygen. The burning tinder heats the end of the spring, the heated part burns, and in so doing heats the further portions of the spring, which then burns completely if sufficient oxygen be present.

²⁸ The sparks of rust are produced, owing to the fact that the volume of the oxide of iron is nearly twice that of the iron, and as the heat evolved is not sufficient to entirely

In order to demonstrate by experiment the **combustion of hydrogen** in oxygen, a gas-conducting tube, bent so as to form a convenient jet, is led from the vessel evolving hydrogen. The hydrogen is first ignited in air, and then the gas-conducting tube is let down into a flask containing oxygen. The combustion in oxygen will be similar to that in air; the flame remains pale, notwithstanding the fact that its temperature rises considerably. It is instructive to remark that oxygen may burn in hydrogen, just as hydrogen does in oxygen. In order to show the combustion of oxygen in hydrogen, a tube bent vertically upwards and ending in a fine orifice is attached to the stopcock of a gas-holder full of oxygen. Two wires placed at such a distance from each other as to allow of the passage of a series of sparks from a Ruhmkorff's coil, are fixed in front of the orifice of the tube. This is in order to ignite the oxygen, which may be also done by attaching tinder round the orifice, and burning it. When the wires are arranged at the orifice of the tube, and a series of sparks passes between them, an inverted (because of the lightness of the hydrogen) jar full of hydrogen is placed over the gas-conducting tube. When the jar covers the orifice of the gas-conducting tube (and not before, as otherwise an explosion might take place) the cock of the gasometer is opened, and the oxygen flows into the hydrogen and is set light to by the sparks. The flame obtained is similar to that formed by the combustion of hydrogen in oxygen.²⁹ From this it is evident that the flame is the locality where

melt the oxide or the iron, the particles must be torn off and fly about. Similar sparks are also formed in the combustion of iron in other cases. We called attention in the Introduction to the combustion of iron filings. In the welding of iron, small iron splinters fly off in all directions and burn in the air, as is seen from the fact that whilst flying through the air they remain red-hot, and also because, on cooling, they are seen to be no longer iron, but a compound of it with oxygen. The same thing takes place when the hammer of a gun strikes against the flint. Small scales of steel are heated by the friction, and glow and burn in the air. The combustion of iron is still better seen by taking it as a very fine powder, such as is obtained by the decomposition of certain of its compounds, for instance, by heating Prussian blue, or by the reduction of its compounds with oxygen by hydrogen; when this fine powder is strewn in air, it burns by itself, even without being previously heated (it forms pyrophorus). This depends on the physical state of the surface of the powder after reduction and on the fact that the powder of iron presents a larger surface of contact with air than an equal weight in a compact form.

²⁹ The experiment may be conducted without the wires, if the hydrogen be lighted in the orifice of an inverted cylinder, and at the same time the cylinder be brought over the end of a gas-conducting tube connected with a gas-holder containing oxygen. Thomsen's method may be adopted for a lecture experiment. In this, two glass tubes with platinum ends are passed through orifices, about 1-1½ centimetre apart, in a cork. One tube is connected with a gas-holder containing oxygen and the other with a gas-holder full of hydrogen. Having turned on the gases, the hydrogen is lighted, and a common lamp glass, tapering towards the top, is placed over the cork. The hydrogen continues to burn inside the lamp glass, at the expense of the oxygen. If the current of oxygen is then decreased little by little, a point is reached when, owing to the insufficient supply of

the oxygen combines with the hydrogen, so that a flame of burning oxygen can be obtained as well as a flame of burning hydrogen.

If, instead of hydrogen, any other combustible gas be taken—for example, ordinary coal gas—then the phenomenon of combustion will

be exactly the same, only a bright flame will be obtained, and the products of combustion will be different. However, as coal gas contains a considerable amount of free and combined hydrogen, it will also form a considerable quantity of water in its combustion.

If hydrogen be mixed with oxygen in the proportion in which these gases form water—i.e., if two volumes of hydrogen be taken for each volume of oxygen—the mixture will then be the same as that obtained by the decomposition of water by a galvanic current, i.e., detonating gas.

We have already mentioned in the last chapter that the combination of these gases, or their explosion, may be brought about by the action of an electric spark, because the spark heats the space through which it passes,

and consequently acts in a manner similar to ignition by means of contact with an incandescent or burning substance.³⁰ Cavendish made this experiment on the ignition of detonating gas at the end of the eighteenth

oxygen, the flame of the hydrogen increases in size, disappears for several moments, and then reappears at the tube supplying the oxygen. If the flow of oxygen be now increased again the flame reappears at the hydrogen tube. Air may be taken instead of oxygen, and ordinary coal-gas instead of hydrogen, and it will then be shown how air burns in an atmosphere of coal-gas, and it can easily be proved that the lamp glass is full of a gas combustible in air, because it may be lighted at the top.

³⁰ In fact, instead of a spark, a fine wire may be taken, and an electric current passed through it to bring it to a state of incandescence; in this case there will be no sparks, but the gases will inflame if the wire be fine enough to become red-hot by the passage of the current.

FIG. 35.—Cavendish's apparatus for exploding detonating gas. The bell jar standing in the bath is filled with a mixture of two volumes of hydrogen and one volume of oxygen, and the thick glass vessel A is then serewed on to it. The air is first pumped out of this vessel, so that when the stopcock C is opened, it becomes filled with detonating gas. The stopcock is then re-closed, and the explosion produced by means of a spark from a Leyden jar. After the explosion has taken place the stopcock is again opened, and the water rises into the vessel A.

century, in the apparatus shown in fig. 35. Ignition of gases by the aid of the electric spark is convenient, for the reason that it may then be brought about in a closed vessel, and hence chemists employ this method when it is required to ignite a mixture of oxygen with a combustible gas in a closed vessel. For this purpose, especially since Bunsen's time,³¹ a **eudiometer** is employed. It consists of a thick glass tube graduated along its length in millimetres (for indicating the height of the mercury column), and calibrated for a definite volume (weight of mercury). Two platinum wires are fused into the upper closed end of the tube, as shown in fig. 36.³² By the aid of the eudiometer we may not only determine the volumetric composition of water,³³ and the quantitative content of oxygen in air, but may also make a number of experiments explaining the phenomenon of combustion.

Thus, for example, it may be demonstrated, by the aid of the eudiometer, that, **for the ignition** of detonating gas (like all combustible bodies), a **definite temperature** is required. If the temperature be below that required, combination will not take place, but if at any spot within the tube it rises to the temperature of inflammation, then combination will ensue at that spot, and evolve enough heat for the ignition of the adjacent portions of the detonating mixture. If to 1 volume of detonating gas there be added 10 volumes of oxygen, or 4 volumes of hydrogen, or 3 volumes of carbonic anhydride, we shall not then obtain an explosion by passing a spark through the diluted mixture. This depends on the fact that the temperature falls with dilution of the detonating gas by another gas, because the heat evolved by the combination of the small quantity of hydrogen and oxygen brought to incandescence by the spark is transmitted, not only to the water proceeding from the combination, but also to the foreign substance mixed

FIG. 36.
Eudiometer

³¹ At the present time, a great many other different forms of apparatus, sometimes designed for special purposes, are employed in the laboratory for the investigation of gases. Detailed descriptions of the methods of gas analysis and of the apparatus employed must be looked for in works on analytical and applied chemistry.

³² They must be sealed into the tube in such a manner as to leave no aperture between them and the glass. In order to test this, the eudiometer is almost filled with mercury, and its open end placed in mercury. If there be the smallest orifice at the wires, the external air will enter the cylinder and the mercury will fall, although not rapidly if the orifice be very fine.

³³ Concerning this application of the eudiometer, see the chapter on Nitrogen. It may be mentioned, as illustrating the various uses of the eudiometer, that Professor Timera-seff employed microscopically small eudiometers to analyse the bubbles of gas given off from the leaves of plants.

with the detonating gas.³⁴ The necessity of a definite temperature for the ignition of detonating gas is also seen from the fact that pure detonating gas explodes in the presence of a red-hot iron wire, or of charcoal heated to 275° ; but with a lower degree of incandescence there is no explosion. It may also be brought about by rapid compression, when, as is known, heat is evolved.³⁵ Experiments made in the

³⁴ Further, $\frac{1}{2}$ volume of carbonic oxide, an equal volume of marsh gas, two volumes of hydrogen chloride or of ammonia, or six volumes of nitrogen or twelve of air added to one volume of detonating gas prevent its explosion.

³⁵ If the compression be brought about slowly, so that the heat evolved succeeds in passing to the surrounding space, then the combination of the oxygen and hydrogen does not take place, even when the mixture is compressed 150 times, for the gases are not heated. If paper soaked with a solution of platinum (in aqua regia) and sal-ammoniac is burnt, the ash obtained contains very finely divided platinum, and in this form it is best fitted for igniting hydrogen and detonating gas. Platinum wire requires to be heated, but platinum in so finely divided a state as it occurs in this ash inflames hydrogen, even at -20° . Many other metals, such as palladium (175°), iridium, and gold, act on a slight rise of temperature, like platinum; but mercury, at its boiling-point, does not inflame detonating gas, although the slow formation of water begins at 305° . All data of this kind show that the explosion of detonating gas forms one of the many cases of contact phenomena. This conclusion is further confirmed by the researches of V. Meyer (1892). He showed that only a very slow formation of steam begins at 448° , and that it only proceeds more rapidly at 518° . The temperature of the explosion of detonating gas, according to the same author, varies according to whether the explosion is produced in open vessels or in closed tubes. In the first case the temperature of explosion lies between 530° – 606° , and in the second between 630° – 730° . In general it may be remarked that the temperature of explosion of gaseous mixtures is always lower in closed vessels than when the detonating mixture flows freely through tubes. According to Freyer and V. Meyer, the following gases when mixed with the requisite amount of oxygen explode at the following temperatures:

—	When flowing freely	In closed vessels
H ₂ with oxygen	630° – 730°	530° – 606°
CH ₄ "	650° – 730°	606° – 650°
C ₂ H ₆ "	606° – 650°	530° – 606°
C ₂ H ₄ "	606° – 650°	530° – 606°
CO "	650° – 730°	650° – 730°
H ₂ S "	315° – 320°	250° – 270°
H ₂ + Cl ₂	430° – 440°	240° – 270°

Baker (1892) showed that perfectly pure detonating gas, prepared by the action of an electric current on a solution of caustic baryta (BaH₂O₂) and very carefully dried by volatilised phosphoric anhydride, does not give water or explode at those temperatures (even at 950°) at which moist detonating gas immediately forms water (compare Chap. IX., note 29). Besides which, Baker proved that the moist gas gradually gives water when exposed to sunlight, but that the dry gas does not react at all. In my opinion, all such instances are due to phenomena of contact; that is, in other words, they are determined by changes in the distribution of the atoms in the molecules which take place to a greater or less degree at all the planes of contact of different bodies. This is particularly clear in the above influence of metals.

The velocity of the transmission of explosion in gaseous mixtures is as characteristic a magnitude for gaseous systems as the velocity of the transmission of sound. Berthelot

eudiometer showed that the ignition of detonating gas takes place at a temperature between 450° and 560° .³⁶

showed that this velocity depends neither upon the pressure nor upon the size of the tubes in which the gaseous mixture is contained, nor upon the material of which the tube is made. Dixon (1891) determined the magnitude of these velocities for various mixtures, and his results agreed well with those previously given by Berthelot. For comparison we give the velocities expressed in metres per second:

	Dixon	Berthelot
$\text{H}_2 + \text{O}$	2,821	2,810
$\text{H}_2 + \text{N}_2\text{O}$	2,305	2,284
$\text{CH}_4 + 4\text{O}$	2,322	2,287
$\text{C}_2\text{H}_2 + 6\text{O}$	2,364	2,210
$\text{C}_2\text{H}_2 + 5\text{O}$	2,391	2,482
$\text{C}_2\text{N}_2 + 4\text{O}$	2,321	2,195

The addition of oxygen to detonating gas lowers the velocity of the transmission of explosion almost as much as the introduction of nitrogen. An excess of hydrogen, on the contrary, raises the velocity of transmission. It is remarked that the explosion of mixtures of oxygen with marsh gas, ethylene, and cyanogen is transmitted more quickly if the oxygen be taken in such a proportion that the carbon should burn to oxide of carbon, i.e., the velocity of the explosion is less if the oxygen be taken in sufficient quantity to form carbonic anhydride. Observations upon liquid and solid explosives (Berthelot) show that, in these cases, the velocity of transmission of explosion is dependent upon the material of the tube. Thus the explosion of liquid nitro-methyl ether in glass tubes travels at the rate (with variation of the diameter from 1 mm. to 45 mm.) of from 1,890 to 2,482 metres, and in tubes of Britannia metal (3 mm. in diameter) at the rate of 1,230 metres. The harder the tube the greater the velocity of transmission of explosion. The following are the velocities for certain bodies:

	metres per second
Nitro-glycerine	1,300
Dynamite	2,500
Nitro-mannite	7,700
Picric acid	6,500

In conclusion we may add that Mallard and Le Chatelier (1882) observed that in the explosion of a mixture of 1 volume of detonating gas with n volumes of an inert gas, the pressure is approximately equal to $9.20 - .9n$ atmospheres.

³⁶ From the very commencement of the promulgation of the idea of dissociation, it might have been imagined that reversible reactions of combination (the formation of H_2O from H_2 and O belongs to this class) commence at the same temperature as that at which dissociation begins. And in many cases this is so, but not always, as may be seen from the facts: (1) that at 450 – 560° , when detonating gas explodes, the density of aqueous vapour not only does not vary (and it hardly varies at higher temperatures, probably because the amount of the products of dissociation is small), but there are not, as far as is yet known, any traces of dissociation; (2) that under the influence of contact the temperature at which combination takes place falls even to the ordinary temperature, at which water and similar compounds are, of course, not dissociated; and, judging from the data communicated by D. P. Konovaloff (Introduction, note 39) and others, it is impossible to escape the phenomena of contact. All vessels, whether of metal or glass, show the same influence as spongy platinum, although to a much less degree. The phenomena of contact, judging from a review of the data referring to it, must be especially sensitive in reactions which are powerfully exothermic, and the explosion of detonating gas is of this kind.

The combination of hydrogen with oxygen is accompanied by the evolution of a very considerable amount of heat; according to the determinations of **Favre and Silbermann**,³⁷ 1 part by weight of hydrogen

³⁷ The amount of heat evolved in the combustion of a known weight (for instance, 1 gram) of a given substance is determined by the rise in temperature of a quantity of water, to which the whole of the heat evolved in the combustion is transmitted. A **calorimeter**, for example that shown in fig. 37, is employed for this purpose. It consists of a thin (in order that it may absorb less heat), polished (that it should transmit a minimum of heat) metallic vessel, surrounded by down (*c*), or some other bad conductor of heat, and an outer metallic vessel. This is necessary in order that the least possible amount of heat should be lost from the vessels; nevertheless, there is always a certain loss, the magnitude of which is determined by preliminary experiment (by taking warm water, and determining its fall in temperature after a definite period of time) as a correction for the results of observations. The water to which the heat of the burning substance

FIG. 37.—Favre and Silbermann's calorimeter for determining the heat evolved in combustion.

is transmitted is poured into the vessel. The stirrer *g* allows of all the layers of water being brought to the same temperature, which is determined by the thermometer. The heat evolved passes, naturally, not to the water only, but to all the parts of the apparatus. The quantity of water corresponding with the whole amount of those objects (the vessels, tubes, &c.) to which the heat is transmitted is previously determined, and in this manner another most important correction is made in the calorimetric determinations. The combustion itself is carried on in the vessel *a*. The ignited substance is introduced through the tube at the top, which closes tightly. In fig. 37 the apparatus is arranged for the combustion of a gas, introduced by a tube. The oxygen required for the combustion is led into *a* by the tube *e*, and the products of combustion either remain in the vessel *a* (if liquid or solid), or escape by the tube *f* into an apparatus in which their quantity and properties can easily be determined. Thus the heat evolved in combustion passes to the walls of the vessel *a*, and to the gases which are formed in it, and these transmit it to the water of the calorimeter.

The construction of the calorimeter and even the method of determination vary considerably in different cases. Since the beginning of the nineties, a large number of determinations of the heat of combustion have been conducted in closed bombs containing compressed oxygen. The greatest number of calorimetric determinations were made by Berthelot and by Thomsen. They are given in their works: *Essai de mécanique chimique fondée sur la thermochimie*, by M. Berthelot, 1879 (2 vols.), and *Thermochemische Untersuchungen*, by J. Thomsen, 1886 (4 vols.) The most important methods of recent thermochemistry, and all the trustworthy results of experiment, are given in Professor W. F. Louginin's *Description of the different Modes of determining the Heat of Combustion of Organic Compounds*, Moscow, 1894. The student must refer to works on theoretical and physical chemistry for a description of the elements and methods of **thermochemistry**, into the details of which it is impossible to enter in this work. One of the originators of thermochemistry, Hess, was a member of the St. Petersburg Academy of Sciences. Since 1870 a large amount of research has been carried out in this province of chemistry, especially in France and Germany, after the investigations of the French Academician, Berthelot, and Professor Thomsen, of Copenhagen. Among

in forming water evolves 34,462 units of heat. Many later determinations agree closely with this figure, so that it may be taken that in the formation of 18 parts of water (H_2O) there are evolved 69 major calories (each 1,000 times greater than the normal calorie, and therefore called kilogram-calories), or 69,000 units of heat.³⁸ *If the specific heat of aqueous vapour (0.48) remained constant from the ordinary temperature to that at which the combustion of detonating gas takes place* (and there is now no doubt that it increases rapidly, especially beyond $1,000^\circ$), were the combustion concentrated at one point³⁹ (but it occurs in the whole region of a flame), were there no loss from radiation and heat conduction, and *did dissociation* (which absorbs heat and consequently increases the apparent specific heat) *not take place*—that is, did not a state of equilibrium between the hydrogen, oxygen, and water come about—*then it would be possible to calculate the temperature of the flame of detonating gas.* It would then be $7,700^\circ$.⁴⁰ In reality it is

Russians, Beketoff, Werner, Louginin, Cheltzoff, Chroustchhoff, and others are known by their thermochemical researches. The present epoch of thermochemistry must be considered rather as a collective one, wherein the material of facts is being amassed, and the first consequences arising from them are being noticed. In my opinion two essential circumstances prevent the possibility of deducing any exact consequences, of importance to chemical mechanics, from the immense store of thermochemical data already collected: (1) The majority of the determinations are conducted in weak aqueous solutions, and, the heat of solution being known, are referred to the substances in solution; yet there is much (Chap. I.) which leads to the conclusion that water in solution does not play the simple part of a diluting medium, but of itself acts independently in a chemical sense on the substance dissolved. (2) Physical and mechanical changes (decrease of volume, diffusion, and others) invariably proceed side by side with chemical changes, and for the present it is impossible, in a number of cases, to distinguish the thermal effects of the one and the other kind of change. It is evident that the one kind of change (chemical) is essentially inseparable and incomprehensible without the other (mechanical and physical); and therefore it seems to me that thermochemical data will only acquire their true meaning when the connection between the phenomena of both kinds (on the one hand chemical and atomic, and on the other, mechanical and molecular or between entire masses) is explained more clearly and fully than is at present the case. As there is no doubt that the simple mechanical contact, or the action of heat alone, on substances sometimes causes an evident and always a latent (incipient) chemical change—that is, a different distribution or motion of the atoms in the molecules—it follows that purely chemical phenomena are inseparable from physical and mechanical phenomena. A mechanical change may be imagined without a physical change, and a physical without a chemical change; but it is impossible to imagine a chemical change without a physical and mechanical one, for without the latter we should not be able to recognise the former, and it is by their means that we are enabled to do so.

³⁸ This quantity of heat corresponds with the formation of water at the ordinary temperature from detonating gas at the same temperature. If the water be as vapour, the heat evolved is 58 major calories (because the latent heat of evaporation takes 600 calories per 1 part by weight of water, and there are 18 parts); if as ice, 70.4 major calories.

³⁹ This flame, or locality where the combustion of gases and vapours takes place, is a complex phenomenon, 'an entire factory,' as Faraday says, and therefore we will consider flame in some detail in one of the following notes.

⁴⁰ If 34,500 units of heat are evolved in the combustion of 1 part of hydrogen, and

very much lower, but it is nevertheless higher than the temperature

FIG. 38.—Safety burner for detonating gas, described in text.

attained in furnaces and flames, and is as high as $2,000^{\circ}$. The explosion of detonating gas is explained by this high temperature, because the aqueous vapour formed must occupy a volume at least five times greater than that occupied by the detonating gas at the ordinary temperature. Detonating gas emits a sound, not only as a consequence of the commotion which occurs from the rapid expansion of the heated vapour, but also because it is immediately followed by a cooling effect, the conversion of the vapour into water, and a rapid contraction.⁴¹

Mixtures of hydrogen and of various other combustible gases and vapours with oxygen are taken advantage of for obtaining high temperatures. By

the aid of such high temperatures, metals like platinum may be this heat is transmitted to the resulting 9 parts by weight of aqueous vapour, then we find that, taking the specific heat of the latter as 0.475 , each unit of heat raises the temperature of 1 part by weight of aqueous vapour 2.1° and 9 parts by weight ($2.1 \div 9$) 0.23° ; hence the $34,500$ units of heat raise its temperature $7,935^{\circ}$. If detonating gas is converted into water in a closed space, then the aqueous vapour formed cannot expand, and therefore, in calculating the temperature of combustion, the specific heat at constant volume must be taken into consideration; for aqueous vapour this is 0.36 . This figure gives a still higher temperature for the flame. In reality it is much lower, but the results given by different observers are very contradictory (from $1,700^{\circ}$ to $2,400^{\circ}$), the discrepancies depending on the fact that flames of different sizes are cooled by radiation to a different degree, but mainly on the fact that the methods and apparatus (pyrometers) for the determination of high temperatures, although they enable relative changes of temperature to be judged, are of little use for determining their absolute magnitudes. By taking the temperature of the flame of detonating gas as $2,000^{\circ}$, I give, I think, the average of the most trustworthy determinations and calculations based upon the determination of the variation of the specific heat of aqueous vapour and other gases.

The determination of the temperature of combustion or heating power (pyrometric effect, as it is often called) is considered more fully in speaking of combustion in my work, *The Principles of Industry. Fuel*, 1897, pp. 93–98. Why only $2,000^{\circ}$ is attained instead of $8,000^{\circ}$ is explained by the fact that between 0° and $2,500^{\circ}$ the *mean* apparent (combined with dissociation) specific heat of steam probably exceeds (judging from Mallard and Le Chatelier's observations, 1888) the specific heat of liquid water, and if the mean specific heat of steam be taken as about 1.9 , it is evident that only about $2,000^{\circ}$ will be obtained instead of $8,000^{\circ}$. Mallard and Le Chatelier showed that the mean specific heat of aqueous vapour up to the distinct commencement of dissociation may be taken as $0.4 + 0.0002t$. Dissociation is very considerable at the temperature of the flame of detonating gas, and this lowers the temperature or increases the apparent specific heat.

⁴¹ It is evident that not only hydrogen, but every other combustible gas and vapour, can

melted on a large scale, which cannot be performed in furnaces heated with charcoal and fed by a current of air of the ordinary temperature.^{41a} The burner shown in fig. 38 is constructed for the application of detonating gas to the purpose. It consists of two brass tubes, one fixed inside the other, as in the drawing. The inner central tube C C conducts the oxygen, and the outer, enveloping, tube, E' E', the hydrogen. Previous to their egress the gases do not mix together, so that there can be no explosion inside the apparatus. When the burner is in use, C is connected with a gas-holder containing oxygen, and E with a gasholder containing hydrogen (or sometimes coal-gas). The flow of the gases can be easily regulated by the stop-cocks O and H. The flame is shortest and evolves the greatest heat when the gases burning are in the proportion of 1 volume of oxygen to 2 volumes of hydrogen. The degree of heat may be easily judged from the fact that a thin platinum wire placed in the flame of a properly proportioned mixture readily melts. By placing the burner in the orifice of a hollow piece of lime, a crucible A B is obtained in which platinum may be readily melted, even in large quantities, if the current of oxygen and hydrogen be sufficiently great (Deville). The flame of detonating gas may also be used for illuminating purposes. By itself it is very pale, but owing to its high temperature, it serves for rendering infusible objects incandescent, and at the very high temperature produced by the detonating gas the incandescent substance gives a most intense light. For this purpose, lime, magnesia, or oxide of zirconium is used, as these are not fusible at the very high temperature generated by the detonating gas. A small cylinder of lime placed in the flame of detonating gas, if regulated to the required point, gives a very brilliant white light, which was at one time proposed for illuminating lighthouses. At present, in the majority

give an explosive mixture with oxygen. For this reason coal-gas mixed with air explodes when the mixture is ignited. The pressure obtained in the explosions serves as the **motive power of gas engines**. In this case advantage is taken, not only of the pressure produced by the explosion, but also of the contraction which takes place after the explosion. On this is based the construction of several motors, of which Lenoir's was formerly, and Otto's is now, the best known. The explosion is usually produced by coal-gas and air, but of late the vapours of combustible liquids (kerosene, benzine, naphtha) and the combustible gases of blast furnaces are also being employed (Chap. XXII.) In Lenoir's engine a mixture of coal-gas and air is ignited by means of sparks from a Ruhmkorff's coil; but in the most recent machines the gases are ignited by the direct action of a gas jet, or by contact with the hot walls of a side tube.

^{41a} However, if the air used for combustion be previously strongly heated, and charcoal or some combustible gas (lighting or generator, see Chap. IX., note 19) be burnt in it, then the melting-point of platinum (1,780°) and iron (1,450°) may be attained; and this is now taken advantage of in works in the so-called regenerator furnaces (see Chap. IX., note 19).

of cases, the electric light, owing to its constancy and other advantages, has replaced it for this purpose. The light produced by the incandescence of lime in detonating gas is called the **Drummond light** or **limelight**.

The above cases form examples of the combustion of elements in oxygen, but exactly similar phenomena are observed in the **combustion of compounds**. Thus, for instance, the solid, colourless, shiny substance, naphthalene, $C_{10}H_8$, burns in the air with a smoky flame, whilst in oxygen it continues to burn with a very brilliant flame. Alcohol, oil, and other substances burn brilliantly in oxygen on conducting the oxygen by a tube to the flames of lamps burning these substances. A high temperature is thus evolved, which is sometimes made practical use of in chemistry.

In order to understand why combustion in oxygen proceeds more rapidly, and is accompanied by a more intense heat effect, than combustion in air, it must be recollected that air is oxygen diluted with nitrogen, which does not support combustion, and therefore fewer particles of oxygen flow to the surface of a substance when burning in air than when burning in pure oxygen, and the heat evolved has, moreover, to heat the mass of nitrogen accompanying the oxygen as well as the products of combustion (and the oxygen).⁴²

⁴² Let us consider as an example the combustion of sulphur in air and in oxygen. If 1 gram of sulphur burns in air or oxygen it evolves in either case 2,250 units of heat, i.e., sufficient heat for heating 2,250 grams of water 1° C. This heat is first of all transmitted to the sulphurous anhydride, SO_2 , formed by the combination of sulphur with oxygen. In its combustion, 1 gram of sulphur forms 2 grams of sulphurous anhydride—i.e., 1 gram of the sulphur combines with 1 gram of oxygen. In order that 1 gram of sulphur should have access to 1 gram of oxygen in air, it is necessary that 3.4 grams of nitrogen should simultaneously reach the sulphur, because air contains 77 parts of nitrogen (by weight) per 23 parts of oxygen. Thus, in the combustion of 1 gram of sulphur, the 2,250 units of heat are transmitted to 2 grams of sulphurous anhydride and at least 3.4 grams of nitrogen. As 0.155 unit of heat is required to raise the temperature of 1 gram of sulphurous anhydride 1° C., 2 grams will require 0.31 unit. So also, 3.4 grams of nitrogen require 3.4×0.244 or 0.83 unit of heat, and therefore, in order to raise both gases 1° C., $0.31 + 0.83$ or 1.14 unit of heat is required; but as the combustion of the sulphur evolves 2,250 units of heat, the gases might be heated (if their specific heats remained constant) to $\frac{2250}{1.14}$ or $1,974^\circ$ C. That is, the

maximum possible temperature of the flame of sulphur burning in air will be $1,974^\circ$ C. In the combustion of the sulphur in oxygen the heat evolved (2,250 units) can only pass to the 2 grams of sulphurous anhydride, and therefore the highest possible temperature of the flame of sulphur in oxygen will be $= \frac{2250}{0.31}$ or $7,258^\circ$. This formation of

gaseous products in combustion must also lower the temperature of combustion. Therefore when a reaction takes place between solid bodies with the formation of solid bodies (or in general when the volume does not increase or varies but little, and all the more if contraction takes place), the heating effect may be very great. This is illustrated by a powdered mixture of molecular proportions of oxide of iron and metallic aluminium,

Among the phenomena accompanying the combustion of certain substances, the **phenomenon of flame** attracts attention. Sulphur, phosphorus, sodium, magnesium, naphthalene, &c. burn, like hydrogen, with a flame, whilst in the combustion of other substances no flame is observed, as, for instance, in the combustion of iron and of charcoal. The appearance of flame depends on the capacity of the combustible substance to yield gases or vapours at the temperature of combustion. At the temperature of combustion, sulphur, phosphorus, sodium, and naphthalene pass into vapour, whilst wood, alcohol, oil, &c. are decomposed into gaseous and vaporous substances. The combustion of gases and vapours forms flames, and therefore *a flame is composed of the hot incandescent gases and vapours produced by combustion*. It may easily be proved, by placing a tube in the flame connected with an aspirator, that the flames of such non-volatile substances as wood contain volatile and combustible substances formed from them. Besides the products of combustion, combustible gases and liquids, previously in the flame as vapours, collect in the aspirator. For this experiment to succeed—i.e., in order to really extract combustible gases and vapours from the flame—it is necessary that the suction tube should be placed *inside* the flame. The combustible gases and vapours can only remain unburnt inside the flame, for at its surface they come into contact with the oxygen of the air and burn.^{42a} Flames are of different degrees of **brilliancy**, according to whether *solid* incandescent particles occur in the combustible gas or vapour, or not. Incandescent gases and vapours emit but little light by themselves, and therefore give a paler flame.⁴³ If a flame does not contain solid particles it is transparent, pale, and emits but little light.⁴⁴ The flames of burning

Goldschmidt's thermite, which after ignition (by a magnesium wire bent into the mixture) burns and gives a temperature as high as $3,000^{\circ}$ (according to the equation $\text{Fe}_2\text{O}_3 + \text{Al}_2 = \text{Al}_2\text{O}_3 + \text{Fe}_2$) at which the resultant iron melts. The temperature is undoubtedly higher than in the hydrogen flame.

^{42a} Faraday proved this by a very convincing experiment on a candle flame. If one arm of a bent glass tube be placed in a candle flame in the dark portion of the flame above the wick, then the products of the partial combustion of the stearin will pass up the tube, condense in the other arm, and collect in a flask placed under it (fig. 39) as heavy white fumes which burn when lighted. If the tube be raised into the upper luminous portion of the flame, a dense black smoke which will not inflame accumulates in the flask. Lastly, if the tube be let down until it touches the wick, little but stearic acid condenses in the flask.

⁴³ All transparent substances which transmit light with great ease (that is, which absorb but little light) are but slightly luminous when heated; so also substances which absorb but few heat rays, when heated, transmit few rays of heat.

⁴⁴ There is, however, no doubt but that very heavy dense vapours or gases under pressure (according to the experiments of Frankland) are luminous when heated, because, as they become denser, they approach a liquid or solid state. Thus, detonating gas, when exploded under pressure, gives a brilliant light.

alcohol, sulphur, and hydrogen are of this kind. A pale flame may be rendered luminous by placing fine particles of solid matter in it. Thus, if a very fine platinum wire be placed in the pale flame of burning alcohol—or, better still, of hydrogen—the flame emits a bright light.

FIG. 39.—Faraday's experiment for investigating the different parts of a candle flame.

This is still better seen by sifting the powder of an incombustible substance, such as fine sand, into the flame, or by placing a bunch of asbestos threads in it. A brilliant flame always contains some kind of solid particles, or at least some very dense vapour. The flame of sodium burning in oxygen has a brilliant yellow colour, from the presence of particles of solid sodium oxide. The flame of magnesium is brilliant from the fact that, in burning, it forms solid magnesia, which becomes white hot, and similarly the brilliancy of the Drummond light is

due to the heat of the flame raising the lime to a state of incandescence. The flames of a candle, wood, and similar substances are brilliant, because they contain particles of charcoal or soot. It is not the flame itself which is luminous, but the incandescent soot it contains. These particles of charcoal which occur in flames may be easily observed by introducing a cold object, like a knife, into the flame.⁴⁵ The particles of charcoal burn at the outer surface of the flame if the supply of air is sufficient; but if the supply of air—that is, of oxygen—be insufficient for their combustion the flame will smoke, because the

⁴⁵ If hydrogen gas be passed through a volatile liquid hydrocarbon—for instance, through benzine (the benzine may be poured directly into the vessel in which the hydrogen is generated)—its vapour then burns with the hydrogen and gives a very bright flame, because the resultant particles of carbon (soot) become incandescent. Benzine or platinum gauze, introduced into a hydrogen flame, may be employed for illuminating purposes. The smoke of stoves, owing to imperfect combustion (due to various causes, especially to the imperfect mixture of the products of combustion with air and a local fall of temperature) of the fuel, frequently contains soot. This could not occur unless the soot had been previously formed in the flame.

unconsumed particles of charcoal are carried off by the current of air.⁴⁶

⁴⁶ In **flames**, the separate parts may be distinguished]with more or less distinctness. That portion of the flame to which the combustible vapours or gases flow is not luminous because its temperature is still too low for the process of combustion to take place in it. This is the space which in a candle surrounds the wick, or in a gas jet is immediately above the orifice from which the gas escapes. In a candle, the combustible vapours and gases formed by the action of heat on the melted tallow or stearin, rise in the wick and are heated by the high temperature of the flame. By the action of the heat, the solid or liquid substance is here, as in other cases, decomposed, forming products of dry distillation, and these products occur in the central portion of the flame of a candle. The air travels to it from the outside, and is not able to intermix equally with the vapours and gases in all parts of the flame at once; consequently in the outer portion of the flame the amount of oxygen will be greater than in the interior portions. But, owing to diffusion, the oxygen, of course mixed with nitrogen, flowing towards the combustible substance, does finally penetrate to the interior of the flame (when the combustion takes place in ordinary air). The combustible vapours and gases combine with this oxygen, evolve a considerable amount of heat, and bring about that state of incandescence which is so necessary both for keeping up the combustion and also for the uses to which the flame is applied. Passing from the colder envelope of air through the interior of the flame to the source of the combustible vapours (for instance, the wick), we evidently first traverse layers of higher and higher temperature, and then portions which are less and less hot, in which the combustion is less complete, owing to the limited supply of oxygen.

Thus, unburnt products of the decomposition of organic substances occur in the interior of the flame. But there is always free hydrogen in the interior of the flame, even when oxygen is introduced there, or when a mixture of hydrogen and oxygen burns, because the temperature evolved in the combustion of hydrogen or the carbon of organic matter is so high that the products of combustion are themselves partially decomposed—that is, dissociated—at this temperature. Hence, in a flame a portion of the hydrogen and of the oxygen which might combine with the combustible substances must always be present in a free state. If a hydrocarbon burns, and we imagine that a portion of the hydrogen is in a free state, then a portion of the carbon must also occur in the same form in the flame, because, other conditions being unchanged, carbon burns after hydrogen, and this is actually observed in the combustion of various hydrocarbons. Charcoal, or the soot of a common flame, arises from the dissociation of organic substances contained in the flame. The majority of hydrocarbons, especially those containing much carbon—for instance, naphthalene—burn, even in oxygen, with separation of soot. In that portion of the flame where the hydrogen burns, the carbon remains unburnt, or at least partly so. That the interior of the flame contains a mixture which is still capable of combustion may be proved by the following experiment. A portion of the gases may be withdrawn by an aspirator from the central portion of the flame of carbonic oxide, which is combustible in air. For this purpose Deville passed water through a metallic tube, having a fine lateral orifice, placed in the flame. As the water flows along the tube, portions of the gases of

FIG. 40.—In the candle flame the portion C contains the vapours and products of decomposition; in the bright zone A the combustion has commenced, and particles of carbon are emitted; and in the pale zone B the combustion is completed.

The combination of various substances with oxygen may not present any signs of combustion—that is, the temperature may rise but inconsiderably. This may proceed from the fact that either the reaction of the substance (for example, tin, mercury, lead at a high temperature, or a mixture of pyrogallol with caustic potash at the ordinary temperature) evolves but little heat, or the heat evolved is transmitted to good conductors of heat, like metals, and so dispersed, or combination with oxygen takes place so slowly that the heat evolved succeeds in gradually passing to the surrounding objects. Combustion is only a particular, intense, and evident case of combination with oxygen. Respiration is also an act of combination with oxygen: it also serves, like combustion, for the development of heat by those chemical processes which accompany it (the transformation of

the flame enter, and, passing along the tube alternately with small cylinders of water, are carried away into an apparatus where they can be investigated. It appears that all portions of the flame obtained by the combustion of a mixture of carbonic oxide and oxygen contain a portion of this mixture still unburnt. The researches of Deville and Bunsen showed that in the explosion of a mixture of hydrogen or of carbonic oxide with oxygen in a closed space, complete combustion never takes place immediately. If two volumes of hydrogen and one volume of oxygen be confined in a closed space and exploded, the pressure will not attain that magnitude which it would do, were there immediate and complete combustion. It may be calculated that the pressure should attain 20–30 atmospheres; but in reality it does not exceed $9\frac{1}{2}$ atmospheres.

Hence the admixture of the products of combustion with an explosive mixture prevents the combustion of the remaining mass, although this is capable of burning. Admixture of carbonic anhydride prevents carbonic oxide from burning. The presence of any other foreign gas interferes in the same manner. This indicates that every portion of a flame must contain combustible, burning, and already burnt substances—i.e., oxygen, carbon, carbonic oxide, hydrogen, hydrocarbons, carbonic anhydride, and water—in one place. Consequently **it is impossible to attain instantaneous complete combustion**, and this is one of the reasons of the phenomenon of flame. A certain space is required, and the temperature must be unequal in different parts of it. In this space different quantities of the component parts are successively subjected to combustion, and to partial cooling under the influence of adjacent objects. If the combustion could be concentrated at one spot, the temperature would be incomparably higher than it is under the actual circumstances.

The various regions of the flame have frequently formed the subject of experimental research, and the experiments conducted by Smithells and Ingle (1892) are particularly instructive: they show that the reducing (inner) and oxidising (outer) portions of the flame of a burning gas may be separated by taking a Bunsen burner and surrounding the flame of the gas burnt in it by another wider tube (either without the access of air to the annular space or allowing only a small current of air to pass), when a gaseous mixture, containing oxide of carbon and capable of further combustion, will issue from this enveloping tube, so that a second flame, corresponding to the exterior (oxidising) portion of an ordinary flame, may be obtained above the enveloping tube. This division of the flame into two portions is particularly clear when cyanogen, C_2N_2 , is burnt, because the interior portion (where CO is chiefly formed, according to the equation, $C_2N_2 + O_2 = 2CO + N_2$, but a portion of the nitrogen is oxidised) is of a rose colour, while the exterior portion (where the CO burns into CO_2 at the expense of a fresh quantity of oxygen and of the oxides of nitrogen proceeding from the interior portions) is of a bluish-grey colour.

oxygen into carbonic anhydride). Lavoisier enunciated this in the lucid expression, 'Respiration is slow combustion.'

Reactions involving slow combination of substances with oxygen are termed **oxidations**. Combination of this kind (and also combustion) often results in the formation of acid substances, and hence the name **oxygen** (*Sauerstoff*). Combustion is only rapid oxidation. Phosphorus, iron, and wine may be taken as examples of substances which oxidise slowly in air at the ordinary temperature. If such a substance is left in contact with a definite volume of air or oxygen, it will absorb the oxygen little by little. This slow oxidation is not often accompanied by a sensible evolution of heat; an evolution of heat really does occur, but is not apparent to our senses owing to the small rise in temperature which takes place; this is due to the slow rate of the reaction and to the dispersion of the heat formed as radiant heat, &c. Thus, in the oxidation of wine and its transformation into vinegar by the usual method of preparation of the latter, the heat evolved cannot be observed, because the process extends over several weeks; but in the so-called rapid process of the manufacture of vinegar, when a large quantity of wine is comparatively rapidly oxidised, the evolution of heat is quite apparent.

Such slow processes of oxidation are always taking place in nature by the action of the atmosphere. Dead organisms and the substances obtained from them—such as bodies of animals, wood, wool, grass, &c.—are especially subject to this action. They **rot** and **decompose**—that is, their solid matter is gradually transformed, completely or partially, into gases, under the influence of moisture and atmospheric oxygen, and generally under the influence of other organisms, such as moulds, worms, micro-organisms (bacteria), and the like. These are processes of slow combustion, of slow combination with oxygen. It is well known that manure rots and develops heat and that stacks of damp hay, damp flour, straw, &c., become heated and are changed in the process.⁴⁷ In all these transformations the same chief products of combustion are formed as those which are contained in smoke: the carbon gives carbonic anhydride, and the hydrogen, water. Hence these processes require oxygen just like combustion. This is the reason why the entire prevention of access of air hinders these transformations⁴⁸ and an

⁴⁷ Cotton waste (used in factories for cleaning machines from lubricating oil), soaked in oil and lying in heaps, is self-combustible, being oxidised by the air. In general, the oxidation of combustible bodies (for instance, of coal containing pyrites undergoing oxidation) may produce spontaneous combustion.

⁴⁸ When it is desired to preserve a supply of vegetable and animal food, the access of the oxygen of the atmosphere (and also of the germs of organisms present in the air) is often prevented. With this object, articles of food are often kept in hermetically closed

increased supply of air accelerates them. The mechanical treatment of arable lands by the plough, harrow, and other similar means has not only the object of facilitating the spread of roots in the ground, and of making the soil more permeable to water, but it also serves to facilitate the access of the air to the component parts of the soil, as a consequence of which the organic remains of soil rot—as it were, breathe air and evolve carbonic anhydride. One acre of good garden land, in the course of a summer, evolves more than sixteen tons of carbonic anhydride.

It is not only vegetable and animal substances which are subject to slow oxidation in the presence of water and air. Some metals rust under these conditions. Many metallic sulphides (for example, pyrites) are very easily oxidised with access of air and moisture. So that processes of slow oxidation proceed throughout nature. However, there are many elements which do not, under any circumstances, combine directly with gaseous oxygen; nevertheless, their compounds with oxygen may be obtained. Platinum, gold, iridium, chlorine, and iodine are examples of such elements. In this case recourse is had to a so-called **indirect method of oxidation**—i.e., the given substance is combined with another element, and by a method of double decomposition, this element is replaced by oxygen. The oxides so formed often readily lose their oxygen. Such, for example,* are the compounds of oxygen with chlorine, nitrogen, and platinum, which evolve oxygen on heating, so that they may be used as oxidising agents. In this respect **oxidising agents**, or those compounds of oxygen which are employed in chemical and technical practice for transferring oxygen to other substances, are especially noteworthy. The most important among these is nitric acid or **aqua fortis**, which is rich in oxygen and capable of evolving it when heated, and easily oxidises a great number of substances. Thus, nearly all metals and organic substances containing carbon and hydrogen are more or less oxidised when heated with nitric acid. If strong nitric acid be taken, and a piece of burning charcoal be immersed in the acid, it continues to burn. Chromic acid acts like nitric acid, alcohol burning when mixed with it. Although the action is not so marked, even water may oxidise with its oxygen. Sodium is not oxidised in perfectly dry oxygen at the ordinary tem-

vessels, from which the air has been withdrawn; vegetables are dried and soldered up, while hot, in tin boxes; sardines are immersed in oil, &c. The removal of water from substances is also sometimes resorted to with the same object (the drying of hay, corn, fruits), as also is saturation with substances which absorb oxygen (such as sulphurous anhydride) or which hinder the growth of organisms forming the first cause of putrefaction, as in processes of smoking, embalming, and in the keeping of fishes and other animal specimens in spirit, &c.

perature, but it burns very easily in water and aqueous vapour. Charcoal can burn in carbonic anhydride—a product of combustion—forming carbonic oxide. Magnesium burns in the same gas, separating carbon from it. Speaking generally, combined oxygen can pass from one compound to another.

The products of combustion or oxidation—and in general the definite compounds of oxygen—are termed **oxides**. Some oxides are not capable of combining with other oxides—or combine with only a few, and then with the evolution of very little heat; others, on the contrary, easily enter into combination with many other oxides, and in general possess remarkable chemical activity. This difference, however, is not well defined, and will become clearer as we become acquainted with the various oxides.

The class of oxides capable of entering into mutual combination we will term **saline oxides**. They fall into two chief groups—at least as regards the most extreme members. The members of one group combine with the members of the other group with particular ease. As representative of one group may be taken the oxides of the metals, magnesium, sodium, calcium, &c. Representatives of the other group are the oxides formed by the non-metals, sulphur, phosphorus, carbon. Thus, if we take the oxide of calcium, or lime, and bring it into contact with oxides of the second group, combination very readily ensues with the evolution of heat. For instance, if we mix calcium oxide with oxide of phosphorus they form phosphate of lime. If we pass the vapour of sulphuric anhydride, obtained by the combination of sulphurous oxide with oxygen, over pieces of lime heated to redness, the sulphuric anhydride is absorbed by the lime with the formation of a substance called ‘calcium sulphate.’ The oxides of the first kind, which contain metals, are termed **basic oxides** or **bases**. Lime is a familiar example of this class. The oxides of the second group, which are capable of combining with the bases, are termed **anhydrides of the acids** or **acid oxides**. Sulphuric anhydride, SO_3 , may be taken as a type of the latter group. It is a compound of sulphur with oxygen, formed not directly, but by the addition of a fresh quantity of oxygen to sulphurous anhydride, SO_2 , by passing it together with oxygen over incandescent spongy platinum. Carbonic anhydride, phosphoric anhydride, sulphurous anhydride, are all acid oxides.

If a given element forms but one basic oxide, it is termed the **oxide**; for example, calcium oxide, magnesium oxide, potassium oxide. Some indifferent oxides are also called ‘oxides,’ if they have not the properties of peroxides and at the same time do not show the properties of acid anhydrides; for example, carbonic oxide, of which mention has already

been made. If an element forms two basic oxides (or two indifferent oxides not having the characteristics of a peroxide), that of the lower degree of oxidation is called a **suboxide**—that is, suboxides contain less oxygen than oxides. Thus, when copper is heated to redness in a furnace, it increases in weight and absorbs oxygen, until for 63 parts of copper there is absorbed not more than 8 parts of oxygen by weight, forming a red mass, which is suboxide of copper, Cu_2O ; but if the roasting be prolonged, and the draught of air increased, 63 parts of copper absorb 16 parts of oxygen, and form black oxide of copper, CuO . Sometimes, to distinguish between the degrees of oxidation, a change of suffix is made in the oxidised element, **-ic** oxide denoting the higher degree of oxidation, and **-ous** oxide the lower degree. Thus ferrous oxide, FeO , and ferric oxide, Fe_2O_3 , are the same as suboxide of iron and oxide of iron. If an element forms one acid anhydride only, it is then named by an adjective formed from the name of the element made to end in **-ic** and the word **anhydride**. When an element forms two anhydrides, then the suffixes **-ous** and **-ic** are used to distinguish them, **-ous** signifying less oxygen than **-ic**; for example, sulphurous and sulphuric anhydrides.⁴⁹ When several oxides are formed from the same

⁴⁹ It must be remarked that certain elements form oxides of both chief kinds—i.e., basic and acid; for example, manganese forms the basic oxides: manganous oxide and manganic oxide, and the acid oxides: red oxide of manganese and manganic anhydride. Between them stands the dioxide (or peroxide) which was mentioned above and is a feeble base and a feeble acid anhydride. The basic oxides contain less oxygen than the peroxides, and the peroxides less than the acid anhydrides. The majority of elements, however, do not give all three kinds of oxides, some giving only one degree of oxidation. It must further be remarked that there are oxides formed by the combination of acid anhydrides with basic oxides, or, in general, of oxides with oxides. For every oxide having a higher and a lower degree of oxidation, it might be said that the intermediate oxide was formed by the combination of the higher with the lower oxide. But this is not true in all cases—for instance, when the oxide under consideration forms a whole series of independent compounds—for oxides which are really formed by the combination of two other oxides do not give such independent compounds, but in many cases decompose into the higher and lower oxides. As the intensity of the basic and acid properties varies considerably in different oxides, and some oxides combine (form salts) both with powerful bases and with strong acids, the nomenclature of the oxides, based on their salt-forming capacity, is more or less conventional and founded on historical tradition. Therefore, it is now often customary to name the oxides after the number of atoms of oxygen they contain; for instance, SO_2 , dioxide of sulphur; SO_3 , trioxide of sulphur; MnO , monoxide of manganese; Mn_2O_3 , sesquioxide of manganese; MnO_2 , dioxide of manganese, &c. But this method has the disadvantage of ignoring the qualities of the oxides, which are historically of primary importance in chemistry. Therefore (for science not founded on history is absurd), in this work, the *quantitative* nomenclature is only had recourse to where the oxides do not possess distinctly basic, acid, or peroxide properties; for example, MnO_2 and PbO_2 are better named dioxides than peroxides, as the latter (see Chapter IV.) are assumed to possess a special series of particular properties. A nomenclature, like a language, must always be a matter of conventional agreement. The propagation of knowledge depends largely upon it; but the substance and essence of knowledge do not, for language is a means and not an end

element, the prefixes **mono-**, **di-**, **tri-**, **tetra-**, are used, thus; chlorine monoxide, chlorine dioxide, chlorine trioxide, and chlorine tetroxide or chloric anhydride.

The majority of, if not all, basic and acid oxides combine with water, either by a direct or an indirect method, forming **hydrates**, that is, compounds which split up only into water and an oxide. It is well known that many substances are capable of combining with water. Oxides possess this property in the highest degree. We have already seen examples of this (Chapter I.) in the combination of lime, and of sulphuric and phosphoric anhydrides, with water. The resulting combinations are basic and acid hydrates. Acid hydrates are called **acids** because they have an acid taste when dissolved in water (or saliva), for then only can they act on the palate. Vinegar, for example, has an acid taste because it contains acetic acid dissolved in water. Sulphuric acid, H_2SO_4 , to which we have frequently referred, because it is the acid of the greatest importance both in practical chemistry and for its technical applications, is really a hydrate formed by the combination of sulphuric anhydride, SO_3 , with water, H_2O . Besides their acid taste, dissolved acids or acid hydrates have the property of changing the blue colour of certain vegetable dyes to red. Of these dyes **litmus** is especially noticeable and is much used. It is the blue substance extracted from certain lichens, and is used for dyeing tissues blue: it gives a blue infusion with water. This infusion, on the addition of an acid, **changes from blue to red.**⁵⁰

⁵⁰ Blotting or unsized paper, soaked in a solution of litmus, is usually employed for detecting the presence of acids. This paper is cut into strips, and is called *test paper*; when dipped into acid it turns red. This is a most sensitive reaction, and may be employed for testing for the smallest traces of acids. If 10,000 parts by weight of water be mixed with 1 part of sulphuric acid, the coloration is distinct, and it is even perceptible on the addition of ten times more water. Certain precautions must, however, be taken in the preparation of such very sensitive litmus paper. Litmus is sold in lumps. Take, say, 100 grams of it; powder it, and add it to pure cold water in a flask; shake and decant the water. Repeat this three times. This is done to wash away easily soluble impurities, especially alkalies. Transfer the washed litmus (it is washed with absolute alcohol to remove the non-sensitive reddish colouring matter) to a flask, and pour in 600 c.c. of water, heat, and allow the hot infusion to remain for some hours in a warm place. Then filter, and divide the filtrate into two parts. Add a few drops of nitric acid to one portion, so that a faint red tinge is obtained, and then mix the two portions. Add spirit to the mixture, and keep it in a stoppered bottle (it soon spoils if left open to the air). This infusion may be employed directly; it reddens in the presence of acids, and turns blue in the presence of alkalis. If evaporated, a solid mass is obtained which is soluble in water, and may be kept unchanged for any length of time. The test paper may be prepared as follows:—Take a strong infusion of litmus and soak blotting-paper with it; dry the latter and cut it into strips, and use it as test paper for acids. For the detection of alkalis, the paper must be soaked in a solution of litmus just reddened by a few drops of acid; if too much acid be taken, the paper will not be sensitive. Such acids as sulphuric acid colour litmus, and especially its infusion, a brick-red colour, whilst more feeble acids,

Basic oxides, in combining with water, form hydrates, of which, however, very few are soluble in water. Those which are soluble in water have an alkaline taste like that of soap or of water in which wood ashes have been boiled, and are called **alkalies**. Alkalies have the property of restoring the blue colour to litmus which has been reddened by the action of acids. The hydrates of the oxides of sodium and potassium, NaHO and KHO , are examples of basic hydrates easily soluble in water. They are true alkalis, and are termed **caustic**, because they act very powerfully on the tissues of animals and plants. Thus NaHO is called 'caustic' soda.

The saline oxides are capable of combining together and with water. Water itself is an oxide, and not an indifferent one, for it can, as we have seen, combine with basic and acid oxides: it is a representative of a whole series of saline oxides, **intermediate oxides**, capable of combining with both basic and acid oxides. There are many such oxides, which, like water, combine with basic and acid anhydrides; for

such as carbonic, give a faint wine-red tinge. Test paper of a yellow colour is also employed: it is dyed by an infusion of turmeric roots in spirit. In alkalis it turns brown, but regains its original hue in acids. Many blue and other vegetable colouring matters may be used for the detection of acids and alkalis; for example, infusions of cochineal, violets, logwood, &c. Certain artificially prepared substances and dyes may also be employed. Thus rosolic acid, $\text{C}_{20}\text{H}_{16}\text{O}_8$, and phenolphthaleïn, $\text{C}_{20}\text{H}_{14}\text{O}_4$ (which is used in an alcoholic solution, and is not suitable for the detection of ammonia), are colourless in an acid, and red in an alkaline, solution. Cyanine is also colourless in the presence of acids, and gives a blue coloration with alkalis. Methyl-orange (yellow in an aqueous solution) is not altered by alkalis, but becomes pink with acids (weak acids have no action), &c. These are very sensitive tests. Their behaviour in respect to various acids, alkalis, and salts sometimes gives the means of distinguishing substances from each other, and even for distinguishing different stages of combination between bases and acids; but we will not enter upon the details of this subject, because it chiefly concerns certain portions of analytical chemistry.

However certain peculiarities of these two reagents, phenolphthaleïn and methyl-orange, deserve our attention, all the more as they may both be obtained in a perfectly chemically pure form exhibiting their peculiarities, and they were recommended by a special committee of the Paris Congress of Chemists in 1900. The former (phenolphthaleïn) reacts equally well with feeble and strong acids; whilst methyl-orange (otherwise known as helianthine) only reacts with strong mineral acids (H_2SO_4 , HCl , &c.), and is not acted upon by such feeble acids as carbonic, salicylic, &c. (which is often very convenient). The transition from the reddish acid solution to the colourless (from the addition of alkalis) and back is so distinct with phenolphthaleïn that it forms one of the most sensitive reagents. Methyl-orange is less sensitive, especially under artificial (yellow) illumination.

Attention must also be drawn to the fact that in calling a solution neutral, acid, or basic, according to the change of colour of litmus paper, it is necessary to add (or understand) 'with regard to litmus,' as other reagents may give other results. Here, again, as in the case of distinguishing bases from acids, or neutral salts from acid salts, &c., there is a certain conventionalism of speech or expression which it is very difficult to avoid, but which has very little significance to the science itself, although apparently important to the beginner. In such cases the student is advised, like Arago, to go on further, and the details will become gradually clear of themselves.

instance, the oxides of aluminium and tin, &c. From this it may be concluded that all oxides might be placed, in respect to their capacity for combining with one another, in one uninterrupted series, at one extremity of which would stand those oxides which do not combine with the bases—that is, the alkalis—while at the other end would be the acid oxides, and in between, those oxides which combine with one another and with both the acid and basic oxides. The further apart the members of this series are, the more stable are the compounds they form together, the more energetically do they act on each other, the greater as a rule the quantity of heat evolved in their reaction, and the more marked is their saline chemical character.

Although basic and acid oxides combine together, they rarely react on each other; this depends on the fact that the majority of them are solids or gases—that is, they occur in the state least prone to chemical reaction. The gaseo-elastic state is with difficulty destroyed, because it necessitates overcoming the elasticity proper to the gaseous particles. But the solid state is characterised by the immobility of its particles, whilst chemical action requires contact and hence a displacement and mobility. If solid oxides be heated, and especially if they be melted, reaction proceeds with great ease. But such a change of state rarely occurs in nature or in practice. For example, in the manufacture of glass, the oxides contained in it are combined together in a molten mass. But when oxides combine with water, and especially when they form hydrates soluble in water, the mobility of their particles increases to a considerable extent, and their interaction is greatly facilitated. Reaction then often takes place at the ordinary temperature—easily and rapidly; so that this kind of reaction belongs to the class of those which take place with unusual facility, and are, therefore, very often taken advantage of in practice, and are going on in nature at every step. We will now consider the reactions of oxides in the state of hydrates, not losing sight of the fact that water is itself an oxide with definite properties, and has, therefore, no little influence on the course of those changes in which it takes part.

If we take a definite quantity of an acid, and add an infusion of litmus to it, it turns red; the addition of an alkaline solution does not immediately alter the red colour of the litmus, but on adding more and more of the alkaline solution a point is reached when the red colour changes to violet, and then the further addition of a fresh quantity of the alkaline solution changes the colour to blue. This change of the colour of the litmus is a consequence of the formation of a new compound. This reaction is termed the **saturation** or **neutralisation** of the acid by the base, or *vice versâ*. The solution in which the acid

properties of the acid are saturated by the alkaline properties of the base is termed a **neutral** solution. Such a solution, although derived from the mixture of a base with an acid, does not exhibit either an acid or basic reaction towards litmus; yet it preserves many other signs of the acid and alkali. What takes place is essentially the same as in the formation of water from hydrogen and oxygen. It is observed that in such a definite admixture of an acid with an alkali, besides the changes in the colour of litmus there is a heating effect—i.e., an evolution of heat—which is alone sufficient to prove that there was chemical action. And, indeed, if the resultant violet solution be evaporated, there separates out, not the acid or the alkali originally taken, but a substance which has neither acid nor alkaline properties, but is usually solid and crystalline, having a saline appearance: this is a **salt** in the chemical sense of the word. Hence a salt is derived from the reaction of an acid on an alkali, in a certain definite proportion. The water here taken for solution plays no part other than that of a medium, facilitating the progress of the reaction. This is seen from the fact that the anhydrides of the acids are able to combine with basic oxides, and give the same salts as do the acids with the alkalis or hydrates. Hence, a salt is a compound of definite quantities of an acid and an alkali. In the latter reaction, water is separated out if the substance formed is the same as is produced by the combination of anhydrous oxides together.⁵¹ Examples of the formation of salts from acids and bases are easily observed, and are very often applied in practice. If we take, for instance, insoluble magnesium oxide (magnesia), it is easily dissolved in sulphuric acid, and on evaporation gives a saline substance, bitter, like all the salts of magnesium, and familiar to all under the name of Epsom salts, which is used as a purgative. If a solution of caustic soda—which is obtained, as we saw, by the action of water on sodium oxide—be poured into a flask in which charcoal has been burnt; or if carbonic anhydride, which is produced under so many circumstances, be passed through a solution of caustic soda, sodium carbonate or soda, Na_2CO_3 , of which we have spoken several times, and which is prepared on a large scale and often used in manufactures, is obtained. This reaction

⁵¹ That water really is separated in the reaction of acid on alkaline hydrates may be shown by taking some other intermediate hydrate—for example, alumina—instead of water. Thus, if a solution of alumina in sulphuric acid be taken, it will have, like the acid, an acid reaction, and will therefore colour litmus red. If, on the other hand, a solution of alumina in an alkali—say potash—be taken, it will have an alkaline reaction, and will turn red litmus blue. On adding the alkaline to the acid solution until neither an alkaline nor an acid reaction is produced, a salt is formed, consisting of sulphuric anhydride and potassium oxide. In this, as in the reaction of hydrates, an intermediate oxide is separated out—namely, alumina. Its separation will be very evident in this case, as alumina is insoluble in water.

is expressed by the equation, $2\text{NaHO} + \text{CO}_2 = \text{Na}_2\text{CO}_3 + \text{H}_2\text{O}$. Thus, the various bases and acids form an innumerable number of different salts.⁵² Salts constitute an example of definite chemical compounds, and both in the history and practice of science are most often cited as confirming the conception of definite chemical compounds. Indeed, all the indications of a definite chemical combination are clearly seen in the formation and properties of salts. Thus, they are produced from definite proportions of oxides, heat is evolved in their formation,⁵³ and

⁵² The mutual interaction of hydrates, and their capacity of forming salts, may be taken advantage of for determining the character of those hydrates which are insoluble in water. Let us imagine that a given hydrate, whose chemical character is unknown, is insoluble in water, so that it is impossible to test its reaction on litmus. It is then mixed with water, and an acid—for instance, sulphuric acid—is added to the mixture. If the hydrate taken be basic, reaction will take place, either directly or on heating, with the formation of a salt. In certain cases, the resultant salt is soluble in water, and this will at once show that combination has taken place between the insoluble basic hydrate and the acid, with the formation of a soluble salt. In those cases where the resultant salt is insoluble, the water still loses its acid reaction, and therefore it may be ascertained, by the addition of an acid, whether a given hydrate has a basic character, like the hydrates of oxide of copper, lead, &c. If the acid does not act on the given insoluble hydrate (at any temperature), then it has not a basic character, and it should be tested as to whether it has an acid character. This is done by taking an alkali, instead of the acid, and by observing whether the unknown hydrate then dissolves, or whether the alkaline reaction (entirely or partially) disappears. Thus it may be proved that hydrate of silica is acid, because it dissolves in alkalis and not in acids. If it be a case of an insoluble intermediate hydrate, then it will be observed to react on both the acid and alkali. An instance of this is hydrate of alumina, which is soluble both in caustic potash and in sulphuric acid.

The **degree of affinity** or chemical **energy** proper to oxides and their hydrates is very variable; some extreme members of the series possess it to a great extent. When acting on each other they evolve a large quantity of heat, and when acting on intermediate hydrates they also evolve heat to a considerable degree, as we saw in the combinations of lime and sulphuric anhydride with water. When extreme oxides combine they form stable salts, which are decomposed with difficulty, and often show characteristic properties. The compounds of the intermediate oxides with each other, or even with basic and acid oxides, present a very different case. However much alumina we may dissolve in sulphuric acid, we cannot saturate the acid properties of the sulphuric acid, and the resulting solution will always have an acid reaction towards litmus. So also, whatever quantity of alumina is dissolved in an alkali, the resulting solution will always present an alkaline reaction.

⁵³ In order to give an idea of the quantity of heat evolved in the formation of salts, I append a table of data for *very dilute aqueous solutions* of acids and alkalis, according to the determinations of Berthelot and Thomsen. The figures are given in major calories—that is, in thousands of units of heat. For example, 49 grams of sulphuric acid, H_2SO_4 , taken in dilute aqueous solution, when mixed with such an amount of a weak solution of caustic soda, NaHO , that a neutral salt is formed (when all the hydrogen of the acid is replaced by the sodium), evolves 15,800 units of heat.

	49 parts of H_2SO_4	63 parts of HNO_3		49 parts of H_2SO_4	63 parts of HNO_3
NaHO . . .	15·8	13·7	MgO . . .	15·6	13·8
KHO . . .	15·7	13·8	FeO . . .	12·5	10·7 (?)
NH_3 . . .	14·5	12·5	ZnO . . .	11·7	9·8
CaO . . .	15·6	13·9	Fe_2O_3 . . .	5·7	5·9
BaO . . .	18·4	13·9			

the chemical character of the oxides and many of the physical properties become hidden in their salts. For example, when gaseous carbonic anhydride combines with a base to form a solid salt, the elasticity of the gas quite disappears in its passage into the salt,⁵⁴ just as the elasticity of hydrogen and oxygen does in the formation of water.

Judging from the above, a salt is a compound of basic and acid oxides, or the result of the action of hydrates of these classes on each other, with separation of water. But salts may be obtained by other methods. It must not be forgotten that basic oxides are formed by metals, and acid oxides usually by non-metals. But metals and non-metals are capable of combining together, and a salt is frequently formed by the oxidation of such a compound. For example, iron very easily combines with sulphur, forming iron sulphide, FeS (as we saw in the Introduction); in air, and especially moist air, this absorbs oxygen, with the formation of the same salt, FeSO_4 , as may be obtained by the combination of the oxides of iron and sulphur ($\text{FeO} + \text{SO}_3$) or of the hydrates of these oxides ($\text{FeH}_2\text{O}_2 + \text{H}_2\text{SO}_4 = \text{FeSO}_4 + 2\text{H}_2\text{O}$). In general, salts are formed in most diverse reactions.^{54a} Hence, it cannot be said or supposed that a salt has the properties of the oxides, or must necessarily contain two kinds of oxides in itself. The derivation of

These figures cannot be considered as the heats of neutralisation, because the water here plays its part. Thus, for instance, sulphuric acid and caustic soda, in dissolving in water, evolve very much heat, and the resultant sodium sulphate, in dissolving in water, very little; consequently, the amount of heat evolved in an anhydrous combination will be different from that evolved in a hydrated combination. Those acids which are not energetic in combining with the quantities of alkalis required for the formation of normal salts of sulphuric or nitric acids always, however, give less heat. For instance, with caustic soda: carbonic acid gives 10.2, hydrocyanic 2.9, and hydrogen sulphide 3.9, major calories. And as feeble bases (for example, Fe_2O_3) also evolve less heat than those which are more powerful, so a certain general correlation between thermochemical data and the degree of affinity shows itself here, as in other cases (see Chapter II., note 7). This does not, however, give any reason for measuring the affinity which binds the elements of salts by the heat of their formation in dilute solutions. This is very clearly demonstrated by the fact that water is able to decompose many salts, and is separated in their formation.

⁵⁴ Carbonic anhydride evolves heat in dissolving in water. The solution easily dissociates and evolves carbonic anhydride, according to the law of Henry and Dalton (see Chapter I.). In dissolving in caustic soda, it either gives a normal salt, Na_2CO_3 , which does not evolve carbonic anhydride, or an acid salt, NaHCO_3 , which easily evolves carbonic anhydride when heated. The same gas, when dissolved in solutions of salts, acts in one or the other manner (see Chapter II., note 38). Here it is seen what a successive series of relations exists between compounds of a different order, between substances of different degrees of stability. By making a distinction between solutions and chemical compounds, we overlook those neutral transitions which in reality exist.

^{54a} For example, the sodium salt of formic acid, CHNaO_2 , is formed by the direct absorption of carbonic acid gas, CO_2 , by sodium hydride, NaH ; ammonium nitrite is formed directly from the nitrogen of the air, N_2 , and water, as a by-product in many cases of oxidation taking place in the air; calcium sulphite is obtained from the oxidation of calcium sulphide and polysulphides, and so on.

salts from oxides is merely one of the methods of their preparation. We saw, for instance, that in sulphuric acid it was possible to replace the hydrogen by zinc, and that by this means zinc sulphate was formed; so likewise the hydrogen in many other acids may be replaced by zinc, iron, potassium, sodium, and a whole series of similar metals, corresponding salts being obtained. The hydrogen of the acid, in all these cases, is exchanged for a metal, and a salt is obtained from the hydrate. Regarding a salt from this point of view, it may be said that **a salt is an acid in which hydrogen is replaced by a metal**. This definition shows that a salt and an acid are essentially compounds of the same series, with the difference that the latter contains hydrogen and the former a metal. Such a definition is more exact than the first definition of salts, inasmuch as it likewise includes those acids which do not contain oxygen, and, as we shall afterwards learn, there is a series of such acids. Such an element as chlorine gives compounds with hydrogen in which the hydrogen may be replaced by a metal, forming substances which in their reactions and external characters resemble the salts formed from oxides. Table salt, NaCl , is an example of this. It may be obtained by the replacement of hydrogen in hydrochloric acid, HCl , by the metal sodium, just as sulphate of sodium, Na_2SO_4 , may be obtained by the replacement of hydrogen in sulphuric acid, H_2SO_4 , by sodium. The external appearance of the resulting products, their neutral reaction, and even their saline taste, show their resemblance to one another.

To the fundamental properties of salts yet another must be added—namely, that they are more or less **decomposed by the action of a galvanic current**. The results of this decomposition are very different according to whether the salt is taken in a fused or dissolved state. But the decomposition may generally be so represented that the metal or cation appears at the electro-negative pole or cathode (like hydrogen in the decomposition of water, or its mixture with sulphuric acid), and the remaining parts of the salt, the anion, appear at the electro-positive pole or anode (where the oxygen of water appears). If, for instance, an electric current acts on an aqueous solution of sodium sulphate, Na_2SO_4 , we may assume that the sodium appears at the negative pole, and oxygen and the anhydride of sulphuric acid, i.e., the anion SO_4 , at the positive pole. But in the solution itself the result is different, for sodium decomposes water with evolution of hydrogen, forming caustic soda; consequently hydrogen will be evolved and caustic soda appear at the negative pole, while at the positive pole the sulphuric anhydride combines with water and forms sulphuric acid, and therefore oxygen

will be evolved and sulphuric acid formed round this pole.⁵⁵ In other cases, when the metal separated is not able to decompose water, it will be deposited in a free state. Thus, for example, in the decomposition of copper sulphate, copper separates out at the cathode, and oxygen and sulphuric acid appear at the anode; and if a copper plate be attached to the positive pole, then the oxygen evolved will oxidise the copper, and the oxide of copper will dissolve and be deposited at the negative pole—that is, a transference of copper from the positive to the negative pole ensues. The galvanoplastic art (electrotyping) is based on this principle.⁵⁶ The most radical and general properties of salts (including also such salts as table salt, which contain no oxygen) may therefore be expressed by representing the salt as composed of a metal M and a haloid X—that is, by expressing the salt by MX. In common table salt the metal is sodium, and the haloid, an elementary body, chlorine. In sodium sulphate, Na_2SO_4 , sodium is again the metal, but the complex group, SO_4 , is the haloid. In sulphate of copper, CuSO_4 , the metal is copper and the haloid the same as in the preceding salt. Such a representation of salts expresses with great simplicity the **capacity of every salt to enter into saline double decompositions with other salts**, this consisting in a mutual replacement of the metals in the salts. This exchange of their metals is the fundamental property of salts.^{56a} In the case of two salts with different metals

⁵⁵ This kind of decomposition may be easily observed by pouring a solution of sodium sulphate into a U-shaped tube and inserting electrodes in the two branches. If the solution be coloured with an infusion of litmus, it will easily be seen that it turns blue at the cathode, owing to the formation of sodium hydroxide, and red at the electro-positive pole, from the formation of sulphuric acid.

⁵⁶ In other cases the decomposition of salts by the electric current may be accompanied by much more complex results. Thus, when the metal of the salt is capable of a higher degree of oxidation, such a higher oxide may be formed at the positive pole by the oxygen which is evolved there. This takes place, for instance, in the decomposition of salts of silver and manganese by the galvanic current, peroxides of these metals being formed. Thus in the electrolysis of a solution of KCl, KClO_4 is formed, while with sulphuric acid (corresponding to SO_3) persulphuric acid, corresponding to S_2O_7 , is formed. But all the phenomena as yet known may be expressed by the above hypothesis, that the current decomposes salts into metals, which appear at the negative pole, and the remaining component parts, which appear at the positive pole. Many physico-chemical researches, starting with those of Faraday, Hittorf, and Kohlrausch, have been made on the mechanism of the transference of the ions, the velocity of their motion and their condition in solutions, especially during the last ten years. Further details on this complex subject and a criticism of the existing theories must be looked for in works on physical chemistry. Here it would be out of place to enlarge upon this subject, all the more so, as it has not yet had any direct influence upon purely chemical knowledge.

^{56a} The presence in salts MX of a metallic element M (in acids it is equivalent to hydrogen, in ammonium salts to ammonium, &c.) capable of easily entering into double decomposition with metals, taken either in the form of other salts, or in general of saline compounds, or else in the form of the metals themselves (especially Na, K, Zn, &c.), forms

and haloids, which are in solution or fused, or in any other manner brought into contact, the metals of these salts will always partially or wholly exchange places. If we designate one salt by MX, and the other by NY, then we either partially or wholly obtain from them new salts, MY and NX. Thus we saw, in the Introduction, that on mixing solutions of table salt, NaCl, and silver nitrate, AgNO₃, a white insoluble precipitate of silver chloride, AgCl, is formed and a new salt, sodium nitrate, NaNO₃, obtained in solution. If the metals of salts exchange places in reactions of double decomposition, it is clear that metals themselves, taken in a separate state, are able to act on salts, as zinc evolves hydrogen from acids, and as iron separates copper from copper sulphate. When, to what extent, and which metals displace each other, and how the metals are distributed between the haloids, will be discussed in Chapter X., where we shall be guided by those reflections and deductions which Berthollet introduced into the science at the beginning of the last century.

According to the above observations, an acid is nothing more than a salt of hydrogen. Water itself may be looked upon as a salt in which the hydrogen is combined with either oxygen or the aqueous radicle, OH; water will then be HOH, and alkalis or basic hydrates, MOH. The group OH, or the **aqueous radicle**, otherwise called **hydroxyl**, may be looked on as a haloid (a special X), like the chlorine in table salt, not only because the element Cl and the group OH very often change places, and combine with one and the same element, but also because free chlorine is very similar in many properties and reactions to peroxide of hydrogen, which has the same composition as the aqueous radicle, as we shall afterwards see in Chapter IV. Alkalis and basic hydrates are also salts consisting of a metal and hydroxyl; for instance,

the fundamental characteristic of the saline substances or primary compound bodies formed by the elements. These primary compounds form the first step in the study of chemistry. The further development of chemistry proved the existence of a vast series of more complex compounds, especially hydrocarbons, which do not evince the clearly expressed peculiarities of salts. Such are chiefly the 'organic' or complex carbon compounds studied by 'organic chemistry.' Although they include their acids, bases, and salts, the primary grouping of the elements of which they are made up is evidently different from that in salts, acids, &c., as the hydrogen in the hydrocarbons from which they proceed has not, or but rarely has (for instance, in acetylene, C₂H₂) the property possessed by 'metallic' hydrogen (as in HCl, H₂SO₄, NaHO, &c.) of being replaced by metals. The cause of this must evidently be looked for in the fundamental properties of the carbon, which enters into the composition of these compounds; but it must be confessed that at present there is no satisfactory or legitimate explanation for these peculiarities (the recognition of 'complex radicles' and such like concessions only presents a scheme or generalisation of the phenomenon, but not an explanation), or of the fundamental difference between the saline compounds of the elements and those organic compounds which do not evince saline properties. This is one of the great problems awaiting solution in chemistry, a science which is, strictly speaking, still young and new.

caustic soda, NaOH , which is therefore termed sodium hydroxide. According to this view, **acid salts** are those in which only a portion of the hydrogen is replaced by a metal, and a portion of the hydrogen of the acid remains. Thus sulphuric acid, H_2SO_4 , not only gives the normal salt Na_2SO_4 , with sodium, but also an acid salt, NaHSO_4 . A **basic salt** is one in which the metal is combined, not only with the haloids of acids, but also with the aqueous radicle of basic hydrates—for example, bismuth gives, not only a normal salt of nitric acid, $\text{Bi}(\text{NO}_3)_3$, but also basic salts, like $\text{Bi}(\text{OH})_2(\text{NO}_3)$.

As basic and acid salts of the oxygen acids contain hydrogen and oxygen, they are able to part with these as water and to give anhydro-salts, which it is evident will be compounds of normal salts with anhydrides of the acids or with bases. Thus the above-mentioned acid sodium sulphate corresponds with the anhydro-salt, $\text{Na}_2\text{S}_2\text{O}_7$, equal to 2NaHSO_4 , less H_2O . The loss of water is here, and frequently in other cases, brought about by heat alone, and therefore such salts are frequently termed **pyro-salts**; for instance, the preceding is sodium pyrosulphate ($\text{Na}_2\text{S}_2\text{O}_7$), or it may be regarded as the normal salt Na_2SO_4 + sulphuric anhydride, SO_3 . **Double salts** are those which contain either two metals, $\text{KAl}(\text{SO}_4)_2$, or two haloids.⁵⁷

⁵⁷ The above-enunciated generalisation of the conception of salts as compounds of the metals (simple, or compound, like ammonium, NH_4), with the haloids (simple, like chlorine, or compound, like cyanogen, CN , or the radicle of sulphuric acid, SO_4), capable of entering into double saline decomposition, which is in accordance with the general data respecting salts, was only gradually arrived at after a succession of most varied *propositions as to the chemical structure of salts*.

Salts belong to the class of substances which have been known since very early times, and have long been investigated in many directions. At first, however, no distinction was made between salts, acids, and bases. Glauber prepared many artificial salts during the latter half of the seventeenth century. Up to that time the majority of salts were obtained from natural sources, and that salt which we have referred to several times—namely, sodium sulphate—was named Glauber's salt, after this chemist. Rouelle distinguished normal, acid, and basic salts, and showed their action on vegetable dyes; but he also confounded many salts with acids (even now every acid salt ought to be regarded as an acid, because it contains hydrogen, which may be replaced by metals, and is hence the hydrogen of an acid). Baumé disputed Rouelle's opinion concerning the subdivision of salts, contending that only normal salts are true salts, and that basic salts are simple mixtures of normal salts with bases, and acid salts, mixtures with acids, since washing alone could remove the base or acid from them. Rouelle, in the middle of the last century, however, rendered a great service to the study of salts and the diffusion of knowledge respecting this class of compounds by his attractive lectures. Like the majority of the chemists of that period, he did not employ the balance in his researches, but satisfied himself with purely qualitative data. The first quantitative researches on salts were carried on about this time by **Wenzel**, who was the director of the Freiberg mines, in Saxony. Wenzel studied the double decomposition of salts, and observed that, in the double decomposition of neutral salts, a neutral salt was always obtained. He proved, by a method of weighing, that this is due to the fact that the saturation of a given quantity of a base requires equal relative quantities of different acids. Having taken two neutral salts—for example, sodium sulphate and calcium nitrate—let us mix their

Inasmuch as oxygen compounds predominate in nature, it should be expected from what has been said above that salts, rather than acids or bases, would occur most frequently in nature, for these latter would

solutions together. Double decomposition takes place, because calcium sulphate is formed, which is almost insoluble. However much we might add of each of the salts, the neutral reaction will still be preserved; consequently the neutral character of the salts is not destroyed by the interchange of metals; that is to say, that quantity of sulphuric acid which saturated the sodium is sufficient for the saturation of the calcium, and that amount of nitric acid which saturated the calcium is enough to saturate the sodium contained in combination with sulphuric acid in sodium sulphate. Wenzel was even convinced that matter does not disappear in nature, and on this principle he corrects, in his *Doctrine of Affinity*, the results of his experiments when he found that he obtained less than he had originally taken. Although Wenzel deduced the law of the double decomposition of salts quite correctly, he did not determine those quantities in which acids and bases act on each other. This was carried out at the end of the eighteenth century by **Richter**. He determined the quantities by weight of the bases which saturate acids, and of the acids which saturate bases, and obtained comparatively accurate results, although his conclusions were not correct, for he states that the quantity of a base saturating a given acid varies in arithmetical progression, and the quantity of an acid saturating a given base in geometrical progression. Richter studied the deposition of metals from their salts by other metals, and observed that the neutral reaction of the solution is not destroyed by this exchange. He also determined the quantities by weight of the metals replacing one another in salts. He showed that copper displaces silver from its salts, and that zinc displaces copper and a whole series of other metals. Those quantities of metals which were capable of replacing one another were termed **equivalents**.

Richter's teaching found no followers, because, although he fully believed in the discoveries of Lavoisier, yet he still held to the phlogistic reasonings which rendered his expositions very obscure. The work of the Swedish savant **Berzelius** in the beginning of the nineteenth century freed the facts discovered by Wenzel and Richter from the obscurity of former conceptions and led to their being explained in accordance with Lavoisier's views, and in the sense of the law of multiple proportions which had already been discovered by Dalton. On applying to salts those conclusions which Berzelius arrived at by a whole series of researches of remarkable accuracy, we arrive at the following law of equivalents—*one part by weight of hydrogen in an acid is replaced by the corresponding equivalent weight of any metal*; and, therefore, when metals replace each other, their respective weights are in the same ratio as their equivalents. Thus, for instance, one part by weight of hydrogen is replaced by 23 parts of sodium, 39 parts of potassium, 12 parts of magnesium, 20 parts of calcium, 28 parts of iron, 108 parts of silver, 33 parts of zinc, &c.; and, therefore, if zinc replaces silver, 33 parts of the zinc will take the place of 108 parts of silver, or 33 parts of zinc will be substituted by 23 parts of sodium, &c.

The doctrine of equivalents would be precise and simple did every metal only give one oxide or one salt. It is rendered complicated from the fact that many metals form several oxides, and consequently offer different equivalents in their different degrees of oxidation. For example, there are oxides containing iron in which its equivalent is 28—this is in the salts formed by the suboxide; and there is another series of salts in which the equivalent of iron equals $18\frac{2}{3}$ —which contain less iron, and consequently more oxygen, and correspond with a higher degree of oxidation—ferric oxide. It is true that the former salts are easily formed by the direct action of metallic iron on acids, and the latter only by a further oxidation of the compound formed already; but this is not always so. In the cases of copper, mercury, and tin, under different circumstances, salts are formed which correspond with different degrees of oxidation of these metals, and many metals have two equivalents in their different salts—that is, in salts corresponding with the

always tend to combine forming salts, especially through the medium of the all-pervading water. And, as a matter of fact, salts are found everywhere in nature. They occur in animals and plants, although in but

different degrees of oxidation. Thus it is impossible to endow every metal with one definite equivalent weight. Hence the conception of equivalents, while playing an important part from an historical point of view, appears, with a fuller study of chemistry, to be but subordinate to a higher conception, with which we shall afterwards become acquainted.

The fate of the theoretical views of chemistry was for a long time bound up with the history of salts. The clearest representation of this subject dates back to Lavoisier, and was systematically developed by Berzelius. This representation is called the **binary theory**. All compounds, and especially salts, are represented as consisting of two parts. Salts are represented as compounds of a basic oxide (a base) and an acid (that is, an anhydride of an acid, then termed an acid), whilst hydrates are represented as compounds of anhydrous oxides with water. Such an expression was employed not only to denote the most usual method of formation of these substances (where it would be quite true), but also to express that internal distribution of the elements by which it was proposed to explain all the properties of these substances. Copper sulphate was supposed to contain two most intimate component parts—copper oxide and sulphuric anhydride. This is an hypothesis. It arose from the so-called **electro-chemical hypothesis**, which supposed the two component parts to be held in mutual union, because one component (the anhydride of the acid) has electro-negative properties, and the other (the base in salts) electro-positive. The two parts are attracted together, like substances having opposite electrical charges. But as the decomposition of salts in a state of fusion by an electric current always gives a metal, that representation of the constitution and decomposition of salts called the **hydrogen theory of acids** is nearer the truth than that which considers salts as made up of a base and an anhydride of an acid. But the hydrogen theory of acids is also a binary hypothesis, and does not contradict the electro-chemical hypothesis, but is rather a modification of it. The binary theory dates from Rouelle and Lavoisier, the electro-chemical aspect was zealously developed by Berzelius, and the hydrogen theory of acids is due to Davy and Liebig.

These hypothetical views simplified and generalised the study of a complicated subject, and served to support further arguments; but when salts were in question it was equally convenient to follow one or the other of these hypotheses. But these theories were brought to bear on all other substances, on all compound substances. Those upholding the binary and electro-chemical hypotheses searched for two anti-polar component parts, and endeavoured to express the process of chemical reactions by electro-chemical and similar differences. As zinc replaces hydrogen, they concluded that it is more electro-positive than hydrogen, whilst they forgot that hydrogen may, under different circumstances, displace zinc—for instance, at a red heat. Chlorine and oxygen were considered as being of opposite polarity to hydrogen, because they easily combine with it; nevertheless both are capable of replacing hydrogen, and, what is very characteristic, in the replacement of hydrogen by chlorine in carbon compounds, not only does the chemical character often remain unaltered, but even the external form may remain unchanged, as was shown by Laurent and Dumas. These considerations undermine the binary, and more especially the electro-chemical, theory. An explanation of known reactions then began to be sought for, not in the difference of the polarity of the different substances, but in the joint influences of all the elements on the properties of the compound formed. This is the reverse of the preceding hypothesis.

This reversal was not, however, limited to the destruction of the tottering foundations of the preceding theory: it proposed a new doctrine, and laid the foundation for the modern progress of our science. This doctrine may be termed the **unitary theory**—that is, it strictly acknowledges the joint influences of the elements in a compound substance, denies the existence of separate and contrary components in them, regards copper

small quantity, because, as forming the last stage of chemical reaction, they are capable of only a few simple chemical transformations. And organisms are bodies in which a series of uninterrupted, varied, and active chemical transformations proceed, whilst salts, which only enter into double decompositions between each other, are little prone to such changes. But organisms always contain salts. Thus, for instance, bones contain calcium phosphate, the juice of grapes potassium tartrate (cream of tartar), certain lichens calcium oxalate, and the shells of mollusca calcium carbonate, &c. As regards water and soil, portions of the earth in which the chemical processes are less active, these are full of salts. Thus the waters of the oceans, and all others (Chap. I.), abound in salts, and in the soil, in the rocks of the earth's crust, in the upheaved lavas, and in the falling meteorites the salts of silicic acid, and especially its double salts, predominate. Saline substances also make up the composition of those limestones which often form mountain chains and whole thicknesses of the earth's strata, these consisting of calcium carbonate, CaCO_3 .

Thus we have seen oxygen in a free state and in various compounds of different degrees of stability, from unstable and slightly stable compounds (like Berthollet's salt and nitre) to the most stable silicon compounds, such as exist in granite. We saw an entirely similar gradation of stability in the compounds of water and of hydrogen. In all its aspects oxygen, as an element, or single substance, remains the same, however varied its chemical states, just as a substance may appear in many different physical states of aggregation. But our notion of the immense variety of the chemical states in which oxygen can occur would not be completely understood if we did not make ourselves acquainted with it in the form in which it occurs in ozone and peroxide

sulphate, for instance, as a strictly definite compound of copper, sulphur, and oxygen; then seeks for compounds which are analogous in their properties, and, placing them side by side, endeavours to express the influence of each element in determining the united properties of its compound. In the majority of cases it arrives at conclusions similar to those which are obtained by the above-mentioned hypotheses, but in certain special cases the conclusions of the unitary theory are in entire opposition to those of the binary theory and its corollaries. Cases of this kind are most often met with in the consideration of compounds of a more complex nature than salts, especially organic compounds containing hydrogen. But it is not in this change from an artificial to a natural system, important as it is, that the chief service and strength of the unitary doctrine lies. By a simple review of the vast store of data regarding the reactions of typical substances, it succeeded from its first appearance in establishing a new and important law; it introduced a new conception into science—namely, the conception of *molecules*, with which we shall soon become acquainted. The deduction of the law and of the conception of molecules has been verified by facts in a number of cases, and was the cause of the majority of chemists of our times deserting the binary theory and accepting the unitary theory, which forms the basis of the present work. **Laurent** and **Gerhardt** must be considered as the founders of this doctrine.

of hydrogen. In these it is most unstable and active, its energy having apparently increased. They illustrate fresh aspects of chemical correlations, and the variety of the forms in which matter can appear stand out clearly. We will therefore consider these two substances somewhat in detail.⁵⁸

⁵⁸ This consignment of ozone and peroxide of hydrogen to a separate chapter is all the more necessary, as the difference between saline oxides (capable of forming acids, bases, and salts) and peroxides, is held to all through this work. The former, which have been cursorily considered in the present chapter, correspond with water, the latter with peroxide of hydrogen and ozone. The peroxides always contain more oxygen than the saline oxides, and easily part with their excess of oxygen, which oxidises and in general reacts like the excess of oxygen in ozone and peroxide of hydrogen. Although in an arithmetical sense peroxide of hydrogen, H_2O_2 , is related to water in the same way as SO_3 to SO_2 , or Cu_2O_2 to Cu_2O or in general a higher degree of oxidation to a lower, yet in its reactions the difference appears to be far deeper, as I trust the reader will gradually recognise. Moreover water and the saline oxides corresponding with it have been studied far more than the peroxides, which play a more modest part in nature and the industries. The peroxides have their own special and important interest, which is not, however, so general a one as that presented by water and salts.

CHAPTER IV

OZONE AND HYDROGEN PEROXIDE—DALTON'S LAW

VAN MARUM, during the eighteenth century, observed that air, when subjected to the action of a series of electric sparks, acquired a peculiar smell and the property of combining with mercury at the ordinary temperature. This was afterwards confirmed by a number of fresh experiments. Even in the simple revolution of an electrical machine, when electricity diffuses into the air or passes through it, the peculiar and characteristic smell of ozone, proceeding from the action of the electricity on the oxygen of the atmosphere, is recognised. In 1840 Professor Schönbein, of Basle, turned his attention to this odoriferous substance, and showed that it is also formed, with the oxygen evolved at the positive pole, in the decomposition of water by the action of a galvanic current; also in the oxidation of phosphorus in damp air, and in the oxidation of a number of other substances (especially turpentine), although it is distinguished for its instability and capacity for oxidising other substances. The same gas is also formed in many cases where oxygen is formed at the ordinary (or a lower) temperature; for instance, in the decomposition of acidulated water by the galvanic current, by the action of gaseous fluorine on water ($3\text{H}_2\text{O} + 3\text{F}_2 = 6\text{HF} + \text{O}_3$), or by the action of sulphuric acid on permanganate of potassium,¹ &c. The characteristic smell of this substance gave it its name, from the Greek ὄζω, 'I emit an odour.' Schönbein pointed out that **ozone** is capable of oxidising many substances on which oxygen does not act at the ordinary temperature. For instance, that it oxidises silver, mercury, charcoal, and iron with great energy at the ordinary

¹ This experiment must be made with small quantities and with caution, as an explosion may easily take place.

Jörissen (1897) found that ozone is formed whenever oxygen oxidises at the ordinary temperature (in the slow oxidation of zinc, of $\text{P}(\text{C}_2\text{H}_5)_3$, of lead in the presence of sulphuric acid, the potassium in KCN in acting on gold, &c.). The molecules of oxygen then, as it were, always split up into two portions, one going to oxidise and the other forming ozone. This coincides with what is said later respecting the difference between oxygen gas, O_2 , and ozone, O_3 , in which only $\frac{1}{3}$ of the oxygen acts.

temperature, decolorises (oxidises) blue indigo and many other organic colouring matters, &c. It might be thought that ozone was some new compound substance, as it was at first supposed to be; but careful observations made in this direction have long since led to the conclusion that ozone is nothing but oxygen altered in its properties. This is most strikingly proved by the complete transformation of oxygen containing ozone into ordinary oxygen when it is passed through a tube heated to 250° . Further, at a low temperature pure oxygen gives ozone when electric sparks are passed through it (Marignac and De la Rive). Hence it is proved, both by synthesis and analysis, that ozone is that same oxygen with which we are already acquainted, only endowed with particular properties and in a particular state. By whatever method it be obtained, the amount of it contained in the oxygen is inconsiderable, generally only a small fraction per cent., rarely 2 per cent., and only under low temperatures as much as 20 per cent. The reason of this must be looked for first in the fact that *ozone in its formation from oxygen absorbs heat*, i.e., evolves heat, in its conversion into ordinary oxygen. If any substance be burnt in a calorimeter at the expense of ozonised oxygen, more heat is evolved than when it is burnt in ordinary oxygen, and Berthelot showed that this difference is very large—namely, 29,600 heat units correspond with every forty-eight parts by weight of ozone. This signifies that the transformation of forty-eight parts of oxygen into ozone is accompanied by the absorption of this quantity of heat, and that the reverse process evolves this quantity of heat. Therefore the passage of ozone into oxygen should take place easily and completely (as an exothermal reaction), like combustion. At 250° ozone entirely disappears, forming oxygen. Any rise of temperature may thus bring about the breaking up of ozone, and as a rise of temperature takes place in the action of an electrical discharge, there are, in an electric discharge, the conditions both for the preparation of ozone and for its destruction. Hence it is clear that the transformation of oxygen into ozone *as a reversible reaction* has a limit when a state of equilibrium is arrived at between the products of the two opposite reactions, that the phenomena of this transformation accord with the phenomena of *dissociation*, and that a fall of temperature should aid the formation of a large quantity of ozone.^{1a} Further, it is evident, from what has been said, that the

^{1a} This conclusion, deduced by me as far back as 1878 (*Moniteur Scientifique*) by conceiving the molecules of ozone (see later) as more complex than those of oxygen, and ozone as containing a greater quantity of heat than oxygen, has been proved experimentally by the researches of Mailfert (1880), who showed that the passage of a silent discharge through a litre of oxygen at 0° may form up to 14 milligrams of ozone, and at -30° up to 60 milligrams; but best of all in the determinations of Chappuis and Haute-

best way of preparing ozone is not by electric sparks,² which raise the temperature, but by the employment of a continual discharge or flow of electricity—that is, by the action of a **silent discharge**.³ For this reason all **ozonisers** (which are of most varied construction), or forms of apparatus for the preparation of ozone from oxygen (or air) by the action of electricity, now usually consist of sheets of metal—for instance, tinfoil—or a solution of sulphuric acid mixed with chromic acid, &c., separated by thin glass surfaces placed at short distances from each other, and between which the oxygen or air to be ozonised is introduced and subjected to the action of the silent discharge.⁴ Thus in Berthelot's

feuille (1880), who found that at a temperature of -25° a silent discharge converted 20 per cent. of oxygen into ozone, whilst at 20° it was impossible to obtain more than 12 per cent., and at 100° less than 2 per cent. of ozone was obtained.

² A series of electric sparks may be obtained by an ordinary electrical machine, the electrophorus machines of Holtz and Teploff, &c., Leyden jars, Ruhmkorff coils, or similar means, when the opposite electricities are able to accumulate at the terminals of conductors, and a discharge of sufficient electrical intensity passes through the non-conducting air or oxygen.

³ A silent discharge is such a combination of opposite statical (potential) electricities as takes place (generally between large surfaces) regularly, without sparks, slowly, and quietly (as in the dispersion of electricity). The discharge is only luminous in the dark; there is no observable rise of temperature, and therefore a larger amount of ozone is formed. But nevertheless, on continuing the passage of a silent discharge through ozone it is destroyed. For the action to proceed well a large surface is necessary, and consequently a source of electricity at a high potential. For this reason the silent discharge is best produced by a Ruhmkorff coil, this being the most convenient means of obtaining statical electricity at a considerable potential when the comparatively feeble current of a galvanic battery is employed.

⁴ *v. Babo's apparatus* was one of the first constructed for ozonising oxygen by means of a silent discharge (and is still one of the best). It is composed of a number (twenty or more) of long, thin, capillary glass tubes closed at one end. A platinum wire, extending along their whole length, is introduced into the other end of each tube, and this end is then fused up round the wire, the end of which protrudes outside the tube. The protruding ends of the wires are arranged alternately on two sides in such a manner that on each side there is an equal number of closed ends and wires. A bunch of such tubes (forty should make a bunch of not more than 1 cm. diameter) is placed in a glass tube, and the ends of the wires are connected with two conductors, and are fused to the ends of the surrounding tube. The discharge of a Ruhmkorff coil is passed through these ends of the wires, and the dry air or oxygen to be ozonised is passed through the tube. If oxygen be passed through, ozone is obtained in large quantities and free from oxides of nitrogen, which are formed to some extent when air is acted on. At low temperatures ozone is formed in large quantities. As ozone acts on corks and indiarubber, the apparatus should be made entirely of glass. With a powerful Ruhmkorff coil and forty tubes the ozonation is so powerful that the gas when passed through a solution of iodide of potassium not only sets the iodine free, but even oxidises it to potassium iodate, so that in five minutes the gas-conducting tube is choked up with crystals of the insoluble iodate. In the majority of ozonisers the two tubes are lined with sheet tin or other metal and oxygen is passed through the annular space through which the silent discharge takes place. This kind of ozoniser may be used for ozonising the air of hospitals, &c., for the purpose of disinfection (Chap. V.). Ozone is employed for bleaching, &c., but its application in general requires perfecting.

apparatus (fig. 41), the glass F and the tube A contain sulphuric acid, connected with the poles of a source of electricity, e.g., with the terminals

FIG. 41.—Berthelot's apparatus for the production of ozone by the silent discharge.

of a Ruhmkorff's coil. A silent discharge passes through the thin walls of the glass cylinders A and B, over all their surfaces, and consequently, if oxygen be passed through the apparatus by the tube C, it will be ozonised in the annular space between A and B. The ozonised oxygen escapes by the tube D, and may be introduced into any other apparatus.⁵

The properties of ozone⁶ distinguish it in many respects from oxygen. Ozone very rapidly decolorises indigo, litmus, and many other dyes by oxidising them. Silver is oxidised by it at the ordinary temperature, whilst oxygen is not able to oxidise silver even at high temperatures; a bright silver plate rapidly turns black (from oxidation) in ozonised oxygen. It is rapidly absorbed by mercury, forming the oxide; it transforms the lower oxides into

higher—for instance, sulphurous anhydride into sulphuric, nitrous oxide into nitric, arsenious anhydride (As_2O_3) into arsenic anhydride

⁵ In order to connect the ozoniser with any other apparatus it is impossible to make use of indiarubber, mercury, or cements, &c., because they are themselves acted on by, and act on, ozone. All connections must, as was first proposed by Brodie, be hermetically closed by sulphuric acid, which is not acted on by ozone. Thus, a cork is passed over the vertical end of a tube, over which a wide tube passes, so that the end of the first tube protrudes above the cork; mercury is first poured over the cork (to prevent its being acted on by the sulphuric acid), and then sulphuric acid is poured over the mercury. The protruding end of the first tube is covered by the lower end of a third tube immersed in the sulphuric acid.

⁶ The method above described is the only one which has been well investigated. The admixture of nitrogen, or even of hydrogen, and especially of silicon fluoride, appears to aid the formation and preservation of ozone. Amongst other methods for preparing ozone we may mention the following:—1. In the action of oxygen on phosphorus at the ordinary temperature, a portion of the oxygen is converted into ozone. At the ordinary temperature a stick of phosphorus, partially immersed in water and partially in air in a large glass vessel, causes the air to acquire the odour of ozone. It must further be remarked that if the air be left for long in contact with the phosphorus, or without the presence of water, the ozone formed is destroyed by the phosphorus. 2. By the action of sulphuric acid on peroxide of barium. If the latter be covered with strong sulphuric acid (the acid, if diluted with only one-tenth of water, does not give ozone), then at a low temperature the oxygen evolved contains ozone, and in much greater quantities than is obtained by the action of electric sparks or phosphorus. 3. Ozone may also be obtained by decomposing strong sulphuric acid by potassium manganate, especially with the addition of barium peroxide.

(As_2O_5), &c.⁷ But what is especially characteristic in ozone is the decomposing action it exerts on potassium iodide. Oxygen does not act on this salt, but ozone passed into a solution of potassium iodide **liberates iodine**, whilst the potassium is obtained as caustic potash, which remains in solution: $2\text{KI} + \text{H}_2\text{O} + \text{O} = 2\text{KHO} + \text{I}_2$. As the presence of minute traces of free iodine may be discovered by means of starch, with which it forms a very dark blue-coloured substance, a mixture of potassium iodide with starch paste will detect the presence of very small traces of ozone.⁸ Ozone is destroyed or converted into ordinary oxygen not only by heat, but also by long keeping, especially in the presence of alkalis, peroxide of manganese, chlorine, &c., and also when it acts by oxidation (see later).

⁷ It is said that ozone oxidises water and converts it into peroxide of hydrogen. Ozone takes up the hydrogen from hydrochloric acid; chlorine is liberated, and can dissolve gold. Iodine is directly oxidised by ozone, but not by oxygen. Ammonia, NH_3 , is oxidised by ozone into ammonium nitrite (and nitrate), $2\text{NH}_3 + \text{O} = \text{NH}_4\text{NO}_2 + \text{H}_2\text{O}$, and therefore a drop of ammonia, on falling into the gas, gives a thick cloud of the salts formed. Ozone converts colourless lead oxide into brown dioxide, and suboxide of thallium (which is colourless) into oxide (which is brown), so that this reaction is made use of for detecting the presence of ozone. Lead sulphide, PbS (black), is converted into sulphate, PbSO_4 (colourless), by ozone. A neutral solution of manganese sulphate gives a precipitate of manganese peroxide, and an acid solution may be oxidised into permanganic acid, HMnO_4 . With respect to the oxidising action of ozone on organic substances, it may be mentioned that with ether, $\text{C}_4\text{H}_{10}\text{O}$, ozone gives ethyl peroxide, which is capable of decomposing with explosion (according to Berthelot), and is decomposed by water into alcohol, $2\text{C}_2\text{H}_5\text{O}$, and hydrogen peroxide, H_2O_2 .

⁸ This reaction is the one usually made use of for detecting the presence of ozone. In the majority of cases paper is soaked in solutions of potassium iodide and starch. Such **ozonometrical** or iodised starch-paper, when damp, turns blue in the presence of ozone, and the tint obtained varies considerably (to black), according to the length of time it is exposed and to the amount of ozone present. Even the amount of ozone in a given gas may to a certain degree be judged by the shade of colour acquired by the paper if preliminary tests be made.

Test-paper for ozone is prepared in the following manner:—One gram of neutral potassium iodide is dissolved in 100 grams of distilled water; 10 grams of starch are then shaken up in the solution, and the mixture is boiled until the starch is converted into a jelly. This jelly is then smeared over blotting-paper and left to dry. It must be remarked, however, that *the colour of iodised starch-paper is changed, not only by the action of ozone, but by that of many other oxidisers*, the oxides of nitrogen (especially N_2O_4) and hydrogen peroxide. Houzeau proposed soaking common litmus-paper with a solution of potassium iodide, which in the presence of ozone would turn blue, owing to the formation of KHO. In order to determine if the blue colour is not produced by an alkali (ammonia) in the gas, a portion of the paper is not soaked in the potassium iodide, but moistened with water: this portion will then also turn blue if ammonia be present. A reagent for distinguishing ozone from hydrogen peroxide with certainty is not known, and therefore these substances in very small quantities (for instance, in the atmosphere) may easily be confounded. Formerly the mistake has frequently been made of ascribing the alteration of iodised starch-paper in the air to the presence of ozone (note 13a); at the present time there is reason to believe that it is most often due to the presence of nitrous acid (Illosvay, 1889).

Hence **ozone**, although it has the same **composition as oxygen**, differs from it in stability, and by the fact that it **oxidises** a number of substances very **energetically** at the ordinary temperature. In this respect ozone resembles the oxygen of certain unstable compounds, or oxygen at the moment of its liberation.

In ordinary oxygen and ozone we see an example of one and the same substance, in this case an element, appearing in two states. This indicates that the properties of a substance, and even of an element, may vary without its composition varying. Very many such cases are known. Such cases of a chemical transformation which determines a difference in the properties of one and the same element are termed cases of **isomerism**. The isomerism of elements is termed **allotropy**. The cause of isomerism evidently lies deep within the essential nature of a substance, and its investigation has already led to a number of results of unexpected importance and of immense scientific significance. It is easy to understand the difference between substances containing different elements or the same elements in different proportions. That a difference should exist in these cases necessarily follows, if, as our knowledge compels us, we admit that there is a radical difference between the various simple bodies or elements. But when the composition—i.e., the quality and quantity—of the elements in two substances is the same and yet their properties are different, it is clear that the conceptions of diverse elements and of the varying composition of compounds alone are insufficient for the expression of all the diversity of properties of matter in nature. Something else, still more profound and internal than the composition by weight of substances, must, judging from isomerism, determine the properties and transformation of substances.^{8a}

^{8a} Under that atomic (Chap. VII.) conception of matter which is recognised by modern science, isomerism cannot be regarded otherwise than as a modification in the distribution of similar atoms in space, that is, with respect to each other. Hence, among isomerides, we distinguish polymerides, which differ from each other chiefly in the number of atoms forming the individual system or molecule of the substance. Thus ozone, O_3 , by its density, is regarded as the polymeride of oxygen, O_2 . But isomerism may also occur with an equal number of atoms in the molecules, if their mutual distribution or *structure* (constitution) be different. In organic chemistry, where polymerides and other isomerides are very frequent, it is especially important to have in view not only the composition but also the structure of compounds. But this is a matter of secondary importance in the study of the elements, which forms the main object of the present work, because the properties of substances are chiefly determined by the properties of the elements they contain, and the main problem of study should be deducing the properties of substances from those of the elements, and therefore I consider the chief object of this work to be an expression of the properties of the chemical elements. And as the chemical elements can only be conceived from the simple and compound substances they form, they compose the chief subject of our work. It does not aim at embracing the whole province of

On what are the isomerism of ozone and oxygen, and the peculiarities of ozone, dependent? On what, besides the extra store of energy, which clearly expresses the peculiarities of ozone, rests the cause of its difference from oxygen? These questions for long occupied the minds of investigators, and were the motive for the most varied, exact, and accurate researches, which were chiefly directed to the study of the volumetric relations exhibited by ozone. In order to acquaint the reader with the previous researches of this kind, I cite the following from a memoir by Soret, in the 'Transactions of the French Academy of Sciences' for 1866:

'Our present knowledge of the volumetric relations of ozone may be expressed in the following manner:

'1. "Ordinary oxygen in changing into ozone under the action of electricity shows a diminution in volume." This was discovered by Andrews and Tait.

'2. "In acting on ozonised oxygen with potassium iodide and other substances capable of being oxidised, we destroy the ozone, but the volume of the gas remains unchanged." For the researches of Andrews, Soret, von Babo, and others showed that the proportion of ozonised oxygen absorbed by the potassium iodide is equal to the original contraction of volume of the oxygen—that is, in the absorption of the ozone the volume of the gas remains unchanged. From this it might be imagined that ozone, so to speak, occupies no space—is indefinitely dense.

'3. "By the action of heat ozonised oxygen increases in volume, and is transformed into ordinary oxygen. This increase in volume corresponds with the quantity of ozonised oxygen which is given up to the potassium iodide in its decomposition" (the same observers).

'4. These unquestionable experimental results lead to the conclusion that ozone is denser than oxygen, and that in its oxidising action it gives off that portion of its substance to which is due the increased density distinguishing it from ordinary oxygen.'

If we imagine (says Weltzien) that n volumes of ozone consist of n volumes of oxygen combined with m volumes of the same substance, and that ozone in oxidising gives up m volumes of oxygen and leaves n volumes of ordinary oxygen gas, then all the above facts can be explained; otherwise it must be supposed that ozone is infinitely dense. 'In order to determine the density of ozone' (we again cite Soret) 'recourse cannot be had to the direct determination of the weight of a given

chemistry, but only at acquainting the reader with that portion which concerns the doctrine of the chemical elements. In this respect it forms an introduction to chemistry as a science, but even then it is impossible to avoid mentioning the fundamental conceptions of structure and isomerism.

volume of the gas, because ozone cannot be obtained in a pure state. It is always mixed with a very large quantity of oxygen. It was necessary, therefore, to have recourse to such substances as would absorb ozone without absorbing oxygen and without destroying the ozone. Then the density might be deduced from the decrease of volume produced in the gas by the action of such solvents in comparison with the quantity of oxygen given up to potassium iodide. Advantage must also be taken of the determination of the increase of volume produced by the action of heat on ozone, if the volume occupied by the ozone before heating be known.' Soret found two such substances, turpentine and oil of cinnamon. 'Ozone disappears in the presence of turpentine. This is accompanied by the appearance of a dense vapour, which fills a vessel of small capacity (0.14 litre) to such an extent that it is impenetrable to direct solar rays.' On measuring the gaseous volume before and after the action of both volatile oils, a considerable decrease is remarked. On applying all the necessary corrections (for the solubility of oxygen in the oily liquids named above, for the pressures of their vapour, for the change of pressure, &c.) and making a series of comparative determinations, Soret obtained the following result: two volumes of ozone capable of being dissolved, when changed to ordinary oxygen (by heating with a wire brought to a red heat by a galvanic current) increase by one volume. Hence it is evident that in the formation of ozone three volumes of oxygen give two volumes of ozone—that is, its density (referred to hydrogen) is 24 if the density of oxygen is 16. Ladenburg (1900) verified and confirmed Soret's conclusion by a modified method and direct weighings.

The observations and determinations of Soret showed, therefore, that ozone is heavier than oxygen, and even than carbonic anhydride (because ozonised oxygen passes through fine orifices more slowly than either pure oxygen or its mixtures with carbonic anhydride), although lighter than chlorine (it flows more rapidly through such orifices than chlorine), and they indicated that **ozone is one and a half times denser than oxygen**, which may be expressed by designating a molecule of oxygen by O_2 and of ozone by O_3 , and hence ozone, OO_2 , is comparable with compound substances⁹ formed by oxygen, as, for instance, CO_2 ,

⁹ Ozone is, as it were, an oxide of oxygen, just as water is an oxide of hydrogen. Just as aqueous vapour is composed of two volumes of hydrogen and one volume of oxygen, which on combining condense into two volumes of aqueous vapour, so also two volumes of oxygen are combined with one volume of oxygen to give two volumes of ozone. In the action of ozone on different substances it is only that additional portion of the molecule, by which it differs from ordinary oxygen, that combines with other bodies, and that is why, under these circumstances, the volume of the ozonised oxygen does not change. Starting with two volumes of ozone, one-third of its weight is parted with, and two volumes of oxygen remain.

SO₂, NO₂, &c. This explains the chief differences between ozone and oxygen, and the cause of the isomerism, and at the same time leads one to expect ¹⁰ that ozone, being a gas which is denser than oxygen, would be liquefied much more easily. This was actually shown to be the case by Chappuis and Hautefeuille in 1880, in their researches on the **physical properties of ozone**, and therefore if ozonised air or oxygen be passed through a tube cooled by liquid air, the ozone is converted into a blue liquid of sp. gr. 1.46, which must be manipulated with extreme caution, as it passes into ordinary oxygen at the ordinary temperature, with the evolution of heat and violent explosion (owing to the rapid increase in volume). Its boiling-point under a pressure of 760 mm. is about -106° according to Olzewsky, and -125° according to Ladenburg. Liquid and compressed ¹¹ ozone is **sky-blue**. It explodes violently when suddenly compressed and heated, changing into ordinary oxygen and evolving, like all explosive substances, ¹² that excess of heat which distinguishes it from oxygen.

Thus, judging by what has been said above, ozone should be formed in nature, not only in the many processes of oxidation which go on, but also by the condensation of atmospheric oxygen. The significance of

The above observations of Soret on the capacity of turpentine for dissolving ozone, together with Schönbein's researches on the formation of ozone in the oxidation of turpentine and of similar volatile vegetable oils (entering into the composition of *perfumes*), also explain the action of this ethereal oil on a great many substances. It is known that turpentine oil, when mixed with many substances, promotes their oxidation. In this case it probably not only itself promotes the formation of ozone, but also dissolves ozone from the atmosphere, and thus acquires the property of oxidising many substances. It bleaches linen and cork, decolorises indigo, promotes the oxidation and hardening of boiled linseed oil, &c. These properties of turpentine oil are made use of in practice. Dirty linen and many stained materials are easily cleaned by turpentine, not only because it dissolves the grease, but also because it oxidises it. The admixture of turpentine with drying (boiled) oil, oil-colours, and lacs aids their rapid drying because it attracts ozone. Ozonisation perhaps explains the refreshing influence ethereal oils have in scents and other similar preparations, and also the salubrity of the air of pine forests. Water upon which a layer of turpentine oil has been poured acquires, when left standing in the light, the disinfecting and oxidising properties of ozonised turpentine (is this due to the formation of H₂O₂?).

¹⁰ The densest, most complex, and heaviest particles of matter, under similar conditions, should evidently be less capable of passing into a state of gaseous motion, should sooner attain a liquid state, and have a greater cohesive force. These theoretical premises, having been verified, do much to confirm the modern (Avogadro-Gerhardt's) theory of chemical molecules.

¹¹ The blue colour proper to ozone may be seen through a tube one metre long, filled with oxygen, containing 10 per cent. of ozone.

¹² All explosive bodies and mixtures (gunpowder, detonating gas, &c.) evolve heat in exploding—that is, the reactions which accompany explosions are exothermal. In this manner ozone in decomposing evolves latent heat, although generally heat is absorbed in decomposition. This shows the meaning and cause of explosion.

ozone in nature has often arrested the attention of observers. There is a series of ozonometrical observations which show the different amounts of ozone in the air at different localities, at different times of the year, and under different circumstances. But the observations made in this direction cannot be considered as sufficiently exact, because the methods in use for determining ozone were not quite accurate. It is, however, indisputable¹³ that the amount of ozone in the atmosphere is subject to variation; that the air of dwellings contains no ozone (it disappears in oxidising organic matter); that the air of fields and forests always contains ozone, or substances (peroxide of hydrogen) which act like it (on iodised starch paper, &c.)^{13a}, that the amount of ozone increases after storms; and that miasmata, &c., are destroyed by ozonising the atmosphere. It readily oxidises organic substances, and miasmata are produced by organic substances and the germs of organisms, all of which are easily changed and oxidised. Indeed, many miasmata—for instance, the volatile substance of decomposing organisms—are clearly destroyed or changed, not only by ozone, but also by many other powerfully oxidising substances, such as peroxide of hydrogen, chlorine water, potassium permanganate, and the like.¹⁴ All that is now known respecting the presence of ozone in the air may be summed up in the following words: A small quantity of an oxidising substance, resembling ozone in its reactions, has undoubtedly been observed and determined in the atmosphere, especially in fresh air, for instance after a storm; and it is very likely that this substance contains a mixture of such oxidising substances as ozone, peroxide of hydrogen, and the lower oxides of nitrogen (especially nitrous acid and its ammonium salt)

¹³ In Paris it has been found that the further one goes from the centre of the town the greater becomes the amount of ozone in the air. The reason of this is evident: in a city there are many conditions for the destruction of ozone. This is why we distinguish country air from that of cities by its freshness. In spring the air contains more ozone than in autumn; the air of fields more than the air of towns.

^{13a} The question of the presence of ozone in the air has not yet been fully elucidated, as those reactions by which ozone is generally detected are also common to nitrous acid (and its ammonium salt). Ilosvay de Ilosva (1889), in order to exclude the influence of such bodies, passed air through a 40 per cent. solution of caustic soda, and then through a 20 per cent. solution of sulphuric acid (these solutions, according to this author, do not destroy ozone), and tested the air thus purified for the presence of ozone. As no ozone was then detected, the author concludes that all the effects which were formerly ascribed to ozone should be referred to nitrous acid. But this conclusion requires more careful verification since the researches of Professor Schönbein on the presence of peroxide of hydrogen in the atmosphere.

¹⁴ The oxidising action of ozone may be taken advantage of for technical purposes; for instance, for destroying colouring matters. It has even been employed for bleaching tissues and for the rapid preparation of vinegar, although these methods have not yet received wide application.

produced from the elements of the atmosphere by oxidation and by the action of electrical discharges.¹⁵

Thus in ozone we see (1) the capacity of elements (and it must be all the more marked in compounds) of changing in properties without altering in composition; this is termed **isomerism**; (2) the capacity of certain elements for condensing themselves into molecules of different densities; this forms a special case of isomerism called **polymerism**; (3) the capacity of oxygen for appearing in a still more active and energetic chemical state than that in which it occurs in ordinary gaseous oxygen; and (4) the formation of unstable equilibria or chemical states, which are illustrated both by the ease with which ozone acts as an oxidiser and by its capacity for decomposing with explosion.¹⁶

Hydrogen peroxide.—Many of those properties which we have seen in ozone belong also to a peculiar substance containing oxygen and hydrogen and called hydrogen peroxide or oxygenated water. This substance was discovered in 1818 by Thénard. When heated it is decomposed into water and oxygen, evolving as much oxygen as is contained in the water remaining after the decomposition. That portion of oxygen by which hydrogen peroxide differs from water behaves in a number of cases just like the active oxygen in ozone, which distinguishes it from ordinary oxygen. In H_2O_2 , and in O_3 , one atom of oxygen acts as a powerful oxidiser, and on separating out it leaves H_2O or O_2 , which do not act so energetically, although they still contain oxygen.¹⁷ Both H_2O_2 and O_3 contain the oxygen, as it were, in a condensed state, and when freed from pressure by the forces (internal) of the elements in another substance, this oxygen is easily evolved, and therefore acts as oxygen does at the moment of its liberation. Both substances in decomposing, with the separation of a portion of their oxygen, *evolve* heat, whilst decomposition is usually accompanied by an absorption of heat.

¹⁵ The connection between ozone and peroxide of hydrogen, presently to be described, is so great that wherever one of them occurs, the other is sure to be found if the reaction proceeds in the presence of water; for instance, in the preparation of ozone by phosphorus, in flames, or by the action of BaO_2 on H_2SO_4 , &c. But this is readily understood if ozone and water form peroxide of hydrogen, as is now supposed. This reaction is probably expressed by the equation, $\text{O}_3 + \text{H}_2\text{O} = \text{O}_2 + \text{H}_2\text{O}_2$, although experimental proofs are yet wanting to confirm this.

¹⁶ A number of substances resemble ozone in one or other of these respects. Thus cyanogen, C_2N_2 , nitrogen chloride, &c., decompose with explosion and evolution of heat. Nitrous anhydride, N_2O , forms a blue liquid like ozone, and in a number of cases oxidises like ozone.

¹⁷ It is evident that there is a want of words here for distinguishing oxygen, O , as an ultimate **element** from oxygen, O_2 , as a **free element**. The latter should be termed oxygen gas did not custom and the length of the expression render it inconvenient.

Hydrogen peroxide is formed under many circumstances by combustion and oxidation, but in very limited quantities; thus, for instance, it is sufficient to shake up zinc with sulphuric acid, or even with water, to observe the formation of a certain quantity of hydrogen peroxide in the water.¹⁸ From this cause, probably, a series of different oxidation processes are accomplished in nature, and according to Professor Schöne, of Moscow, hydrogen peroxide occurs in the atmosphere, although in variable and small quantities, and probably its formation is connected with ozone, with which it has much in common. There is reason to think (but it has not been proved) that peroxide of hydrogen is directly formed by the action of ozone on water. The usual mode of formation of hydrogen peroxide, and the method by which it may be indirectly obtained,¹⁹ is by the double decomposition of an acid and

¹⁸ Schönbein states that the formation of hydrogen peroxide is to be remarked in every oxidation in water or in the presence of aqueous vapour. According to Struve, hydrogen peroxide is contained in snow and in rain water, and its formation, together with that of ozone and ammonium nitrate, is even probable in the processes of respiration and combustion. A solution of tin in mercury, or liquid tin amalgam, when shaken up in water containing sulphuric acid, produces hydrogen peroxide, whilst iron under the same circumstances does not give rise to its formation. The presence of small quantities of hydrogen peroxide in these and similar cases is recognised by many reactions. Among them, the action **on chromic acid** in the presence of ether is very characteristic. Hydrogen peroxide converts the chromic acid into a higher oxide, Cr_2O_7 , which is of a dark-blue colour and dissolves in ether. This ethereal solution is to a certain extent stable, and therefore the presence of hydrogen peroxide may be recognised by mixing the liquid to be tested with ether and adding a few drops of a solution of chromic acid. On shaking the mixture, the ether dissolves the higher oxide of chromium which is formed, and on rising to the top acquires a blue colour. The formation of hydrogen peroxide in the combustion and oxidation of substances containing or evolving hydrogen must be understood in the light of the conception, to be considered later, of molecules occupying equal volumes in a gaseous state. At the moment of its evolution a molecule H_2 combines with a molecule O_2 , and gives H_2O_2 . As this substance is unstable, a large proportion of it is decomposed, a small amount only remaining unchanged. If it is obtained, water is easily formed from it: this reaction evolves heat, and the reverse action is not very probable. Direct determinations show that the reaction, $\text{H}_2\text{O}_2 = \text{H}_2\text{O} + \text{O}$, evolves 22,000 heat units. From this it will be understood how easy is the decomposition of hydrogen peroxide, as well as the fact that a number of substances which are not directly oxidised by oxygen are oxidised by hydrogen peroxide or by ozone, which also evolves heat on decomposition. Such a representation of the origin of hydrogen peroxide was developed by me about 1870. Subsequently (1890) Traube has pronounced a similar opinion, stating that Zn under the action of water and air gives, besides ZnH_2O_2 , also H_2O_2 .

¹⁹ The formation of hydrogen peroxide from barium peroxide by a method of double decomposition is an instance of a number of **indirect methods of preparation**. A substance A does not combine with B, but A B is obtained from A C in its action on B D (see Introduction) when C D is formed. Water does not combine with oxygen, but when present in an acid it acts on the compound of oxygen with barium oxide, because this oxide gives a salt with an acid anhydride. It is to be remarked that the passage of barium oxide, BaO , into the peroxide, BaO_2 , is accompanied by the **evolution** of 12,100 heat units per 16 parts of oxygen by weight combined, but the passage of H_2O into the peroxide H_2O_2 does not proceed directly, because it would be accompanied by the **absorp-**

the peroxides of certain metals, especially those of potassium, calcium, and barium.²⁰ We saw, when speaking of oxygen (Chap. III.), that it is only necessary to heat the anhydrous oxide of barium to a red heat in a current of air or oxygen (or, better still, to heat it with potassium chlorate, and then to wash away the potassium chloride formed) to obtain peroxide of barium.²¹ Barium peroxide gives hydrogen peroxide by the action of dilute acids in the cold.²² The process of decomposition is very clear in this case: the hydrogen of the acid replaces the barium of the peroxide, a barium salt of the acid being formed, while the hydrogen peroxide formed in the reaction remains in solution.²³

tion of 22,000 units of heat per 16 parts by weight of oxygen combined. Barium peroxide, in acting on an acid, evidently evolves less heat than the oxide, and it is this difference of heat that is absorbed in the hydrogen peroxide.

²⁰ Dioxides of lead and manganese, and other analogous peroxides (see Chap. III., note 9), do not give hydrogen peroxide under these conditions, but yield chlorine with hydrochloric acid.

²¹ The impure barium peroxide obtained in this manner may be easily purified. For this purpose it is dissolved in a dilute solution of nitric acid. A certain quantity of an insoluble residue always remains, from which the solution is separated by filtration. The solution will contain not only the compound of the barium peroxide, but also a compound of the barium oxide itself, a certain quantity of which always remains uncombined with oxygen. The acid compounds of the peroxide and oxide of barium are easily distinguishable by their different stability. The peroxide gives an unstable compound, and the oxide a stable salt. By adding an aqueous solution of barium oxide to the resultant solution, the whole of the peroxide contained in the solution may be precipitated as a pure aqueous compound (Kouriloff, 1889, obtained the same result by adding an excess of BaO_2). The first portions of the precipitate will consist of impurities—for instance, oxide of iron—which are rejected. The barium peroxide then separates out, and is collected on a filter and washed; it forms a substance having a definite composition, $\text{BaO}_2 \cdot 8\text{H}_2\text{O}$. Pure hydrogen peroxide should always be prepared from such purified barium peroxide.

²² In the cold, strong sulphuric acid with barium peroxide gives ozone; when diluted with a certain amount of water it gives oxygen (see note 6), whilst hydrogen peroxide is only obtained by the action of very weak sulphuric acid. Hydrochloric, hydrofluoric, carbonic, hydrofluosilicic, and other acids, when diluted with water, also give hydrogen peroxide with barium peroxide. Schöne, who very carefully investigated hydrogen peroxide, showed that it is formed by the action of many of the above-mentioned acids on barium peroxide. In preparing peroxide of hydrogen by means of sulphuric acid, the solution must be kept cold. A solution of maximum concentration may be obtained by successive treatments with sulphuric acid of increasing strength. In this manner a solution containing from 2 to 3 grams of pure peroxide in 100 c.c. of water may be obtained.

²³ With the majority of acids, the salt of barium which is formed remains in solution; thus, for instance, by employing hydrochloric acid, hydrogen peroxide and barium chloride remain in solution. Complicated processes would be required to obtain pure hydrogen peroxide from such a solution. It is much more convenient to take advantage of the action of carbonic anhydride on the pure hydrate of barium peroxide (note 21). For this purpose the hydrate is stirred up in water, and a rapid stream of carbonic anhydride is passed through the water. Barium carbonate, insoluble in water, is formed, and the hydrogen peroxide remains in solution, so that it may be separated from the carbonate by filtering. Sometimes hydrofluosilicic acid is employed, its barium salt being also insoluble in water. The purest H_2O_2 is obtained by distilling *in vacuo*. But in the absence of water it easily decomposes, and cannot be kept for long. It keeps better if a small amount of acid be added to it.

The reaction is expressed by the equation, $\text{BaO}_2 + \text{H}_2\text{SO}_4 = \text{H}_2\text{O}_2 + \text{BaSO}_4$. It is best to take a cold dilute solution of sulphuric acid and to almost saturate (testing with litmus) it with barium peroxide, so that a small excess of acid remains; insoluble barium sulphate is formed. A more or less dilute (3–4 per cent.) aqueous solution of hydrogen peroxide is obtained. This solution may be concentrated, that is to say, evaporated in a vacuum over sulphuric acid. In this way the water may even be entirely evaporated from the solution of the hydrogen peroxide; but in this case it is necessary to work at a low temperature, and not keep the peroxide long in the rarefied atmosphere, as otherwise it decomposes.^{23a} A solution of peroxide of hydrogen (mixed with the solution of a salt of sodium, NaX) is used for bleaching (especially silk and wool) on a large scale, and is now usually prepared from peroxide of sodium, Na_2O_2 , by the action of dilute acids: $\text{Na}_2\text{O}_2 + 2\text{HX} = 2\text{NaX} + \text{H}_2\text{O}_2$.²⁴

When pure, hydrogen peroxide is a colourless liquid, without smell, and having a very unpleasant taste—such as belongs to the salts of many metals—the so-called ‘metallic’ taste. Water stored in zinc vessels has this taste, which is probably due to its containing hydrogen peroxide. The pressure of the vapour of hydrogen peroxide is less than that of aqueous vapour; this enables its solutions to be concentrated in a vacuum. The specific gravity of anhydrous hydrogen peroxide is 1.455–1.5. It has a bluish tint and decomposes, with the evolution of oxygen, when heated, especially if it is not perfectly pure. But if no solid powdery matter be present it evaporates without decomposition when heated under a low pressure (10–50 mm. of mercury). This is taken advantage of to obtain it pure. The water then passes over first, because it boils at a lower temperature. The more dilute the aqueous solution, the more stable it is. Very weak solutions may be distilled without decomposing the hydrogen peroxide. It decolorises solutions of litmus and turmeric, and acts in a similar oxidising manner on many colouring matters of organic origin (for which reason it is employed for bleaching tissues).^{24a}

^{23a} Hydrogen peroxide may be extracted from very dilute solutions by means of ether, which dissolves it. A solution of hydrogen peroxide in water may be concentrated by cooling it to a low temperature, when the water crystallises out—that is, is converted into ice—whilst the hydrogen peroxide remains in solution, as it only freezes at very low temperatures (in liquid air). It must be observed that hydrogen peroxide, in a strong solution in a pure state, is exceedingly unstable even at the ordinary temperature, and it must therefore be preserved in vessels always kept cold, as otherwise it evolves oxygen and forms water.

²⁴ Peroxide of sodium (Chap. XII., note 49) is prepared by burning sodium in dry air.

^{24a} Peroxide of hydrogen has an industrial application in the arts; for instance, (1) as a bleaching agent, it having the important advantage over chloride of lime, SO_2 , &c., of

Many substances decompose hydrogen peroxide, forming water and oxygen, without apparently suffering any change. In this case, substances in a state of fine division show a much quicker action than compact masses, from which it is evident that the action is here based on contact (see Introduction). It is sufficient to bring hydrogen peroxide into contact with charcoal, gold, dioxide of manganese, the alkalis, metallic silver, or platinum, to bring about the above decomposition,²⁵ which, if proceeding very rapidly with pure peroxide or strong solutions, may lead to an explosion. Besides which, hydrogen peroxide forms water and parts with its oxygen with great ease to a number of substances which are capable of being oxidised or of combining with oxygen, and in this respect is very like ozone and other **powerful oxidisers**.²⁶ To the class of contact phenomena, which

not acting upon the material under treatment: it may be used for bleaching feathers, hair, silk, wool, wood, &c., and it also removes stains of all kinds, such as wine, ink, and fruit-stains; (2) it destroys bacteria, as does ozone, without having any injurious effect upon the human body. It can also be used for washing all kinds of wounds, for purifying the air in the sick-room, &c.; and (3) as a preserving agent for potted meats, &c. A small amount of sulphuric acid is often added to the aqueous (3 per cent.) solution in order to store it for industrial purposes.

²⁵ As the result of careful research, certain of the *catalytic* or contact phenomena have been subjected to exact explanation, which shows that some substance present participates in these reactions, but does not affect the series of changes proceeding from mechanical actions alone. Thus, for instance, Schöne showed that with hydrogen peroxide, alkalies give peroxides of the alkaline metals, which combine with the remaining hydrogen peroxide, forming unstable compounds which are easily decomposed, and therefore alkalies evince a decomposing (catalytic) influence on solutions of hydrogen peroxide. Only acid solutions of hydrogen peroxide, and then only dilute ones, can be preserved well.

²⁶ **Hydrogen peroxide**, as a substance containing much oxygen (namely, 16 parts to one part by weight of hydrogen), exhibits many **oxidising reactions**. Thus, it oxidises arsenic, converts lime into calcium peroxide and the oxides of zinc and copper into peroxides. It parts with its oxygen to many sulphides, converting them into sulphates, &c.; thus, it converts black lead sulphide, PbS , into white lead sulphate, PbSO_4 , copper sulphide into copper sulphate, and so on. The restoration of old oil paintings by hydrogen peroxide is based on this action. Oil colours are usually admixed with white lead, and in many cases the colour of oil-paints becomes darker in process of time. This is partly due to the sulphuretted hydrogen contained in the air, which acts on white lead, forming lead sulphide, which is black. The intermixture of the black colour darkens the rest. In cleaning a picture with a solution of hydrogen peroxide, the black lead sulphide is converted into white sulphate, and the colours brighten owing to the disappearance of the black substance which previously darkened them. Hydrogen peroxide oxidises with particular energy substances containing hydrogen and capable of easily parting with it to oxidising substances. Thus it decomposes hydriodic acid, setting the iodine free and converting the hydrogen it contains into water; it also decomposes sulphuretted hydrogen in exactly the same manner, setting the sulphur free. Starch paste with potassium iodide is not, however, directly coloured by peroxide of hydrogen in the entire absence of free acids; but the addition of a small quantity of ferrous sulphate (green vitriol) or of lead acetate to the mixture is enough to entirely blacken the paste. This is, like chromic acid and ether (see note 8), a very sensitive reagent (test) for peroxide of hydrogen.

are so characteristic of hydrogen peroxide as a substance which is unstable and easily decomposable with the evolution of heat, must be referred the following: in the presence of many substances containing oxygen it evolves not only its own oxygen, but also that of the substances which are brought into contact with it—that is, **it acts in a reducing manner**. It behaves thus with the oxides of silver, mercury, gold, and platinum, lead dioxide, &c. The oxygen in these substances is not stable, and therefore the feeble influence of contact is enough to destroy its position. Hydrogen peroxide, especially in a concentrated form, in contact with these substances, evolves an immense quantity of oxygen, so that an explosion takes place, and an exceedingly powerful evolution of heat is observed if hydrogen peroxide in a concentrated form be made to drop upon these substances in the form of dry powder. The decomposition also proceeds with dilute solutions,²⁷ but more slowly.

Just as a whole series of saltlike compounds, especially the oxides, hydrates, and salts, correspond with water, so also there are many substances analogous to hydrogen peroxide. Thus, for instance, calcium peroxide is related to hydrogen peroxide in exactly the same way as calcium oxide or lime is related to water. In both cases the hydrogen is replaced by calcium.^{27a} But it is particularly instructive

²⁷ To explain the phenomenon, Brodie, Clausius, and Schönbein suppose ordinary oxygen to be an electrically neutral substance, composed, so to speak, of two oppositely electrified kinds of oxygen—positive and negative. It is supposed that hydrogen peroxide contains one kind of such polar oxygen, whilst in the oxides of the above-named metals the oxygen is of opposite polarity. It is further supposed that in the oxides of the metals the oxygen is electro-negative, and in hydrogen peroxide electro-positive, and that on the mutual contact of these substances ordinary neutral oxygen is evolved as a consequence of the mutual attraction of the oxygens of opposite polarity. Brodie admitted the polarity of oxygen in combination, but not in an uncombined state, whilst Schönbein supposes uncombined oxygen to be polar also and regards ozone as electro-negative oxygen. The supposition that the oxygen of ozone is different from that of hydrogen peroxide is contradicted by the fact that in acting on barium peroxide strong sulphuric acid forms ozone, and dilute acid forms hydrogen peroxide.

^{27a} It should be mentioned that Schiloff (1893) on taking a 3 per cent. solution of H_2O_2 , adding soda to it, and then extracting the peroxide of hydrogen from the mixture by shaking it with ether, obtained a 50 per cent. solution of H_2O_2 , which, although perfectly free from other acids, gave a **distinctly acid reaction** with litmus. And here attention should first of all be turned to the fact that the peroxides of the metals correspond with H_2O_2 , like salts with an acid, for instance, Na_2O_2 and BaO_2 , &c. Furthermore, it must be remembered that O is an analogue of S (Chaps. XV. and XX.), and sulphur gives H_2S , H_2SO_3 , and H_2SO_4 . And sulphurous acid, H_2SO_3 , is unstable as a hydrate, and forms water and the anhydride SO_2 . If the sulphur be replaced by oxygen, then instead of H_2SO_3 and SO_2 , we have H_2OO_3 and OO_2 . The latter is ozone, while K_2O_4 (peroxide of potassium) corresponds with the hydrate H_2O_4 as with an acid. And between H_2O and H_2O_4 there may exist intermediate compounds, the first of which would be H_2O_2 , in which, from analogy to the sulphur compounds, one would expect acid properties. Besides which we may mention that for sulphur, besides H_2S (which is a

to remark that the nearest approach to the properties of hydrogen peroxide is afforded by a non-metallic element, chlorine, which, in its action on colouring matters, its capacity for oxidising and for evolving oxygen from many oxides, exhibits behaviour analogous to that of hydrogen peroxide. Even the very formation of chlorine is closely analogous to the formation of peroxide of hydrogen; chlorine is obtained from manganese peroxide (dioxide), MnO_2 , and hydrochloric acid, HCl , and hydrogen peroxide from barium peroxide (dioxide), BaO_2 , and the same acid. The result in one case is essentially water, chlorine, and manganese chloride; and in the other case, barium chloride and hydrogen peroxide are produced. Hence water + chlorine corresponds with hydrogen peroxide, and the action of chlorine in presence of water is analogous to the action of hydrogen peroxide. This analogy between chlorine and hydrogen peroxide is expressed in the conception of an aqueous radicle, which (Chapter III.) has already been mentioned. **This aqueous radicle** (or hydroxyl, HO) is that which is left if water be imagined to be deprived of half of its hydrogen. According to this method of expression, caustic soda will be a compound of sodium with the aqueous radicle, because it is formed from water with the evolution of half the hydrogen. This is expressed by the following formulæ: water, H_2O or HHO and caustic soda, NaHO , just as hydrochloric acid is HCl and sodium chloride NaCl . Hence the aqueous radicle HO is a compound radicle, just as chlorine, Cl , is a simple radicle. They both

feeble acid), H_2S_2 , H_2S_3 , H_2S_5 are known. Thus, in many respects, H_2O_2 offers points of resemblance to acid compounds, and, as regards its qualitative (reactive) analogies, it not only resembles Na_2O_2 , BaO_2 , &c., but also persulphuric acid HSO_4 (to which the anhydride S_2O_7 corresponds), &c., which will be subsequently described. And here we may add, respecting the now vast class of per-compounds, (*a*) that they are formed under the same conditions as peroxide of hydrogen (for instance, by electrolysis, at the anode) or by its double decomposition or combination; (*b*) that elements like S , C , &c., which give acids, are able to form per-compounds or per-acids, which in their turn form salts with the alkalis; for instance, per-sulphuric acid; (*c*) that metals like molybdenum, vanadium, &c., which give higher acid oxides, R_2O_n , are usually able also to form per-acids corresponding with the higher oxides and oxygen; (*d*) that metals giving bases R_2O_n are often able also to form peroxides, containing a further amount of oxygen; for instance, sodium, barium, &c.; but these peroxides, while able to combine with other peroxides and per-acids, are apparently unable to give salts with ordinary acids; and (*e*) all such per-compounds are able to give peroxide of hydrogen, to the reactions of which their own are similar. Prof. P. G. Melikoff (Odessa) has done much work on the per-compounds of different elements, and has arrived at the following conclusions (1902): 1. The elements of high atomic weights belonging to the even series form per-acids by the action of H_2O_2 . 2. Among the typical elements (see Chap. XV.), only boron forms a per-acid by the action of H_2O_2 . 3. The typical elements, having acid properties (for instance, C , N), only form salts of the per-acids by electrolysis. Per-compounds are formed by the action of H_2O_2 on salts as well as on bases and acids. For instance, Kazanetsky showed that potash, K_2CO_3 , is able to form with H_2O_2 a saline compound, in which the excess of oxygen must be regarded as united, not to the basic or acid oxide, but to the salt formed by them, or else that H_2O_2 is able to attach itself to entire molecules like water of crystallisation.

give hydrogen compounds, HHO, water, and HCl, hydrochloric acid; sodium compounds, NaHO and NaCl, and a whole series of analogous compounds. Free chlorine in this sense will be ClCl, and hydrogen peroxide HOHO, which indeed expresses its composition, because it contains twice as much oxygen as water does.²⁸

Thus in ozone and hydrogen peroxide we see examples of very unstable, easily decomposable (in time spontaneously, and on contact) substances, full of the energy necessary for change,^{28a} capable of being easily reconstituted (in this case decomposing with the evolution of heat); they are therefore examples **of unstable chemical equilibria**. If a substance exists, it signifies that it already presents a certain form of equilibrium between those elements of which it is built up. But chemical, like mechanical, equilibria exhibit different degrees of stability or solidity.²⁹

Besides this, hydrogen peroxide presents another side of the subject which is none the less clear and of general importance.

Hydrogen unites with oxygen in two degrees of oxidation: water

²⁸ Tamman and Carrara showed, by determining the depression (fall of the temperature of the formation of ice, Chapters I. and VII.), that the molecule of peroxide of hydrogen contains H_2O_2 , and not HO or H_3O_3 .

^{28a} The lower oxides of nitrogen and chlorine and the higher oxides of manganese are also formed with the absorption of heat, and therefore, like hydrogen peroxide, act in a powerfully oxidising manner, and are not formed by the same methods as the majority of other oxides. It is evident that, being endowed with a richer store of energy (acquired in combination or by absorption of heat), such substances, compared with others poorer in energy, will exhibit a greater diversity of chemical action with other substances.

²⁹ If the point of support of a body lies in a vertical line below the centre of gravity, it is in unstable equilibrium. If the centre of gravity lies below the point of support, the state of equilibrium is very stable, and a vibration may take place about this position of stable equilibrium, as in a pendulum or balance, where the body finally assumes a position of stable equilibrium. But if, keeping to the same mechanical example, the body be supported, not on a point, in the geometrical sense of the word, but on a small plane, then the state of unstable equilibrium may be preserved, unless destroyed by external influences. Thus a man stands upright supported on a plane, or on several points of the surfaces of his feet, having the centre of gravity above the points of support. Vibration is then possible, but it is limited, otherwise on passing outside the limit of possible equilibrium another more stable position is obtained, about which vibration becomes more possible. A prism immersed in water may have several more or less stable positions of equilibrium. The same is also true with the atoms in molecules. Some molecules present a state of more stable equilibrium than others. Hence, from this simple comparison, it will be at once evident that the stability of molecules may vary considerably; that one and the same elements, taken in the same number, may give isomerides of different stability; and, lastly, that there may exist states of equilibria which are so unstable, so ephemeral, that they will only arise under particularly special conditions—such, for example, as certain hydrates mentioned in the first chapter (see notes 57, 67, and others). And if in one case the instability of a given state of equilibrium is expressed by its instability with a change of temperature or physical state, it is in other cases expressed by the facility with which it decomposes under the influence either of contact or of the chemical influence of other substances.

or hydrogen oxide, and oxygenated water or hydrogen peroxide; for a given quantity of hydrogen, the peroxide contains twice as much oxygen as does water. This is a fresh example confirming the correctness of the law of multiple proportions, to which we have already referred in speaking of the water of crystallisation of salts. We can now formulate this law—the **law of multiple proportions**. *If two substances A and B (either simple or compound) unite together to form several compounds, A_nB_m , A_qB_r , . . ., then, having expressed the compositions of all these compounds in such a way that the quantity (by weight or volume) of one of the component parts is a constant quantity A, it will be observed that in all the compounds AB_m , AB_b , . . . the quantities of the other component part, B, will always be in commensurable relations, generally in simple multiple proportion—that is, that $a : b$. . . (or m/n is to r/q) can be expressed as the ratio of simple whole numbers; for instance, as 1 : 2, 2 : 3, or 3 : 4. . . .*

The analysis of water shows that in 100 parts by weight it contains 11.19 parts by weight of hydrogen and 88.81 of oxygen, and the analysis of peroxide of hydrogen shows that it contains 94.07 parts of oxygen to 5.93 parts of hydrogen. Here the analyses are expressed, as they generally are, in percentages; that is, they give the amounts of the elements in a hundred parts by weight of the substance. The direct comparison of the percentage compositions of water and hydrogen peroxide does not reveal any simple relation. But such a relation is immediately apparent if we calculate the compositions of water and hydrogen peroxide, taking either the quantity of oxygen or the quantity of hydrogen as a constant quantity—for instance, unity. The proportions show that in water there are contained eight parts of oxygen to one part of hydrogen, and in hydrogen peroxide sixteen parts of oxygen to one part of hydrogen; or one-eighth part of hydrogen in water and one-sixteenth part of hydrogen in hydrogen peroxide to one part of oxygen. Naturally, the analysis does not give these figures with absolute exactness—it gives them within a certain degree of error—but they approximate, as the error diminishes, to the limit 1 : 2 here given.

An exactly similar multiple proportion is observed in the composition of all other well-investigated definite chemical compounds,³⁰

³⁰ When, for example, any element forms several oxides, these are subject to the law of multiple proportions. For a given quantity of the non-metal or metal the quantities of oxygen in the different degrees of oxidation will stand as 1 : 2, or as 1 : 3, or as 2 : 3, or as 2 : 7, and so on. Thus, for instance, copper combines with oxygen in at least two proportions, forming the oxides found in nature, and called the suboxide and the oxide of copper, Cu_2O and CuO ; the oxide contains twice as much oxygen as the suboxide. Lead also presents two degrees of oxidation, the oxide and dioxide, and in the latter

and therefore the law of multiple proportions is accepted in chemistry as the starting-point from which other considerations proceed.

The law of multiple proportions was discovered at the beginning of the last century by **John Dalton**, of Manchester, in investigating the compounds of carbon with hydrogen. It appeared that two gaseous compounds of these substances—marsh gas, CH_4 , and olefiant gas, C_2H_4 , contain, for one and the same quantity of hydrogen, quantities of carbon which stand in multiple proportion, marsh gas containing relatively half as much carbon as olefiant gas. Although the analysis of that time was not exact, still the accuracy of this law, recognised by Dalton, was confirmed by later and more accurate investigations. On establishing the law of multiple proportions, Dalton gave a hypothetical explanation for it. This explanation is based on the atomic theory of matter. In fact, the law of multiple proportions may be very easily understood by admitting the atomic structure of matter.

The **essence of the atomic theory** is that matter is supposed to consist of an agglomeration of small and indivisible (by natural forces) parts—atoms—which do not fill up the whole space occupied by a substance, but stand apart from each other, as the sun, planets, and stars do not fill up the whole space of the universe, but are at a distance from each other.^{30a} The form and properties of substances are deter-

there is twice as much oxygen as in the former, the formulæ being PbO and PbO_2 . When a base and an acid are capable of forming several kinds of salts, normal, acid, basic, and anhydro-, it is found that these also clearly exemplify the law of multiple proportions. This was demonstrated by Wollaston soon after the discovery of the law in question. We saw in the first chapter that salts show different degrees of combination with water of crystallisation, and that these obey the law of multiple proportions. By endeavouring in Chap. I. to prove hypothetically that in solutions we have nothing else but the liquid products of the dissociation of definite hydrates which are subject to the law of multiple proportions, it is my aim to bring also this class of indefinite compounds under the general principle enunciated by Dalton; just as astronomers have discovered a proof and not a negation of the laws of Newton in the phenomena known as perturbations.

^{30a} I have no doubt that the atomic theory, so steadfastly applied, after its adoption in chemistry, to all natural science in the nineteenth century, has its philosophical defects proper to materialism. Yet it cannot be denied that atomism presents a sublime generalisation in harmony with the fundamental principles of philosophy, for it directly assimilates the structure of the universe (in the form in which it has been revealed by the conquests of astronomy—consisting of solitary suns and planets separated by space but united by reacting forces), to the structure of matter out of atoms, and by so doing greatly facilitates the comprehension of things and phenomena. According to this view, a molecule of matter is as complex as an entire universe, and it contains its solitary bodies—atoms—maintained, like the suns and planets, by their proper forces in mobile but stable equilibrium, its systems, &c. One of the merits of atomism is that it has brought the infinitely small into harmony with the infinitely great, and by so doing has gained new life. The natural philosophy of modern times has the further merit over that of former ages, that it no longer regards man as the pivot of the universe, but consciously submits itself to harmonious, coherent, and logical laws embracing all time

mined by the positions of their atoms in space and by their state of motion, whilst the reactions accomplished by substances are regarded as redistributions of the relative positions of atoms and as changes in their motion. The atomic representation of matter arose in very ancient times,³¹ and until recently was at variance with the dynamical

and space and extending alike over the immensity of the heavens and the infinitesimal atom. The radical defect of modern atomism, I think, lies in the vagueness of the conception of the 'ether' filling both interplanetary and interatomic space, but in directing its chief attention to the investigation of phenomena which take place in 'ether' (electric, luminiferous, &c.), modern science is, I think, following the right direction for revealing the hidden mysteries of nature. Modern science endeavours to, but cannot yet clearly, interpret by means of ether, as a substance material, though imponderable and chemically active, yet not giving chemically ponderable bodies. This is one of the problems of science which have been bequeathed to us by the nineteenth century.

³¹ Leucippus, Democritus, and especially Lucretius, in the classical ages, represented matter as made up of atoms—that is, of parts incapable of further division. The geometrical impossibility of such an admission, as well as the conclusions which were deduced by the ancient atomists from their fundamental propositions, prevented other philosophers from following them, and the atomic doctrine, like very many others, lived in the imaginations of its followers without being ratified by fact. Between the present atomic theory and the doctrine of the above-named ancient philosophers there is naturally a remote historical connection, as between the doctrines of Pythagoras and Copernicus, but they are essentially different. For us the atom is indivisible, not in the geometrical abstract sense, but only in a physical and chemical sense. It would be better to call the atoms indivisible **individuals**. The Greek 'atom' corresponds with the Latin 'individual,' both according to the etymology and original sense of the words, but in course of time these two words have acquired a different meaning. The 'individual' is mechanically and geometrically divisible, and only indivisible in a special sense. The earth, the sun, a man, and a fly are individuals, although geometrically divisible. Thus the 'atoms' of contemporary science, indivisible in a chemical sense, form those units with which we are concerned in the investigation of the natural phenomena of matter, just as a man is an indivisible unit in the investigation of social relations, or as the stars, planets, and luminaries serve as units in astronomy. The formation of the vortex hypothesis, in which, as we shall afterwards see, atoms are entire whirls, mechanically complex, although physico-chemically indivisible, clearly shows that the scientific men of our time, in holding to the atomic theory, have only borrowed the word and form of expression from the ancient philosophers, and not the essence of their atomic doctrine. It is erroneous to imagine that the contemporary conceptions of the atomists are nothing but the repetition of the metaphysical reasonings of the ancients. To show the true meaning of the atomism of the ancient philosophers, and the profound difference between their points of argument and those of contemporary men of science, I cite the following fundamental propositions of Democritus (B.C. 470–380) as the best expounder of the atomic doctrine of the ancients:—

- (1) Nothing can proceed from nothing, nothing that exists (and hence matter) can disappear or be destroyed, and every change consists only of a combination or separation.
- (2) Nothing is accidental, there is a reason and necessity for everything.
- (3) All except atoms and vacua is reason and not existence.
- (4) The atoms, which are infinite in number and form, constitute the visible universe by their motion, impact, and consequent revolving motion.
- (5) The variety of objects depends only upon a difference in the number, form, and order of the atoms of which they are formed, and not upon a qualitative difference of their atoms, which only act upon each other by pressure and impact.
- (6) The spirit, like fire, consists of minute spherical, smooth, and very mobile and all-penetrating atoms, whose motion forms the phenomenon of life.

These Democritan, chiefly metaphysical, principles of atomism are so essentially different from the principles of the present atomic doctrine, which is exclusively applied to explaining the

hypothesis, which considers matter as only a manifestation of forces. At the present time, however, the great majority of scientific men uphold the atomic hypothesis, but the present conception of an atom is quite different from that of the ancient philosophers. An atom at the present day is regarded rather as an ultimate, measurable individual or unit, which is indivisible by physical ³² and chemical forces, whilst the

phenomena of the external world, that it may be useful to mention the essence of the atomic propositions of Boscovitch, a Slav who lived in the middle of the eighteenth century, and who is regarded as the founder of the modern atomic doctrines, which, however, did not take hold upon the minds of scientific men, and were rarely applied, prior to the time of Dalton—i.e., until the beginning of the nineteenth century. The **doctrine of Boscovitch** was enunciated by him in 1758–1764 in his *Philosophiæ naturalis theoria reducta ad unicam legem virium in natura existentium*. Boscovitch considers matter to be composed of atoms, and the atoms to be the points or centres of forces (just as the stars and planets may be considered as points of space), acting between bodies and their parts. These forces vary with the distance, so that beyond a certain very small distance all atoms, and hence also their aggregates, are attracted according to Newton's law, but at less distances, wavelike spheres of gradually decreasing attraction and increasing (as the distance decreases) repulsion alternate, until at last at a minimum distance only the repellent action remains. Atoms, therefore, cannot merge into each other. Consequently, the atoms are held at a certain distance from each other, and therefore occupy space. Boscovitch compares the spheres of repulsion surrounding the atoms to the spheres of action of firing of a detachment of soldiers. According to his doctrine, atoms are indestructible, do not merge into each other, have mass, and are everlasting and mobile under the action of the forces proper to them. Maxwell rightly calls this hypothesis the 'extreme' among those existing to explain matter, but many aspects of Boscovitch's doctrine repeat themselves in the views of our day, with this essential difference, that instead of a mathematical point furnished with the properties of mass, the atoms are endowed with a corporality, just as the stars and planets are corporal, although in certain aspects of their interaction they may be regarded as mathematical points. In my opinion, the atomism of our day must first of all be regarded merely as a convenient method for the investigation of ponderable matter, a working hypothesis. As a geometrician in reasoning about curves represents them as formed of a succession of straight lines, because such a method enables him to analyse the subject under investigation, so the scientific man applies the atomic theory as a means of analysing the phenomena of nature. Naturally there are people now, as in ancient times, and as there always will be, who apply reality to imagination, and therefore there are to be found atomists of extreme views; but it is not in their spirit that we should acknowledge the great services rendered to all science by the atomic doctrine, which, while it has been essentially independently developed, is, if it be desired to reduce all ideas to the teachings of the ancients, a union of the ancient dynamical and atomic doctrines.

³² Dalton and many of his successors distinguished the atoms of elements and compounds, in which they clearly symbolised the difference between their opinion and the representations of the ancients. At the present time, only the individual particles of the elements, indivisible by physical and chemical forces, are termed atoms, while those of compounds indivisible under physical changes are termed molecules: these latter are divisible into atoms by chemical forces. But the atoms of simple bodies according to many contemporary men of science (Crookes, J. Thomson, Lord Kelvin, and others, especially among the English) split up, under certain circumstances, into primary infinitesimal parts (electrons, radiant matter, &c.), which clearly proves that many now consider the atom to be divisible. But here we stand evidently on the very limits of contemporary knowledge, and I therefore think it my duty to advise the beginner to

atom of the ancients was indivisible even in a geometrical sense, that is, infinitely small. When **Dalton** (1804) discovered the law of multiple proportions, he pronounced himself in favour of the atomic doctrine, because it enables this law to be very easily understood. If the divisibility of every element has a limit, namely, the atom, then the atoms of elements are the extreme limits of all divisibility, and if they differ from each other in their nature, the formation of a compound from elementary matter must consist in the aggregation of several different atoms into one whole or system of atoms, now termed **particles or molecules**. As atoms can only combine in a system in their entire masses, it is evident that not only the law of definite composition, but also that of multiple proportions, must apply to the combination of atoms with one another; for one atom of a substance can combine with one, two, or three atoms of another substance, or in general one, two, or three atoms of one element are able to combine with one, two, or three atoms of another, this being the essence of the law of multiple proportions. Many chemical and physical data are well explained by the aid of the atomic theory. The displacement of one element by another follows the law of equivalence. In this case one or several atoms of a given element take the place of one or several atoms of another element in its compounds. The atoms of different substances can be mixed together in the same sense as sand can be mixed with clay. They do not unite into one whole—i.e., there is not a perfect blending in the one or the other case, but only a juxtaposition, a homogeneous whole being formed from individual parts. This is the first and most simple method of applying the atomic theory to the explanation of chemical phenomena.³³

refrain from this province of thought, for there is here much that is possible, but nothing certain.

³³ In the present condition of science, either the atomic or the dynamical hypothesis is inevitably obliged to admit the existence of an invisible and imperceptible motion in matter, without which it is impossible to understand either light or heat, gaseous pressure, or any of the mechanical, physical, or chemical phenomena. The ancients saw vital motion in animals only, but to us the smallest particle of matter, endowed with *vis viva*, or energy in some degree or other, is incomprehensible without self-existent motion. Thus motion has become a conception inseparably knit with the conception of matter, and this has prepared the ground for the revival of the dynamical hypothesis of the constitution of matter. In the atomic theory there has arisen that generalising idea by which the world of atoms is constructed, like the universe of heavenly bodies, of its suns, planets, and meteors, endowed with everlasting force of motion and forming molecules, just as the heavenly bodies form systems like the solar system; and these molecules are only relatively indivisible in the same way as the planets of the solar system are inseparable, and are stable and lasting like the solar system. Such a representation, without necessitating the absolute indivisibility of atoms, expresses all that science can require for a hypothetical representation of the constitution of matter. In closer proximity to the dynamical hypothesis of the constitution of matter is the oft-times revived **vortex**

A certain number of atoms n of an element A in combining with several atoms m of another element B give a compound A_nB_m , each

hypothesis. Descartes first endeavoured to develop it, while Helmholtz and Thomson (Lord Kelvin) gave it a fuller and more modern form and many scientific men applied it to physics and chemistry. The idea of vortex rings serves as the starting-point of this hypothesis; these are familiar to all in the rings of tobacco smoke, and may be artificially obtained by giving a sharp blow to the sides of a cardboard box having a circular orifice and filled with smoke. Phosphoretted hydrogen, as we shall see later on, when bubbling from water always gives very perfect vortex rings in a still atmosphere. In such rings it is easy to observe a constant circular motion about their axes, and to notice the stability the rings possess in their motion of translation. This unchangeable mass, endowed with a rapid internal motion, is likened to the atom. In a medium deprived of friction, such a ring, as is shown by a theoretical consideration of the subject from a mechanical point of view, would be perpetual and unchangeable. The rings are capable of grouping together, and in combining, without being absolutely indivisible, they do not break up into parts. The vortex hypothesis has been established in our times, but it has not been fully developed; it can be applied to the explanation of chemical phenomena, although not readily; it tells us nothing of the nature of the space existing between the rings (just as it is not clear what exists between atoms and between the planets), neither does it tell us what is the nature of the moving substance of the ring, and therefore for the present it only presents the germ of a hypothetical conception of the constitution of matter; consequently I consider that it would be superfluous to speak of it in greater detail.

However, the thoughts of investigators are now (and naturally will be in the future), as they were in the time of Dalton, often turned to the question of the limitation of the mechanical division of matter, and the atomists have searched for an answer in the most diverse spheres of nature. In order to show how closely all the provinces of natural science are bound together, I select one of the methods of attacking this problem which does not in any way refer to chemistry.

Wollaston suggested investigating the **atmosphere of the heavenly bodies** as a means for confirming the existence of atoms. If the divisibility of matter be infinite, then air must extend throughout the entire space of the heavens, just as it extends all over the earth by virtue of its elasticity and diffusion. If the infinite divisibility of matter be admitted, it is impossible that any portion of the whole space of the universe can be entirely void of the component parts of our atmosphere. But if matter be divisible down to a certain limit only—namely, down to the atom—then there *can exist* a heavenly body void of an atmosphere; and if such a body be discovered, it would serve as an important factor in determining the validity of the atomic doctrine. The moon has long been regarded as such a luminary, and on this account, and especially because of its proximity to the earth, has been cited as the best proof of the validity of the atomic doctrine. This proof is apparently (Poisson) deprived of some of its force by the possibility of the transformation of the component parts of our atmosphere into a solid or liquid state at immense heights above the earth's surface, where the temperature is exceedingly low; but a series of researches (Pouillet) has shown that the temperature of the heavenly space is comparatively not so very low, and is attainable by experimental means, so that at the low existing pressure the liquefaction of the gases of the atmosphere cannot be expected even on the moon. Hence the absence of an atmosphere about the moon, if it were not subject to doubt, would be counted a forcible proof of the atomic theory. As a proof of the absence of a lunar atmosphere, it is cited that the moon, in its independent motion between the stars, when eclipsing a star—that is, when passing between the eye and the star—does not show any signs of refraction at its edge; the image of the star does not alter its position in the heavens on approaching the moon's surface; consequently there is no atmosphere on the moon's surface capable of refracting light rays. It is on this that the proof of the absence of a lunar atmosphere is based. But this is a very weak proof, and there are even facts which are in exact contradiction to it, and by

molecule of which will contain the atoms of the elements A and B in this ratio, and therefore the compound will present a **definite composition**, expressed by the formula A_nB_m , where A and B are the weights of the atoms, and n and m their relative numbers. If the same elements A and B, in addition to A_nB_m , also yield another compound A_rB_q , then by expressing the composition of the first compound by $A_{nr}B_{mr}$ (and

means of which the existence of a lunar atmosphere may be proved. The entire surface of the moon is covered with a number of mountains, having, in the majority of cases, the conical form natural to volcanoes. The volcanic character of the lunar mountains was confirmed in October 1866, when a change was observed in the form of one of them (the crater Linnea). These mountains must be on the edge of the lunar disc. Seen in profile they screen one another and interfere with observations on the surface of the moon, so that when looking at the edge of the lunar disc we are obliged to make our observations not on the moon's surface, but at the summits of the lunar mountains. These mountains are higher than those on our earth, and consequently at their summits the lunar atmosphere must be exceedingly rarefied, even if it possess an observable density at the surface. Knowing the mass of the moon to be eighty-two times less than that of the earth, we are able to show that our atmosphere at the moon's surface would be about twenty-eight times lighter than it is on the earth, and consequently at the very surface of the moon the refraction of light by the lunar atmosphere must be very slight, whilst at the heights of the lunar mountains it must be imperceptible, and would be lost within the limits of experimental error. So that the absence of refraction of light at the edge of the moon's disc cannot as yet be urged in proof of the absence of a lunar atmosphere. There is even a series of observations obliging us to admit the existence of such an atmosphere. These researches are due to Sir John Herschel. This is what he writes: 'It has often been remarked that during the eclipse of a star by the moon there occurs a peculiar optical illusion; it seems as if the star before disappearing passed over the edge of the moon and is seen through the lunar disc, sometimes for a fairly long period of time. I myself have observed this phenomenon, for the occurrence of which there is perfectly trustworthy evidence. I ascribe it to optical illusion; but it must be admitted that the star might have been seen on the lunar disc through some deep ravine on the moon.' Geniller, in Belgium (1856), following the opinion of Cassini, Euler, and others, gave an explanation of this phenomenon: he considers it due to the refraction of light in the valleys of the lunar mountains which occur on the edge of the lunar disc. In fact, although these valleys do not probably present the form of straight ravines, yet it may sometimes happen that the light of a star is so refracted that its image might be seen, notwithstanding the absence of a direct path for the light-rays. He then goes on to remark that the density of the lunar atmosphere must be variable in different parts owing to the very long nights on the moon. On the dark, or non-illuminated portion, owing to the long nights, which last thirteen of our days and nights, there must be excessive cold, and hence a denser atmosphere, whilst, on the contrary, on the illuminated portion the atmosphere must be much more rarefied. This variation in the temperature of the different parts of the moon's surface explains also the absence of clouds, notwithstanding the possible presence of air and aqueous vapour, on the visible portion of the moon. The presence of atmospheres round the sun and planets, judging from astronomical observations, may be considered as fully proved. On Jupiter and Mars bands of clouds may even be distinguished.

Thus the atomic doctrine, admitting only a finite mechanical divisibility, must be, as yet at least, accepted merely as a means, similar to that which a mathematician employs when he breaks up a continuous curvilinear line into a number of straight lines. There is a simplicity of representation in atoms, but there is no absolute necessity to have recourse to them. The conception of the individuality of the parts of matter exhibited in chemical elements is alone necessary and certain.

this is the same composition as A_nB_m), and that of the second compound by $A_{rn}B_{qn}$, we have the law of multiple proportions, because for a given quantity of the first element, A_{rn} , there occur quantities of the second element bearing the same ratio to each other as mr bears to qn ; and as m , r , q , and n are whole numbers, their products are also whole numbers, and it is this that is expressed by the law of multiple proportions. Consequently the atomic theory is in accordance with and evokes the first laws of definite chemical compounds: the law of definite composition and the law of multiple proportions.

The same thing is seen in the relation of the atomic theory to the third law of definite chemical compounds—the **law of reciprocal combining weights**—which is as follows:—If a certain weight of a substance C combine with a weight a of a substance A, and with a weight b of a substance B, then, also, the substances A and B will combine together in quantities a and b (or in multiples of them). This follows at once from our conception of atoms. Let A, B, and C be the weights of the atoms of the three elements, and for simplicity of reasoning let us suppose that combination takes place between single atoms. It is evident that if the element C gives AC and BC, then the elements A and B will give a compound AB, or A_nB_m . And this is what we really find in nature. Sulphur combines with hydrogen and with oxygen. Sulphuretted hydrogen contains thirty-two parts by weight of sulphur to every two parts by weight of hydrogen; this is expressed by the formula H_2S . Sulphur dioxide, SO_2 , contains thirty-two parts of sulphur and thirty-two parts of oxygen, and therefore we conclude, from the law of combining weights, that oxygen and hydrogen will combine in the proportion of two parts of hydrogen and thirty-two parts of oxygen, or in some multiples of these numbers. And we have seen this to be the case. Hydrogen peroxide contains thirty-two parts of oxygen, and water sixteen parts, to every two parts of hydrogen; and so it is in all other cases. This consequence of the atomic theory is in accordance with nature and with the results of analysis, and is one of the most important laws of chemistry. It is a law, because it indicates the *relation between* the weights of substances entering into chemical combination. Further, it is an eminently exact law, and not an approximate one. The law of combining weights is a law of nature, and by no means an hypothesis, for even if the entire theory of atoms be refuted, the laws of multiple proportions and of combining weights will still remain, inasmuch as they are the expression of facts. They may be foreseen from the atomic theory, and historically the law of combining weights is intimately connected with this theory; they are, however, not identical, but only connected, with it. The law of com-

binning weights is formulated with great ease, and is an immediate consequence of the atomic theory, without which it would be difficult to understand. Data for its evolution existed previously, but it was not formulated until those data were interpreted by the atomic theory, an hypothesis which up to the present time has contradicted neither experiment nor fact, and is useful and of general application. Such is the nature of hypotheses. They are indispensable to science; they bestow an order and simplicity which are only attainable with difficulty without their aid. The whole history of science is a proof of this. And it may therefore be truly said that it is better to hold to an hypothesis which may afterwards prove untrue than to have none at all. Hypotheses facilitate scientific work and render it consistent. Like the plough of the husbandman, they help forward the work of the labourer in the search for truth.

CHAPTER V

NITROGEN AND AIR

ALTHOUGH oxygen is chemically the most active component of the atmosphere surrounding us, nitrogen forms the greater part of it by weight and by volume, and indeed constitutes over three-quarters (by volume) of the atmosphere; and as **nitrogen** is only slightly lighter than oxygen, it forms about three-quarters of the air by weight also. While entering in so considerable a quantity into the composition of air, nitrogen does not seem to play any active part in the atmosphere, the chemical action of which is mainly dependent on the oxygen it contains. But a correct idea of the part played by the nitrogen in the air can only be formed when we have learnt that animals cannot exist in pure oxygen, but pass into an abnormal state, and even die; and that the nitrogen of the air, although slowly, forms numerous compounds, many of which play a most important part in nature, especially in the life of organisms. Plants, and especially animals, besides requiring free oxygen, are absolutely dependent upon nitrogenous compounds for their nutrition, because these form their most chemically active components. However, neither plants¹ nor animals directly absorb the gaseous nitrogen of the air, but take it up from ready-formed nitrogenous compounds; further, plants are nourished by the nitrogenous substances contained in the soil and water, and animals by the nitrogenous substances contained in plants and in other animals. Atmospheric electricity is capable of aiding the passage of gaseous nitrogen into nitrogenous compounds, as we shall afterwards see, and the resultant substances are carried to the soil by rain, and there serve for the nourishment of plants. Plentiful harvests, fine crops of hay, vigorous growth of trees—other conditions being equal—are only obtained when the soil contains **ready-formed nitrogenous compounds**, consisting either of those which occur in air and water, or of the residues of the decomposition of other plants or animals (as in manure). The nitrogenous substances contained in animals have their

¹ See note 15^a.

origin in those substances which are formed in plants. Thus the nitrogen of the atmosphere is the origin of all the nitrogenous substances occurring in animals and plants, although not directly so, but only after first combining with the other elements of air.

The nitrogenous compounds which enter into the composition of plants and animals are of primary importance ; no vegetable or animal cell—that is, the elementary form of organism—exists without containing a nitrogenous substance, and, moreover, the life of the organism manifests itself primarily in these nitrogenous substances. The germs, seeds, and those parts by which cells multiply abound in nitrogenous substances ; the sum total of the phenomena which are proper to organisms depends primarily on the chemical properties of the readily changeable complex (albuminous) nitrogenous substances which enter into their composition. It will be sufficient, for instance, to point out the fact that vegetable and animal organisms, clearly distinguishable as such, are characterised by the different degrees of energy they manifest, and at the same time by a difference in the amounts of nitrogenous substances they contain. In plants, which compared with animals possess but little activity, being incapable of independent movement, &c., the proportion of nitrogen is very much less than in animals, whose tissues are almost exclusively formed of nitrogenous substances. It is remarkable that the nitrogenous parts of plants, chiefly of the lower orders, sometimes present both forms and properties resembling those of animal organisms ; this is seen, for example, in the zoospores of seaweeds, or those parts by means of which the latter multiply themselves. On leaving the seaweed these zoospores resemble in many respects the lower orders of animal life, having, like the latter, the property of motion. They also approach the animal kingdom in their composition, their outer coating containing nitrogenous matter. Directly the zoospore becomes covered with that non-nitrogenous or cellular coating which is proper to all the ordinary cells of plants, it loses all resemblance to an animal organism and becomes a small plant. It may be thought from this that the cause of the difference between the vital processes of animals and those of plants lies in the different amounts of nitrogenous substances they contain. The nitrogenous substances which occur in plants and predominate in animals belong to a series of exceedingly complex and very changeable chemical compounds ; their elementary composition alone shows this, for besides nitrogen they contain carbon, hydrogen, oxygen, and sulphur. Being distinguished by a very great instability under many conditions in which other compounds remain unchanged, these substances are fitted for those perpetual and regular changes which form the first condition

of vital activity. These complex and changeable nitrogenous substances of the organism are called **proteid substances**. The white of eggs is a familiar example of such substances. They are also contained in the tissues of the flesh of animals, the curdy elements of milk, the glutinous matter of wheaten flour, or so-called gluten, which forms the chief component of macaroni, &c.

Nitrogen occurs in the earth's crust, in compounds either forming the remains of plants and animals, or derived from the nitrogen of the atmosphere as a consequence of its combination with the other component parts of the air. It is not found in other forms in the earth's crust; so that nitrogen must be considered, in contradistinction to oxygen, as an element which is purely superficial, and extends hardly at all to the depths of the earth.^{1a}

Nitrogen is liberated in a free state in the decomposition—for example, by combustion—of the **nitrogenous organic substances** entering into the composition of organisms. All organic substances burn when heated to redness with oxygen (or substances readily yielding it, such as oxide of copper); the oxygen combines with the carbon, sulphur, and hydrogen, and the nitrogen is evolved in a free state, because at a high temperature it forms no stable compound, but remains uncombined. Carbonic anhydride and water are formed from the carbon and hydrogen respectively, and therefore to obtain pure nitrogen it is necessary to remove the carbonic anhydride from the gaseous products obtained (after drying). This may be done very easily by the action of alkalies—for instance, caustic soda. The amount of nitrogen in organic substances is determined by a method founded on this.

It is also very easy to obtain **nitrogen from air**, because oxygen combines with many substances. Either phosphorus or metallic copper is usually employed for removing the oxygen from air, but, naturally, a number of other substances may also be used. If a small

^{1a} The reason why there are no nitrogenous substances within the earth's mass other than those which have come there with the remains of organisms, or from the air with rain-water, must be looked for in two circumstances. In the first place, in the instability of many nitrogenous compounds, which are liable to break up with the formation of gaseous nitrogen; and in the second place in the fact that the salts of nitric acid, forming the product of the action of air on many nitrogenous and especially organic compounds, are very soluble in water, and on penetrating into the depths of the earth (with water) give up their oxygen. The result of the changes of the nitrogenous organic substances which fall into the earth is without doubt frequently, if not invariably, the formation of gaseous nitrogen. Thus the gas evolved from coal always contains much nitrogen (together with marsh gas, carbonic anhydride, and other gases). The statement that a small amount of nitrogen is evolved during volcanic eruptions cannot be taken as proved, because air easily penetrates into the depths of the earth, whence it is ejected in volcanic disturbances.

saucer on which a piece of phosphorus is laid be placed on a cork floating on water, and the phosphorus be lighted, and the whole covered with a glass bell jar, the air under the jar will be deprived of its oxygen, and nitrogen alone remain; hence, on cooling, the water will rise to a certain extent in the bell jar. The same object (obtaining nitrogen from the air) is attained much more conveniently and perfectly by passing air through a red-hot tube containing copper filings. At a red heat, metallic copper combines with oxygen and gives a black powdery copper oxide. If the layer of copper be sufficiently long and the current of air slow, all the oxygen will be absorbed, and nitrogen alone will pass from the tube.²

Nitrogen may also be procured from many of its **compounds with oxygen** ³ and **hydrogen**,⁴ but the best fitted for this purpose is a saline mixture containing, on the one hand, a compound of nitrogen with oxygen, termed nitrous anhydride, N_2O_3 , and, on the other hand, ammonia (taken as a salt, Chap. VI.), NH_3 —that is, a compound of nitrogen with hydrogen. By heating such a mixture, the oxygen of the nitrous anhydride combines with the hydrogen of the ammonia, forming water, and gaseous nitrogen is evolved, $2NH_3 + N_2O_3 = 3H_2O + N_4$. Nitrogen is obtained by this method in the following manner:—A solution of caustic potash is saturated with nitrous anhydride, by which means potassium nitrite is formed, while a solution of hydrochloric acid is saturated with ammonia, by which means a saline substance called sal-ammoniac, NH_4Cl , is formed. The two solutions thus prepared are mixed together and heated. Reaction takes place according to the equation: $KNO_2 + NH_4Cl = KCl + 2H_2O + N_2$. This reaction proceeds in virtue of the fact that potassium nitrite and ammonium chloride are salts which, on interchanging their metals, give potassium chloride and ammonium nitrite, NH_4NO_2 , which breaks up into water

² In the presence of solutions of acids, copper (best as turnings, which present a large surface) absorbs oxygen at the ordinary temperature, forming CuO ; or, better still, in the presence of a solution of ammonia, when it forms a bluish-violet solution of oxide of copper in ammonia. Nitrogen is very easily procured by this method. A flask filled with copper turnings is closed with a cork furnished with a funnel and stopcock. A solution of ammonia is poured into the funnel, and caused to drop slowly upon the copper. If at the same time a current of air be passed slowly through the flask (from a gasholder), then all the oxygen will be absorbed from it and the nitrogen will pass from the flask. The gas should be washed with water to retain any ammonia that may be carried off with it.

³ The oxygen compounds of nitrogen (for example, N_2O , NO , NO_2) are decomposed at a red heat by themselves, and under the action of red-hot copper, iron, sodium, &c., they give up their oxygen to the metals, leaving the nitrogen free. According to Meyer and Langer (1885), nitrous oxide, N_2O , decomposes below 900° , although not completely

⁴ Chlorine and bromine (in excess), as well as bleaching powder (hypochlorites), take up the hydrogen from ammonia, NH_3 , leaving nitrogen. Nitrogen is best procured from ammonia by the action of a solution of sodium hypobromite on solid sal-ammoniac.

and nitrogen. This reaction does not take place without the aid of heat, but it proceeds very readily at a moderate temperature. Of the resultant substances, the nitrogen alone is gaseous. Pure nitrogen may be obtained by drying the resultant gas and passing it through a solution of sulphuric acid (to absorb a certain quantity of ammonia which is evolved in the reaction).^{4a} Before 1894, it was generally thought that nitrogen obtained from air did not differ in any way from that prepared from its compounds (after being purified); but Lord Rayleigh, in determining the weight of a known volume of nitrogen obtained by different methods, found that the nitrogen of air is almost $\frac{1}{200}$ heavier than that extracted from its compounds. Subsequently Lord Rayleigh, together with W. Ramsay, showed that the difference in density was due to the presence in the atmospheric nitrogen of a small amount of an inactive gas resembling nitrogen, which they named **argon**, and of certain other gases of which mention is made at the end of this chapter.⁵

Nitrogen is a gaseous substance which does not differ much in physical properties from air: its density, referred to that of hydrogen, is equal to 13.9—that is, it is slightly lighter than air; one litre of nitrogen weighs 1.251 gram (at 0° and 760 mm.). Nitrogen mixed with oxygen, which is slightly heavier than air, forms air. It is a gas which, like oxygen and hydrogen, is liquefied with difficulty, and is but slightly soluble in water and other liquids. Its absolute boiling-point⁵ is about -146°. Liquid nitrogen boils at -193°, its specific gravity at this temperature being about 0.89. At about -213°, in vaporising under diminished pressure, nitrogen solidifies into a colourless snow-like mass. Nitrogen does not burn,^{5a} does not support combustion, is not absorbed chemically by any of the reagents used in gas analysis, at least at the ordinary temperature—in a word, it presents a whole series of negative chemical properties. This is expressed by saying that this element has no energy for forming compounds. Although it is capable of forming compounds both with oxygen and hydrogen as well as with carbon, yet these compounds are only formed under special conditions, to which we shall turn our attention directly. At a red heat nitrogen combines with boron, titanium, silicon, barium, magnesium, and lithium,

^{4a} Ammonium nitrite may be prepared separately, only it decomposes with an explosion, and is difficult to deal with (Chap. VI. note 56).

⁵ Owing to this, nitrogen obtained from air differs slightly in some of its properties from pure nitrogen, as will be presently explained. There is no need to say that Rayleigh's and Ramsay's discoveries are among the most remarkable ever made in science, and prove to what a high degree of perfection the exact comparative investigation of substances may be brought.

^{5a} See note 11a.

forming very stable nitrogenous compounds,⁶ whose properties are entirely different from those of nitrogen compounds of hydrogen, oxygen, and carbon. However, the combination of nitrogen with carbon, although it does not take place directly between the elements at a red heat, yet proceeds with comparative ease when a mixture of charcoal with an alkaline carbonate, especially potassium carbonate or barium carbonate, is heated to redness, carbo-nitrides or cyanides of the metals being formed; for instance, $K_2CO_3 + 4C + N_2 = 2KCN + 3CO$.⁷

Nitrogen is found with oxygen in the air, but these two elements do not readily combine. Cavendish, however, in the eighteenth century, showed that **nitrogen combines with oxygen under the influence of a series of electric sparks**. Electric sparks in passing through a moist⁸ mixture of nitrogen and oxygen cause these elements to combine, forming reddish-brown fumes of oxides of nitrogen,⁹ which with water

⁶ The combination of boron with nitrogen, for instance, is accompanied by the evolution of sufficient heat to raise the mass to redness; titanium combines so easily with nitrogen that it is difficult to obtain it free from that element; lithium and magnesium easily absorb nitrogen at a red heat. It is a remarkable and instructive fact that these compounds of nitrogen are very stable and non-volatile. Carbon (C = 12) with nitrogen gives cyanogen, C_2N_2 , which is gaseous and very unstable, and the molecule of which is not large, whilst boron (B = 11) forms a nitrogenous compound which is solid, non-volatile, and very stable. Its composition, BN, is similar to that of cyanogen, but its molecular formula, B_nN_n , is probably greater. Its composition, like those of N_2Mg_3 , NNa_3 , N_2Hg_3 , and of many of the metallic nitrides, corresponds with ammonia in which all the hydrogen is replaced by a metal. A detailed study of the transformations of the nitrides now known may lead to the discovery of many facts in the history of nitrogen.

⁷ This reaction, so far as is known, does not proceed beyond a certain limit, probably because cyanogen, CN, itself breaks up into carbon and nitrogen.

⁸ Frémy and Becquerel took dry air, and observed the formation of brown vapours of oxides of nitrogen when sparks are passed.

⁹ If a mixture of one volume of nitrogen and fourteen volumes of hydrogen be burnt, water and a considerable quantity of nitric acid are formed. It may be partly due to this that a certain quantity of nitric acid is produced in the slow oxidation of nitrogenous substances in an excess of air. This is especially facilitated by the presence of an alkali, with which the nitric acid formed can combine. If a galvanic current be passed through water containing the nitrogen and oxygen of the air in solution, then the hydrogen and oxygen set free combine with the nitrogen, forming ammonia and nitric acid.

When copper is oxidised at the expense of the air at the ordinary temperature in the presence of ammonia, oxygen is absorbed, not only for combination with the copper, but also for the formation of nitric acid.

The combination of nitrogen with oxygen, even, for example, by the action of electric sparks, is not accompanied by an explosion or rapid combination, as in the action of a spark on a mixture of oxygen and hydrogen. This is explained by the fact that heat is not evolved in the combination of nitrogen with oxygen, but is absorbed—an expenditure of energy is required, there being no evolution of energy. In other words, the combination of hydrogen with oxygen is an exothermal reaction, and the combination of nitrogen with oxygen an endothermal reaction.

A condition particularly favourable to the oxidation of nitrogen is the explosion of detonating gas and air if the former be *in excess*. If a mixture of two volumes of detonating gas and one volume of air be exploded, one-tenth of the air is converted

form nitric acid,¹⁰ NHO_3 . The presence of the latter is easily recognised, not only from its reddening of litmus paper, but also from its acting as a powerful oxidiser, even of mercury. Conditions similar to these occur in nature, during a thunderstorm or in other electric discharges which take place in the atmosphere; whence it may be taken for granted that air and rain-water always contain a certain amount of nitric and nitrous acids.¹¹ Besides which, Crookes (1892) showed that under certain circumstances, and when electricity of high potential^{11a} passes through the air, the combination of nitrogen with oxygen is accompanied by the formation of a true flame. This was also observed previously during the passage of electric discharges through the air.

Further observations showed that under the influence of electric discharges,¹² silent as well as with sparks, nitrogen is able to enter into

into nitric acid, and consequently after the explosion has taken place there remain only nine-tenths of the volume of air originally taken. If a larger proportion of air be taken—for instance, four volumes to two of detonating gas—then the temperature of the explosion is lowered, the volume of air taken remains unchanged, and no nitric acid is formed. This gives a rule to be observed in making use of the eudiometer—namely, that to diminish the force of the explosion not less than an equal volume of air should be added to the explosive mixture. On the other hand a large excess must not be taken, as no explosion would then ensue (see Chapter III., note 34). Probably, in the future, means will be found for obtaining compounds of nitrogen on a large industrial scale by the aid of electric discharges, and by making use of the inexhaustible mass of nitrogen in the atmosphere.

¹⁰ In reality, nitric oxide, NO , is first formed, but with oxygen and water it gives (brown fumes) nitrogen peroxide, which, as we shall afterwards learn, in the presence of water and oxygen gives nitric acid.

¹¹ The nitric acid contained in soil, river water (Chapter I., note 2), wells, &c., proceeds (like carbonic anhydride) from the oxidation of organic compounds which have fallen into the water, soil, &c.

^{11a} Crookes employed a current of 15 ampères at 65 volts, and passed it through an induction coil with 330 vibrations per second, and obtained a flame between the poles placed at a distance of 46 mm., which after the appearance of the arc and flame could be increased to 200 mm. A platinum wire was fused in the flame of the burning nitrogen.

¹² This property of nitrogen, which under normal conditions is inactive, leads to the idea that, under the influence of an electric discharge, gaseous nitrogen changes in its properties, if not permanently like oxygen (electrolysed oxygen or ozone does not react on nitrogen, according to Berthelot), it may be temporarily at the moment of the action of the discharge, just as some substances under the action of heat are permanently affected (that is, when once changed remain so—for instance, white phosphorus passes into red, &c.), whilst others are only temporarily altered (the dissociation of S_6 into S_2 or of sal-ammoniac into ammonia and hydrochloric acid). Such a proposition is favoured by the fact that nitrogen gives two kinds of spectra, with which we shall afterwards become acquainted. It may be that the molecules of gaseous nitrogen, N_2 , then give less complex molecules, N , containing one atom, or that the bond between the atoms in the molecules is weakened. Probably under a silent discharge the molecules of oxygen, O_2 , are partly decomposed and the individual atoms O combine with O_2 , forming ozone O_3 .

many reactions with hydrogen and with many hydrocarbons, although these reactions cannot be effected by exposure to a red heat. Thus, for instance, a series of electric sparks passed through a mixture of nitrogen and hydrogen causes these gases to combine and **form ammonia**¹³ or nitrogen hydride, NH_3 , composed of one volume of nitrogen and three volumes of hydrogen. This combination is limited to the formation of 6 per cent. of ammonia, because ammonia is decomposed, although not entirely ($\frac{2}{100}$), by electric sparks. This signifies that, under the influence of an electric discharge, the reaction, $\text{NH}_3 = \text{N} + 3\text{H}$, is reversible; consequently it is a dissociation, and in it a state of equilibrium is arrived at. The equilibrium may be destroyed by the addition of gaseous hydrochloric acid, HCl , because with ammonia this forms a solid saline compound, sal-ammoniac, NH_4Cl , which (being formed from a gaseous mixture of 3H , N , and HCl) fixes the ammonia. The remaining mass of nitrogen and hydrogen, under the action of the sparks, again forms ammonia, and in this manner *solid sal-ammoniac is obtained to the end by the action of a series of electric sparks on a mixture of gaseous nitrogen, hydrogen, and hydrogen chloride*. This is also, like the production of nitric acid,¹⁴ an instance of the synthesis of nitrogenous compounds from gaseous nitrogen. Berthelot (1876) showed that, under the action of a silent discharge, many non-nitrogenous organic substances (benzene, C_6H_6 , cellulose in the form of paper, gum, $\text{C}_6\text{H}_{10}\text{O}_5$, &c.) absorb nitrogen and form complex nitrogenous compounds, which are capable, like albuminous substances, of evolving their nitrogen as ammonia when heated with alkalis.¹⁵

¹³ This reaction, discovered by Chabrié and investigated by Thénard, was only rightly understood when Deville applied the principles of dissociation to it.

¹⁴ The action of nitrogen on acetylene (Berthelot) resembles this reaction. A mixture of these gases under the influence of a silent discharge gives hydrocyanic acid, $\text{C}_2\text{H}_2 + \text{N}_2 = 2\text{CNH}$. This reaction cannot proceed beyond a certain limit because it is reversible.

¹⁵ Berthelot successfully employed electricity of even feeble potential in these experiments, which fact led him to think that in nature, where the action of electricity takes place very frequently, a part of the complex nitrogenous substances may be formed in this way from the gaseous nitrogen of the air.

As the nitrogenous substances of organisms play a very important part in them (organic life cannot exist without them), and as the nitrogenous substances introduced into the soil are capable of invigorating its crops (of course in the presence of the other nourishing principles required by plants), the question of the means of converting the atmospheric nitrogen into the nitrogenous compounds of the soil, or into **assimilable nitrogen** capable of being absorbed by plants and of forming complex (albuminous) substances in them, is one of great theoretical and practical interest.

One thousand tons of farmyard manure do not generally contain more than four tons of nitrogen in the form of complex nitrogenous substances, and this amount of nitrogen is contained in twenty tons of ammonium sulphate, so that the effect of a large mass of farmyard manure may, as regards the introduction of nitrogen, be produced by small quantities of artificial nitrogenous fertilisers (see note 15a).

By such indirect methods does the gaseous nitrogen of the atmosphere yield its primary compounds, in which form it enters into plants, and is elaborated in them into complex albuminous substances.^{15a} But, starting from a given compound of nitrogen with hydrogen or oxygen, we may, without the aid of organisms, obtain, as will afterwards be partially indicated, most varied and complex nitrogenous substances, which cannot by any means be formed directly from gaseous nitrogen. In this we see an example, not only of the difference between an element in the free state and an intrinsic element (as a simple body nitrogen is an indifferent gas, but as an element it forms many very active compounds and determines their individual peculiarities; see following chapter), but also of those circuitous or *indirect methods* by which substances are formed in nature. The discovery, prognostication, and, in general, the study of such indirect methods of the preparation and formation of substances form one of the essential problems of chemistry. From the fact that A does not act at all on B, it must not be concluded that a compound AB is not to be formed. The substances A and B contain elementary atoms which occur in AB, but their state or the nature of their motion may not be at all that which is required for the formation of AB, and in this substance the chemical state of the elements may be as different as the states of the atoms of oxygen in ozone and in water. Thus free nitrogen is inactive; but in its compounds it very easily enters into changes and is distinguished by great activity. An acquaintance with the compounds of nitrogen confirms this. But, before entering on this subject (Chap. VI.), let us consider air as a mass containing free nitrogen, and as the medium in which the majority of natural phenomena take place.

Judging from what has been already stated, it will be evident that **atmospheric air**¹⁶ consists of a mixture of several gases and vapours.

^{15a} Although the numerous, and as far as possible accurate and varied researches made in the physiology of plants have proved that the higher forms of plants are not capable of directly absorbing the nitrogen of the atmosphere and converting it into complex albuminous substances, still it has been long and repeatedly observed that the amount of nitrogenous substances in the soil is increased by the cultivation of plants of the bean (leguminous) family, such as the pea, acacia, &c. A closer study of these plants has shown (Hellriegel) that this is connected with the formation of peculiar nodular swellings in their roots caused by the growth of peculiar micro-organisms (bacteria) which live in the soil with the roots, and are capable of absorbing nitrogen from the air, i.e., of converting it into assimilated nitrogen. This branch of plant physiology, which forms another proof of the important part played by micro-organisms in nature, cannot be discussed in this work, but it should be mentioned, since it is of great theoretical and practical interest.

¹⁶ Under the name of atmospheric air the chemist and physicist understand ordinary air containing nitrogen and oxygen, argon, and similar elementary gases, not absorbed

Some of them are met with in it in nearly constant proportions, whilst others, on the contrary, are very variable in their amount. The chief component parts of air, placed in the order of their relative amounts, are the following : nitrogen, oxygen, aqueous vapour, carbonic anhydride, argon, krypton, xenon, neon, nitric acid, salts of ammonia, hydrogen, helium, oxides of nitrogen, and also ozone, hydrogen peroxide, and complex organic nitrogenous substances. Besides these, air generally contains water, as spray, drops, and snow, and particles of solids, perhaps of cosmic origin in certain instances, but in the majority of cases proceeding from the mechanical translation of solid particles from one locality to another by the wind. These small solid and liquid particles (having a large surface in proportion to their weight) are suspended in air just as solid matter is suspended in turbid water : they often settle on the surface of the earth, but the air is never entirely free from them because they are never in a state of complete rest. Then, again, as everyone knows by experience, air not infrequently contains incidental traces of various substances. These incidental substances sometimes act injuriously and sometimes act as carriers of infectious diseases.

In the air of the various countries of the earth, at different latitudes and at different altitudes above its surface, on the ocean or on the dry land—in a word, in the air of the most diverse localities of the earth—the oxygen and nitrogen are found everywhere to be in a constant ratio, and are accompanied by small amounts of argon, krypton, and other gases exhibiting an inactivity similar to that of nitrogen (see later portion of this chapter). This is, moreover, self-evident from the fact that the air is constantly diffusing (intermixing by virtue of the internal motion of the gaseous particles), and is also put into motion and mixed by the

(like H_2O and CO_2) by sulphuric acid or alkalies at the ordinary temperature, although these latter component parts of air have a very important influence on the living matter of the earth's surface. That air is so represented in science is based on the fact that the elementary components are met with in air in a constant quantity, whilst the H_2O and CO_2 are variable. The solid impurities may be separated from air required for chemical or physical research by simple filtration through a long layer of cotton-wool placed in a tube. Organic impurities are removed by passing the air through a solution of potassium permanganate. The carbonic anhydride contained in air is absorbed by alkalies—best of all, soda-lime, which in a dry state in porous lumps absorbs it with exceeding rapidity and completeness. Aqueous vapour is removed by passing the air over calcium chloride, strong sulphuric acid, or phosphoric anhydride. Air thus purified is accepted as containing only nitrogen and oxygen, argon, &c., although in reality it still contains a certain quantity of hydrogen and hydrocarbons, from which it may be purified by passing over copper oxide heated to redness. The copper oxide then oxidises the hydrogen and hydrocarbons—it burns them, forming water and carbonic anhydride, which may be removed as above described. When it is said that, in the determination of the density of gases, the weight of air is taken as unity, it is understood to be air purified in this manner.

wind, so that it becomes equalised in its composition over the entire surface of the earth. In those localities where the air is subject to change, and is in a more or less enclosed space, or, at any rate, in an unventilated space, it may alter very considerably in its composition. For this reason the air in dwellings, cellars, and wells, in which there are substances absorbing oxygen, contains less of this gas, whilst the air on the surface of standing water, which abounds in the lower orders of plant life evolving oxygen, contains an excess of this gas.¹⁷ The constant composition of air—over the whole surface of the earth—has been proved by a number of most careful researches.¹⁸

¹⁷ The air held in the fissures of glaciers contains only 10 per cent. by volume of oxygen. This is owing to the fact that oxygen is much more soluble than nitrogen in snow-water and snow at a low temperature.

¹⁸ The analysis of air by weight conducted by Dumas and Boussingault in Paris, which they repeated many times between April 27 and September 22, 1841, under various conditions of weather, showed that the amount by weight of oxygen only varies between 22·89 per cent. and 23·08 per cent., the average amount being 23·07 per cent. Brunner in Berlin, Bravais at Faulhorn in the Bernese Alps, at a height of two kilometres above the level of the sea, Marignac at Geneva, Lewy at Copenhagen, and Stas at Brussels, have analysed the air by the same methods, and found that its variation in composition does not exceed the limits determined for Paris. The most recent determinations (with an accuracy of $\pm 0\cdot05$ per cent.) confirm the conclusion that the composition of pure air is comparatively constant.

There are some grounds (which will be mentioned shortly) for considering that the composition of the air at great altitudes is slightly different from that at attainable heights—namely, that it is richer in the lighter nitrogen—and several fragmentary observations made at Munich (Jolly, 1880) gave reason for thinking that in the upward currents (that is, in the regions of minimum barometric pressure or at the centres of meteorological cyclones) the air is richer in oxygen than in the descending currents of air (in the regions of anticyclones or of barometric maxima); but more carefully conducted observations showed this supposition to be incorrect. Improved methods for the analysis of air have shown that certain slight variations in its composition do actually occur; but in the first place these depend on incidental local influences (on the passage of the air over mountains and large surfaces of water, regions of forest and herbage, and the like), and are also limited to quantities scarcely distinguishable from possible errors in the analyses. The researches made by Kreisler in Germany (1885) are particularly convincing.

The considerations which lead to the supposition that the atmosphere at great altitudes contains less oxygen than that at the surface of the earth are based on the law of partial pressures (Chap. I.). According to this law, the equilibrium of the oxygen in the strata of the atmosphere is not dependent on the equilibrium of the nitrogen, and the variations in the densities of the two gases with the height are determined by the pressures of separate gases. Details of the calculations and considerations involved therein are contained in my work: *On Barometric Levellings*, 1876, p. 48. On the basis of the law of partial pressures and of hypsometrical formulæ, expressing the laws of the variation of pressures at different altitudes, the conclusion may be deduced that in the upper strata of the atmosphere the proportion of nitrogen with respect to oxygen increases, but the increase will not exceed a fraction per cent., even at altitudes of four and a half to six miles, the greatest height within the reach of man either by climbing mountains or by means of balloons. This conclusion is confirmed by the analysis of air collected by Welch in England during his aëronautic ascents.

The analysis of air is effected by converting the oxygen into a non-gaseous compound, so as to separate it from the air. The original volume of the air is first measured, and then the volume of the remaining nitrogen. The quantity of oxygen is calculated either from the difference between these volumes or by the weight of the oxygen compound formed. All the volumetric measurements have to be corrected for pressure, temperature, and moisture (Chapters I. and II.) The medium employed for converting the oxygen into a non-gaseous substance should enable it to be completely taken away from the nitrogen without evolving any gaseous substance. Thus, for instance,¹⁹ a mixture of pyrogallol, $C_6H_6O_3$, with a solution of a caustic alkali absorbs oxygen with great ease at the ordinary temperature (the solution turns black), but it is unsuited for accurate analysis, because it requires an aqueous solution of an alkali, and it alters the composition of the air by acting on it as a solvent. However, for approximate determinations this simple method gives results which are entirely satisfactory.²⁰

The determinations in a eudiometer (Chapter III.) give more exact results, if all the necessary corrections for changes of pressure, temperature, and moisture are taken into account. This determination is carried out essentially as follows:—A certain amount of air is introduced into the eudiometer, and its volume is determined. About an equal volume of dry hydrogen is then passed into the eudiometer, and the volume again determined. The mixture is then exploded by a spark from a Leyden jar or Ruhmkorff coil. The remaining volume of the gaseous mixture is again measured: it will be less than the second of the previously measured volumes. Of three volumes which have disappeared, one belonged to the oxygen and two to the hydrogen; consequently one-third of the loss of volume indicates the amount of oxygen contained in the air.²¹

¹⁹ The complete absorption of the oxygen may be attained by introducing moist phosphorus into a definite volume of air: this is shown by the fact that the phosphorus becomes non-luminous in the dark. The amount of oxygen may be determined by measuring the volume of nitrogen remaining. This method, however, cannot give accurate results, owing to a portion of the air being dissolved in the water, to the combination of some of the nitrogen with oxygen, and to the necessity for introducing and withdrawing the phosphorus, which cannot be accomplished without admitting bubbles of air.

²⁰ For rapid and approximate analyses (technical and hygienic), such a mixture is very suitable for determining the amount of oxygen in mixtures of gases from which the substances absorbed by alkalies have first been removed. According to some observers, this mixture evolves a certain (small) quantity of carbonic oxide after absorbing oxygen.

²¹ Details of eudiometrical analysis must, as was pointed out in Chap. III., note 32, be looked for in works on analytical chemistry. The same remark applies to the other analytical methods mentioned in this work. They are only described for the purpose of showing the diversity of the methods of chemical research.

The most exact method for the analysis of air, and one which is accompanied by the smallest error, consists in the direct weighing, as far as is possible, of the oxygen, nitrogen, water, and carbonic anhydride contained in it. For this purpose the air is first passed through a weighed apparatus (which will be considered presently) for retaining the moisture and carbonic anhydride, and is then led through a tube which contains shavings of metallic copper and has been previously

FIG. 42.—Dumas and Boussingault's apparatus for the analysis of air by weight. The globe B contains 10–15 litres. The air is first pumped out of it, and it is weighed empty. The tube T connected with it is filled with copper, and is weighed empty of air. It is heated in a charcoal furnace. When the copper has become red-hot, the stopcock *r* (near R) is slightly opened, and the air passes through the vessels L, containing a solution of potash, and *f*, containing solutions and pieces of caustic potash, which remove the carbonic anhydride from the air, and then through *o* and *t*, containing sulphuric acid (which has been previously boiled to expel dissolved air) and pumice-stone, which removes the moisture from the air. The pure air then gives up its oxygen to the copper in T. When the air passes into T the stopcock R of the globe B is opened, and it becomes filled with nitrogen. When the air ceases to flow in, the stopcocks are closed, and the globe B and tube T weighed. The nitrogen is then pumped out of the tube and it is weighed again. The increase in weight of the tube shows the amount of oxygen, and the difference between the second and third weighings of the tube, with the increase in weight of the globe, gives the weight of the nitrogen.

weighed, the remaining nitrogen being afterwards collected and weighed. A long layer of such copper heated to redness absorbs all the oxygen from the air, but does not act on the nitrogen. The nitrogen is determined in a weighed and exhausted globe by ascertaining the increase in weight, while the amount by weight of oxygen is shown by the increase in weight of the tube with the copper.

Air free from moisture and carbonic anhydride ²² contains 23.17 to

²² De Saussure observed that air freed from carbonic anhydride and submitted to the action of a series of electric sparks again shows the presence of a small quantity of carbonic anhydride, and Boussingault found that air free from moisture, after being passed over red-hot copper oxide, invariably appears to contain a small quantity of water. These observations lead to the assumption that air always contains a certain quantity of

23.03 per cent.²³ by weight of oxygen; the mean amount of oxygen will therefore be 23.12 ± 0.05 per cent. by weight, and 20.91 by volume.²⁴

The possibility of the composition of air being altered by the mere action of a solvent very clearly shows that the component parts of air are in a state of mixture, in which any gases may occur; they do not in this case form a definite compound, although the composition of the

FIG. 43.—Apparatus for the absorption and washing of gases, known as Liebig's bulbs. The gas enters *m*, presses on the absorptive liquid, and passes from *m* into *b*, *c*, *d*, and *e* consecutively, and escapes through *f*.

FIG. 44.—Geissler's potash bulbs. The gas enters at *a*, passes through a solution of potash in the lower bulbs, where the carbonic anhydride is absorbed, and then escapes from *b*. The lower bulbs are arranged in a triangle, so that the apparatus can stand without support.

atmosphere does appear constant under ordinary conditions. The fact that its composition varies under different conditions confirms the truth of this conclusion, and therefore the constancy of the composition of air must not be considered as in any way dependent on the nature of the gases entering into its composition, but only as proceeding from cosmic phenomena co-operating towards this constancy. It must be admitted, therefore, that over the entire surface of the earth,²⁵ the

gaseous hydrocarbons, like marsh gas, which, as we shall afterwards learn, is evolved from the earth, marshes, &c. Its amount, however, does not exceed a few hundredths per cent. A. Gauthier's careful researches (1898–1901) proved this beyond doubt, as will be explained presently; but it appeared that the amount of hydrocarbons is variable and in some cases zero, while hydrogen is always present to the amount of about 0.02 per cent. (see note 29).

²³ The analyses of air are accompanied by errors, variations of composition of a few hundredths per cent. being found; the average normal composition of air is therefore only correct to the first decimal place.

²⁴ These figures express the mean composition of pure air as given by the most accurate determinations; they are accurate within ± 0.05 per cent.

²⁵ In Chap. III., note 4, an approximate calculation is made for the determination of the balance of oxygen in the entire atmosphere; it may therefore be supposed that the composition of air will vary from time to time, the relation between vegetation and the oxygen-absorbing processes changing; but as the atmosphere of the earth can hardly have a definite limit and we have already seen (Chap. IV., note 33) that there are observations confirming this, it follows that variations in the composition of our atmosphere are distributed throughout celestial space, and therefore it must be supposed that any variation in the composition of the air in the course of ages can only take place

processes evolving oxygen, and chiefly the processes of the respiration of plants, have an influence equal and opposite to that exerted by those processes which absorb oxygen.

Air always contains more or less moisture ²⁶ and **carbonic anhydride**,

FIG. 45.—Tube for the absorption of carbonic acid. A plug of cotton-wool is placed in the bulb to prevent the powder of soda-lime being carried off by the gas. The tube contains soda-lime and chloride of calcium.

which are produced by the respiration of animals and the combustion of carbon and carboniferous compounds. The latter gas shows the properties of an acid anhydride. In order to determine the amount of carbonic anhydride in air, substances which absorb it—namely, alkalies—are employed, either in solution or in the solid state. A solution of caustic potash, KHO, is poured into light glass vessels, through which the air is passed, and the amount of carbonic anhydride is determined by the increase in weight of the vessel. But it is best to take a porous alkaline solid such as soda-

lime.²⁷ With a slow current of air, a layer of soda-lime 20 cm. in length is sufficient to completely deprive 1 cubic metre of air of the carbonic anhydride it contains. A series of tubes containing calcium

exceedingly slowly, and in a manner imperceptible by direct experiment. The composition of the atmosphere must, however, have undergone considerable changes during the course of the geological history of the earth (i.e., during millions of years). This is particularly true concerning the amount of carbonic anhydride, as it has been largely absorbed by the earth's crust and soil in the sedimentary formations composed of salts of carbonic acid (for instance, limestones, CaCO_3) and in coal. The temperature of the earth's surface must depend greatly upon the amount of CO_2 in the air, because this affects the diathermancy of the atmosphere (just as the glass of a hothouse hinders it from cooling and collects the heat of the sun's rays). The undoubted difference of climate in different geological periods is now accounted for in this manner. Thus the climate of Central Europe was colder during the glacial period and much warmer during the mammoth period. The researches of Brown and Escombe (1902), strange to say, showed that dicotyledons strike not better but far worse when the amount of carbonic anhydride in the air increases (how is it with gymnosperms?).

²⁶ The amount of moisture contained in the air is considered in greater detail in the study of physics and meteorology, and the subject has been mentioned above in Chapter I., note 1, where the methods of absorbing moisture from gases were pointed out.

²⁷ Soda-lime is prepared in the following manner:—Unslaked lime is finely powdered and mixed with a slightly warmed and very strong solution of caustic soda. The mixing should be done in an iron dish, and the materials should be well stirred together until the lime begins to slake. When the mass becomes hot, it boils, swells up, and solidifies, forming a porous mass very rich in alkali and capable of rapidly absorbing carbonic anhydride. A lump of caustic soda or potash presents a much smaller surface for absorption, and therefore acts much less rapidly. It is necessary to place an apparatus for absorbing water after the apparatus for absorbing the carbonic anhydride, because the alkali in absorbing the latter gives off water.

chloride for absorbing the moisture²⁸ is placed before the apparatus for the absorption of the carbonic anhydride, and a measured mass of air is passed through the whole apparatus by means of an aspirator. In this manner the determination of the moisture is combined with the absorption of the carbonic anhydride. The arrangement shown in fig. 42 is such a combination.

The amount of carbonic anhydride²⁹ in free air is incomparably more constant than the amount of moisture. The average amount in 100 volumes of dry air is approximately 0.03 volume—that is, 10,000 volumes of air contain about three volumes of carbonic anhydride, most frequently about 2.95 volumes. As the specific gravity of

²⁸ It is evident that the calcium chloride employed for absorbing the water should be free from lime or other alkalies in order that it may not retain carbonic anhydride. Such calcium chloride may be prepared in the following manner: A perfectly neutral solution of calcium chloride is prepared from lime and hydrochloric acid; it is then carefully evaporated, first on a water-bath and then on a sand-bath. When the solution attains a certain strength a scum is formed, which solidifies at the surface. This scum is collected, and will be found to be free from caustic alkalies. It is necessary in any case to test it before use, as otherwise a large error may be introduced into the results owing to the presence of free alkali (lime). It is best to pass carbonic anhydride through the tube containing the calcium chloride for some time before the experiment in order to saturate any free alkali that may remain from the decomposition of a portion of the calcium chloride by water, $\text{CaCl}_2 + 2\text{H}_2\text{O} = \text{CaOH}_2\text{O} + 2\text{HCl}$.

²⁹ Recourse is had to special methods when the determination only takes note of the carbonic anhydride of the air. For instance, it is absorbed by an alkali which does not contain carbonates (by a solution of baryta or caustic soda mixed with baryta), and then the carbonic anhydride is expelled by an excess of an acid, and its amount determined by the volume given off. A rapid method of determining CO_2 (for hygienic purposes) is given by the fall of pressure produced by the introduction of an alkali (the air having been either brought to dryness or saturated with moisture). Dr. Schidloffsky's apparatus is based upon this principle. The question as to the amount of carbonic anhydride present in the air has been submitted to many voluminous and exact researches, especially those of Reiset, Schloesing, Müntz, and Aubin, who showed that the amount is not subject to such variations as at first stated. The existing data concerning the amount of CO_2 in the air have been supplemented (1902) by observations made by A. Levy and Henriet, who found that, after leaving air in contact with an alkali for several days so that all the CO_2 was absorbed, they obtained a further quantity of CO_2 which varied in different cases, but sometimes approached the normal amount. A commission deputed by the Paris Academy of Sciences to verify this unexpected discovery convinced themselves of its reality, and in one experiment (July 27, 1902) obtained a further 0.0216 per cent. of CO_2 (by volume) after having absorbed all the original CO_2 (about 0.03 per cent. vol.) with baryta. Henriet showed that this second portion of CO_2 originates in the subsequent oxidation of an organic substance which is present in the air and occurs in solution in the water obtained by the condensation of its moisture, and he supposes this body to be an amide of formic acid. These observations were made in Paris and also at Mont Sourie, near Paris. They are, however, too recent to allow of their being regarded as perfectly trustworthy; and what is, in my opinion, still more important, there is no proof either that the air of all localities would exhibit this peculiarity or that it is not a consequence of urban conditions, and hence due to a change produced in the air by the crowded life of cities. Further, it is not known whether it would be observable in air containing such oxidising agents as ozone, peroxide of hydrogen, and oxides of nitrogen. But in any case it is a matter of great interest.

carbonic anhydride referred to air is 1.52, it follows that 100 parts by weight of air contain about 0.045 part by weight of carbonic anhydride. This quantity varies according to the time of year (more in winter), the altitude above the level of the sea (less at high altitudes), the proximity to forests and fields (less) or cities (greater), &c. But the variation is small and rarely exceeds the limits of $2\frac{1}{2}$ to 4 ten-thousandths by volume.³⁰ As there are many natural local influences which either increase the amount of carbonic anhydride in the air (respiration, combustion, decomposition, volcanic eruptions, &c.), or diminish it (absorption by plants and water), the reason of the great constancy in the amount of this gas in the air must be looked for, in the first place, in the fact that the wind mixes the air of various localities together, and, in the second place, in the fact that the waters of the ocean, holding carbonic acid in solution,³¹ form an immense reservoir for regulating the amount of this gas in the atmosphere. Immediately the partial pressure of the carbonic anhydride in the air decreases, the water evolves more of the gas, whilst when its partial pressure increases, some of it is absorbed in this, as in so many other instances.³² Hence nature supplies the conditions for a state of equilibrium.

³⁰ In enclosed spaces, in dwellings, cellars, wells, caves, and mines, where the renewal of air is impeded, the case is different. Under these circumstances large quantities of carbonic anhydride may accumulate. In cities, where many conditions (respiration, decomposition, combustion) for the evolution of carbonic anhydride exist, its amount is greater than in free air; yet even in still weather the difference does not often exceed one ten-thousandth (that is, rarely attains 4 instead of 2.9 vols. in 10,000 vols. of air).

³¹ In the sea, as well as in fresh water, carbonic acid occurs in two forms, being both directly dissolved in the water, and combined with lime as calcium bicarbonate (hard waters sometimes contain very much carbonic acid in this form). The pressure of the carbonic anhydride in the first form varies with the temperature, and its amount with the partial pressure; and the same is the case with that existing in the form of acid salts, for direct experiments show a similar dependence here, although the quantitative relations are different in the two cases.

³² In studying the phenomena of nature the conclusion is arrived at that the universally reigning state of mobile equilibrium forms the chief reason for that harmonious order which impresses all observers. It not unfrequently happens that we do not see the causes regulating the order and harmony; in the particular instance of carbonic anhydride, it is a striking circumstance that in the first instance a search was made for an harmonious and strict uniformity, and in incidental (insufficiently accurate and fragmentary) observations, conditions were even found for concluding it to be absent. When, later, the existence of this uniformity was confirmed, the causes regulating such order were also discovered. The researches of Schloesing were of this character. Deville's idea of the dissociation of the acid carbonates of sea-water is suggested in them. In many other cases also a correct interpretation can only follow from a detailed investigation. It is the function of science to discover the existence of a general reign of order in nature and to find the causes governing this order. And this refers in equal measure to the relations of man (social and political) and to the entire universe as a whole, and also to the world of material inanimate substances, in which natural science is gradually discovering an equilibrated order of things wherever it pursues the requisite research.

Besides nitrogen, oxygen, moisture, and carbonic acid, all the other substances occurring in air are found in infinitesimally small proportions by weight, and therefore the **weight of any volume of air** (at a given temperature and pressure) depends mainly on the above-named components. The weight of a litre of pure air (that of a litre of water at 4° and 760 mm. being 1,000 grams), free from dust, moisture, and carbonic anhydride, at 0° and 760 mm., has been determined as follows : ³³

	Average weight of litre			Under acceleration of		
	gramme			gravity, $g =$ metres		
Regnault (1847)	.	.	1·29347	.	.	9·8100
Jolly (1880)	.	.	1·29316	.	.	9·8073
Leduc (1892)	.	.	1·29330	.	.	9·8100
Rayleigh (1893)	.	.	1·29362	.	.	9·8126

The last column gives the acceleration due to gravity in metres. It has an effect upon the value of the barometric column, for 760 mm. of mercury presents a greater pressure, the greater the acceleration due to gravity. The average weight of a litre of pure air under an acceleration g is :

$$e_0 = g \times 0.131844 \text{ gram.}$$

Defarges gives an average of $g = 9.80665$ ³⁴ for latitude 45° and therefore $e_0 = 1.2929$ gram (the density being about 14.4 with respect to hydrogen). The weight of air containing 0.03 per cent. by volume of CO₂ will be greater by 0.0006 gram. Hence if at a given locality the observed barometric pressure reduced to 0° be P mm., the vapour pressure of water p mm., the temperature t (according to the Centigrade thermometer, and corrected to the hydrogen scale) and the acceleration of gravity g metres, then the weight of a litre of air (with an error not greater than about 0.0002 gram) will be :

$$e = \frac{g}{9.80665} \times 1.2935 \times \frac{P - 0.38p}{760} \times \frac{273}{273 + t} \text{ gram.}^{35}$$

A knowledge of the exact weight of a litre of air is of great

³³ See 'The Publications of the Weights and Measures Department,' 1894, part i., p. 85.

³⁴ The acceleration of gravity for a given latitude L° and elevation above the sea level, H metres, will then (if the terrestrial globe be assumed to be a regular ellipsoid at the level of the sea, which, strictly speaking, is not the case) be given by :

$$g = \frac{9.80665 (1 - 0.0026 \cos 2L)}{1 + 0.000000196 H}.$$

But the most accurate results are obtained by direct experiment, because the proximity of the sea or mountains, the nature of the geological formations of a given locality, and irregularities in the ellipsoidal form of the earth also affect the value of g .

³⁵ The effect of the local acceleration of gravity on the weight of a litre of air is determined exclusively by the dependence of this weight on the pressure and the

importance in determining the exact weight of objects and weights, where it is necessary to introduce corrections for the weight of air displaced,³⁶ and also in investigating many meteorological phenomena, the movements of the atmosphere being determined chiefly by the different densities of different volumes of air which are at the same level and are moving freely.³⁷

Although **liquid air**, as mentioned in Chapter II., was already known in 1877 (Pictet and Cailletet), it was not until much later, in the nineties, that the means were discovered, thanks to the labours of Olzewsky, Wroblewsky, Dewar, Linde, and others, for obtaining it easily in con-

measurement of this pressure by the barometric column. At first it might appear to be a question of the difference (see 'Mechanics and Physics') which exists between the conceptions of mass and weight, as the latter is determined by the acceleration of gravity, for weight is pressure. But the weights, expressing a definite mass, remain the same, and consequently when a weight is expressed by them (as is customary both in chemistry and in ordinary practice) they vary in the pressure they produce according to the locality in which they are situated. In other words, weights, for instance, the gram, as a matter of fact express units of mass; but they are also measures of weight in the generally accepted sense of the word. This is all only a question of nomenclature and of the conditional expression of conceptions, over which I think it is unnecessary to linger, for science should give clear conceptions and not temporise with words, although unfortunately we cannot express our ideas without them; and if the term 'weight' is frequently used in chemistry in the sense of mass (for instance, the weight of an atom or of a gram), still this does not introduce any inexactitude into the science, particularly as words often have more meanings than one. Thus the word 'mass' expresses the conception of a multitude of substances besides the mechanical notion of the amount of ponderable matter, and the word 'weight' not only signifies the amount of a substance in units of weight, but also the counterpoises themselves. I think it only complicates matters to introduce any changes in words or to invent special ones for every conception.

³⁶ For rapid calculation the weight of a litre of air (in a room) in St. Petersburg may under these conditions (P , t , and p) be obtained by the formula, $e = 1.20671 + 0.0016 [P_1 - 755 + 2.6 (18 - t)]$, where $P_1 = P - 0.38p$. In determining the weight of small and heavy objects (crucibles, &c., in analysis, and in determining the specific gravities of liquids, &c.) **a correction may be introduced for the loss of weight** in the air of the room, by taking the weight of a litre of air displaced as 1.2 gram, and consequently allowing 0.0012 gram for every cubic centimetre. But if gases or, in general, large vessels are weighed, and the weighings require to be accurate, it is necessary to take into account all the data (t , P , and p), because sensitive balances can determine the possible variations of the weight of air, as in the case of a litre of air the weight varies in centigrams, even at a constant temperature, with variations of P and p . Some time ago (1859), I proposed the following method and applied it for this purpose. A large light and closed vessel is taken, and its volume and weight in a vacuum accurately determined and verified from time to time. On weighing it we obtain the weight in air of a given density, and by subtracting this weight from its absolute weight and dividing by its volume we obtain the density of the air.

³⁷ At about the normal pressure and within the limits of 0° and 25° , an increase of pressure of about 3 mm. produces the same variation in the density of air, as a fall in temperature of 1° . It appears to me therefore that an investigation of the variation in the distribution of the densities of air at various periods over the surface of the earth (which may be easily accomplished now with kites and self-registering apparatus) might give most important and instructive meteorological data. The following table, which I have compiled from Glaisher's observations, assuming the temperature at the surface of

siderable quantities, and even for using it for scientific and industrial purposes, for obtaining low temperatures and for concentrating the oxygen (boiling at -181°) from the more volatile nitrogen (boiling at -193°)³⁸ by evaporating the liquid mixture. Linde's apparatus for liquefying air is the most widely known.³⁹ It consists of two pumps B_1 and B_2 , which compress the indrawn air to 15–20 and 200 atmospheres respectively. As the compression of air to such an extent as 200 atmospheres evolves considerable heat, and as the liquefaction of air requires a low temperature, the pumps and compressed air are cooled to a low temperature⁴⁰ (a small amount of water is introduced into the cylinder B_1 for this purpose) by three refrigerators D_1 , D_2 , and G after the preliminary compression to 15–20 atmospheres and after the compression to 200 atmospheres. And as the refrigeration and

the earth to be $+15^{\circ}$, pressure 760 mm., and relative moisture 60 per cent., gives an idea of the variation of the density of the air during fine weather:—

Pressure	t° Centigrade	Moisture	Elevation	Weight of a litre of air
mm.		per cent.	m.	gram
760	+ 15.0	60	0	1.222
700	11.0	64	690	1.141
650	7.6	64	1,300	1.073
600	4.3	63	1,960	1.003
550	+ 1.0	62	2,660	0.931
500	— 2.4	58	3,420	0.857
450	— 5.8	52	4,250	0.781
400	— 9.1	44	5,170	0.703
350	— 12.5	36	6,190	0.624
300	— 15.9	27	7,360	0.542

As a matter of fact, especially in cloudy weather, the distribution of the density with the altitude is often much less regular, owing chiefly to the want of uniformity of the fall of temperature with increase of height.

³⁸ Liquid air floats on water, because its density, owing to the larger amount of nitrogen, is less than that of water; but when much of the nitrogen evaporates and the proportion of oxygen becomes greater it sinks under water, because liquid oxygen is slightly heavier than water at the temperature of liquid air. The colourless liquid air acquires a bluish tint as it becomes richer in oxygen.

³⁹ It may be obtained in different sizes. The large Linde machine which E. L. Nobel supplied to the St. Petersburg Weights and Measures Department requires a motive power of 12-horse power, and according to F. T. Blumbach can, when in good working order, supply 5 litres of liquid air per hour.

⁴⁰ The cooling in the refrigerators (D_1 , D_2 , and G) is carried on by cold water or ice, or, better still, by a mixture of salt and snow (about -20° , according to the method used in the Department of Weights and Measures of St. Petersburg) or by a mixture of snow (pounded ice) and crystals of chloride of calcium, or some other freezing mixture (Chap. I., note 26, and Chap. II., note 27). It must be remembered that in general the liquefaction of air (Chap. II., note 29) cannot take place at a temperature above -150° (the critical temperature of oxygen), and therefore expansion (to 1.5 atmosphere) of compressed (to 200 atmospheres) gas will give more liquid air, the lower the original temperature of the compressed gas (i.e., when under a pressure of 200 atmospheres).

compression of the air cause the moisture in it to precipitate partly as water (which is collected in F)⁴¹ and partly as ice, which might

FIG. 46.—Linde's apparatus for the liquefaction of air. A, the entrance for the air (with a small quantity of water from T) into the double-acting pump. B₁, the low-pressure (20 atms.), and B₂, the high-pressure (200 atms.), cylinders. D₂ and D₁, vessels through which runs cold water (d_2-d_1) for cooling the warm compressed air passing to the copper spiral. F, water-separator made of steel. G, steel spiral surrounded by a mixture of ice and salt (-15°). H, the inner tube of a triple copper spiral (the compressed and expanded air take opposite courses) surrounded by wool. K₂, conical cock for the expansion of the compressed air from 200 to 18 atmospheres pressure. J, tube through which the cooled gas returns through the valve L to the piston B₂. K₁, cock for expanding from 18 atms. to the ordinary pressure. The liquid air collects in the Dewar's vessel Q, and that which evaporates escapes from the apparatus through the third exterior spiral P-O. K₀, syphon cock for pouring out the liquid air after closing the aperture O. M₂, M₁, and M₀, manometers for the systems of tubes at pressures of 200, 20, and 1 atm. respectively.

⁴¹ It is evident that the water must be got rid of before letting the compressed air into the refrigerators (which are often spiral in form) where the temperature is below 0° ,

close the pipes conveying the compressed air, it is necessary to have a separator F ⁴² through which the compressed air is made to pass after leaving the pumps. It then travels through a long copper spiral H ,⁴³ situated in three high prism-shaped boxes in which the further refrigeration of the compressed gas takes place. These boxes are lined with bad conductors of heat (wool, down, felt) to prevent the warmth of the external air passing through. Besides which, the internal copper spiral, conveying the compressed air, is surrounded along its entire length by two similar but wider metallic spirals along which the refrigerated air which remains unliquefied is carried back to the pumps or escapes into the room, as will be presently explained.⁴⁴ This facilitates (naturally after the lapse of some time) the further refrigeration of the compressed air, which cannot of course liquefy spontaneously under a pressure of 200 atmospheres and at a temperature of -20° or even -50° (when cooled by a mixture of snow and crystals of calcium chloride), because the critical temperature (absolute boiling-point) of nitrogen lies much lower, namely, at about -146° . To obtain the requisite fall of temperature, the end of the internal copper spiral is furnished with a conical cock, K_2 , by means of which the compressed air is made to expand from a pressure of 200 to 15–20 atmospheres.⁴⁵ And as the increase in volume so produced causes the temperature of the air to fall by about 50° , the air will, on expansion, fall from a temperature t of between -15° and -20° to about -60° . This refrigerated air passes from the expansion box along the annular space surrounding the copper spiral into the pump B_2 , and in so doing cools the air compressed under 200 atmospheres to -50° or -60° , and after this again expands; the

so that the water should not freeze in them and hinder the passage of the compressed air. This must be kept in view in constructing refrigerators of this type.

⁴² The drops of water are collected by a metallic funnel as they enter the separator, and form a stream of water which remains in the separator. As any remaining water and the carbonic anhydride in the air solidify at the temperature of liquid air (about -190°), the liquid air obtained in the apparatus has the appearance of a turbid liquid, which is purified by simply filtering through unsized paper. A double-walled funnel, like the vessels described in Chap. II., note 32, for preserving liquid gases, should be taken for this purpose.

⁴³ In the apparatus at the St. Petersburg Weights and Measures Department it is 25 metres long.

⁴⁴ It is evident that the cold air obtained by expansion travels upwards in the annular space surrounding the inner spiral if the air travels downwards in the internal tube. This facilitates the refrigeration of the air passing through the inner spiral.

⁴⁵ The variation of the pressure in the apparatus is determined by means of pressure gauges. The first, M_2 , indicates about 200 atmospheres and is situated before the entrance for the compressed air into the spiral. The gauge M_1 indicates about 15–20 atmospheres and gives the pressures in the box where the expansion goes on. The third gauge, M_0 , gives the ultimate expansion, about $1\frac{1}{10}$ atmosphere.

temperature falls still further, and so on. In other words, when the apparatus continues working the gas compressed under 200 atmospheres is cooled more and more by expanding to 15–20 atmospheres. If the cock K_1 be now opened sufficiently to allow this refrigerated air to expand once more to a pressure of about one atmosphere,⁴⁶ its rapid expansion will be accompanied by a correspondingly rapid fall of temperature.⁴⁷ Then a portion of the air remains in the form of an exceedingly cold gas and escapes into the atmosphere through a third (external) copper tube which surrounds the whole of the upper portion of the spiral in the box, while the rest of the air passes into a liquid state, having a temperature of about -190° . The stream of liquid air so formed is collected in a double-walled vessel, like that described in Chapter II., note 32. This liquid air can be kept in this state for many days (for even fourteen days if about 2 litres be taken, and there be a perfect vacuum between the walls of the vessel). At first it is chiefly the nitrogen that evaporates, so that in the end a liquid very rich in oxygen is obtained.

As liquid air possesses and preserves (in evaporating) a very low temperature (between -190° and -185° , according to the amount of oxygen it contains), it makes possible many interesting experiments, especially of a physical nature. For instance, when mercury is poured into liquid air it freezes and becomes so cold that it can be hammered and rolled like lead. Alcohol and many other liquids which do not freeze in the most severe frosts are easily converted into solid matter by liquid air. When cooled by liquid air, indiarubber becomes exceedingly brittle, hard, and fragile, and lead sonorous. If an exhausted glass globe be filled with the vapour of mercury (by means of a Sprengel air pump), and any portion of it be cooled by liquid air (by moistening a piece of wadding on a stick with it and then rubbing the exterior of the globe), the mercury is immediately precipitated as a mirror on the spot cooled. If a glass globe be filled with the reddish-brown vapour of bromine (by boiling liquid bromine in the globe and so expelling the air, and then sealing up the globe), and any portion of its surface be cooled by liquid air, the bromine collects so completely about the cold spot in a solid form that the inside of the globe becomes quite colourless.

⁴⁶ The cock K_1 is opened just enough to reduce the pressure to about 1.1 atmosphere. A slight excess of pressure is given to make the cold expanded gas pass into the external annular space surrounding the spiral.

⁴⁷ When the temperature of the compressed air is between 0° and -50° , a fall in pressure of 1 atmosphere only produces a cooling effect of 0.2 – 0.3° ; but when the gas has been cooled to -190° or -200° , the same fall of pressure (1 atmosphere) lowers the temperature of the air by almost 2° , that is, the colder the air is, the more it is chilled by the same fall of pressure.

Those physical properties of the metals which vary to any considerable extent with the temperature are greatly affected by liquid air.⁴⁸ Thus the resistance offered by metals to an electric current, although not completely destroyed, is very greatly diminished in liquid air, and becomes infinitely small at about -273° (absolute zero)⁴⁹ for all metals. A finger may be plunged for a moment into liquid air with impunity, notwithstanding its low temperature, this being due to the formation of a non-conducting layer of gas between the skin and the liquid, which passes into a spheroidal state, similar to that of a drop of water poured on to a red-hot iron. Many chemical reactions which proceed at the ordinary temperature do not take place at the temperature of liquid air (see Introduction, p. 34).^{49a}

Turning to the other components of air (besides N_2 , O_2 , H_2O , and CO_2) the first to be mentioned is **Argon**, Ar (or sometimes A), whose discovery (1894) by Rayleigh and Ramsay has already been described. When Rayleigh discovered that the nitrogen remaining from air after the removal of O_2 , H_2O , and CO_2 was heavier (by $\frac{1}{200}$) than nitrogen prepared from any of its compounds (with oxygen, hydrogen, metals, or carbon), no doubt remained that the nitrogen of the air contained some other gas heavier than nitrogen. To separate this gas it was necessary to convert the nitrogen into some of its non-gaseous compounds, as the new gas evidently did not enter into the composition of any of the compounds formed by nitrogen.⁵⁰ The following two methods were adopted for this purpose: (1) oxidation of the nitrogen and (2) absorption of the nitrogen by metallic magnesium.

⁴⁸ At low temperatures chemical reaction often becomes so feeble (or even ceases altogether) that only the negative side of the question is evident; but this aspect of the subject cannot explain much, because the substances become so hard that they lose the mobility of parts necessary for chemical reaction. But as the oxygen in liquid air is compressed it supports combustion with particular energy (for instance, a smouldering cigarette bursts into flame). This has even been taken advantage of for causing explosions, as a piece of wadding or charcoal moistened with liquid air (especially if it be rich in oxygen) gives a violent explosion if it is set fire to by a spark or pistol-shot. Owing to the cheapness of liquid air this method has its economical advantages.

⁴⁹ The increase in intensity of phosphorescence at low temperatures (paraffin, bone, &c.) is mentioned in Chap. II., note 32.

^{49a} There can be no doubt that the preparation of liquid air on a large scale may prove most valuable for many purposes, and especially for obtaining air rich in oxygen at a low price and for producing extreme cold.

⁵⁰ Rayleigh and Ramsay made many most interesting experiments before they succeeded in isolating argon, proving the substance they were seeking to be heavier than nitrogen and quite distinct from it in its properties. Thus they divided air by diffusion (through a porous clay tube) into a lighter (diffusive) portion and a heavier residue, and obtained nitrogen from both (by absorbing the oxygen with copper). It was found that the nitrogen which diffused through the tube was lighter than the residue, which had therefore accumulated the heavier unknown substance.

Cavendish (1786) knew that the nitrogen of the air, under certain conditions and especially by the action of an electric discharge in the presence of alkalies or in the explosion of detonating gas,⁵¹ can be converted into nitric acid if a sufficient amount of oxygen (and moisture)

FIG. 47.—Apparatus for converting the nitrogen of the air (by the help of added oxygen) into nitric acid. Through C passes air mixed with oxygen. E G and F H are conductors from a Ruhmkorff's coil. The flask B contains a solution of caustic soda, which absorbs the nitric acid formed by the sparks; it is cooled by means of water.

be added to it; and he also observed that a portion of the nitrogen is not converted into nitric acid.⁵² After conversion into nitric acid, that is, after oxidation, the nitrogen can be easily removed (by means of alkalies, which form salts of nitric acid); and if excess of oxygen was taken, this also can be easily removed by passing it over red-hot copper.⁵³

Still this method is complicated, and it was therefore abandoned in favour of the method of absorption by finely powdered magnesium.⁵⁴ When heated, this powdered magnesium converts all the

⁵¹ See note 9.

⁵² Cavendish evidently had argon and its associates in this portion, but the small quantity of the residue probably prevented him from investigating the residual gas more closely.

⁵³ It is most important to note that Rayleigh and Ramsay obtained argon not only from the nitrogen of the air but also from nitrogen obtained from its compounds, although in the first case more than 1 vol. of argon (and its associates; see further) was given by 100 vols. of nitrogen, whilst in the second they only obtained 0.1 vol. The authors explain the presence of argon in the second instance by the fact that they collected the gas over water which might have contained argon in solution. Until this is verified it may be assumed that argon is capable of being formed from nitrogen in some way or another. This view is mentioned in the succeeding notes.

⁵⁴ Magnesium in the form of powder may be bought. Hempel advises mixing it with unslaked lime. Small pieces (thin leaves) of metallic sodium are also sometimes mixed with the magnesium, but the best plan is to add metallic lithium, which absorbs nitrogen with avidity. The magnesium in one of these forms is placed in an iron tube (unsoldered) and heated, and dry air (without CO₂) is then passed over it. The oxygen of the air is absorbed by the magnesium before the nitrogen. In order to absorb all the nitrogen, the gaseous residue (impure argon) must be passed over the magnesium several times until the spectrum (obtained by electric sparks of high intensity) no longer exhibits the characteristic lines of nitrogen. And as the residue of argon is small, and the intricate apparatus employed in its preparation must necessarily embrace a considerable gaseous volume which increases with the number of tubes of magnesium employed, the apparatus is constructed in such a manner as to cause the residue of gas to repeatedly pass over one and the same tube containing magnesium. This may be done in several

nitrogen into solid non-volatile nitride of magnesium, N_2Mg_3 , without absorbing the argon.⁵⁵ The residue, which is left unabsorbed by the magnesium, is a gas having a density of about 20 compared with that of hydrogen, whilst the densities of nitrogen and oxygen are 14 and 16 respectively. A similar gaseous residue, which is not absorbed either by ordinary solutions of reagents (alkalies, acids, salts), or by copper, magnesium, lithium, or other incandescent metals, is obtained from the air (formerly in solution) expelled by boiling from ordinary and sea water and from the water of many mineral springs (in the Pyrenees, Iceland, Germany, &c.); and here the amount of this gaseous residue is even greater than in ordinary air, which gives about 7 litres of residue per 1,000 litres. This residue,⁵⁶ when cooled by liquid air and evaporated under a low pressure (i.e., at about -200°), is entirely converted into a liquid (a portion, however, crystallising, especially at the temperature of liquid hydrogen). If this liquid is evaporated under the ordinary pressure (760 mm.) a portion of it comes over below -186° , and this portion contains helium and neon, of which mention will be made later on, while a portion which remains liquid at temperatures considerably above -186° contains krypton and xenon (see below). The main portion of the residue, however, distils over at about this temperature, and that portion which boils between -185° and -187° (under a pressure of 760 mm.) is true argon.⁵⁷ Air contains about 0.7 per cent. of argon by volume, and somewhat less than 0.2 per cent. of its associates, helium, neon, krypton, and xenon. Argon readily solidifies into a colourless mass, like ice, at about -190° under the atmospheric pressure.⁵⁸ In a gaseous state, argon is 19.8 times

ways, but it is best to make the residual gas return to the point from which it originally entered the tube with magnesium. For this purpose a small mercury aspirator (Chap. II., note 16) is placed at the end of the tube and draws the gas through a glass tube back to that containing the magnesium. As it travels along this path the gas meets two platinum wires soldered into the glass tube, through which electric sparks are passed for exhibiting the spectrum. The mercury falling into the funnel of the aspirator compels the gas to pass once more along the magnesium tube which is furnished with a metallic mixer, worked from time to time by hand, to stir the magnesium and bring fresh surfaces into contact with the gas.

⁵⁵ Professor A. P. Lidoff (1902) showed that this method of absorbing nitrogen may even be employed for the analytical determination of nitrogen by weight.

⁵⁶ This residue was at first considered to be pure argon (1894–1895), but it was afterwards (chiefly owing to the researches of Ramsay and Travers) found to be a mixture of at least five gases—helium, neon, argon, krypton, and xenon.

⁵⁷ As argon has not yet been brought into a state of combination, its further purification is impossible. It is proved, however, to be a uniform substance by the fact that its boiling-point is constant and that diffusion (through porous diaphragms) gives portions of similar density.

⁵⁸ The critical temperature of argon is about -117° and the critical pressure about 53 atmospheres.

heavier than hydrogen,⁵⁹ and in a liquid state (at -186°) 1.5 times heavier than water.⁶⁰ Although so well characterised in its physical properties, argon is distinguished in a chemical sense by such inactivity and immutability that in this respect it stands alone. All endeavours to bring it into chemical reaction have as yet been fruitless.⁶¹ This is all the more remarkable because argon (and its associates) is contained, together with nitrogen,⁶² in a fairly stable condition in certain (especially Scandinavian) minerals containing uranium, tantalum, yttrium, and other rare metals; for instance, in uranite, cleveite, monazite, eshenite, fergusonite, &c. If these minerals are slightly heated, they give off water and carbonic anhydride, but no nitrogen or argon, or their associates. These are only given off by strongly heating (to the temperature at which ordinary glass becomes soft) the minerals with sulphuric acid, or, better still, with acid sulphate of potassium (KHSO_4) or bichromate of potassium ($\text{K}_2\text{Cr}_2\text{O}_7$). If all the air be first exhausted by a Sprengel pump, the gases may be easily collected as they pass over. These gases generally consist of nitrogen, argon, and helium. Previous to Ramsay's discovery they were considered to be nitrogen. It is

⁵⁹ In Chap. XIV., note 7, it is shown that k , or the ratio of the two specific heats (at constant volume and at constant pressure), decreases as the complexity of the molecules of a gas, that is, as the number of atoms in the molecule increases. For gases containing 1 atom in the molecule the ratio is about 1.6–1.8; for 2 atoms, about 1.4; for 3, 1.3, and so on. This ratio was determined for argon (Rayleigh, Dorn) and found to be $=1.67$; from which it is concluded that its molecule is composed of one atom, like that of mercury, i.e., that argon is an element and that its molecule contains 1 atom. However, this cannot be considered as proved, because the value of k varies considerably for gases having the same number of atoms in the molecule, and greatly depends upon the range of temperature and apparently on the store of chemical energy (for instance, for chlorine, Cl_2 , k is less than for N_2 , CO , &c.), which we need not consider further here.

⁶⁰ The luminous spectrum given by the gas when an electric discharge of high intensity is passed through it (between two platinum wires in a Geissler or Plucker tube; see Chap. XIII.) is very important for characterising and determining the individuality of argon and its associates, helium, neon, krypton, and xenon. The spectra of argon and its associates (and also of some other gases) vary with the intensity of the electricity and with the pressure of the gas in which the discharge takes place. The characteristic lines for argon (Crookes, Dorn, &c.) are two red ones with wave lengths of 707 and 696 millionths of a millimetre (thousandths of a micron).

⁶¹ However, Berthelot obtained some argon from Ramsay in 1895, and subjected it to a silent discharge in a vessel together with benzene, C_6H_6 , and observed that the argon was absorbed and gave a substance similar to that given by nitrogen under like conditions. It is not known if the argon was perfectly pure, and no further explanations have been published on this subject.

⁶² It is not known in what form of combination or state the argon, helium, and other gases are present in cleveite, eshenite, and other minerals. It is not even known if they form an essential component of these minerals or if their presence is due to some impurity. Owing to the rarity of these minerals and the small amounts of argon, &c. obtained from them, there yet remains much to be done in this province of research, and many interesting data are yet to be looked for.

evident that the gases are held in the minerals in the form of somewhat stable compounds (decomposed, however, by sulphuric acid, &c.), and not simply in a state of absorption, for absorbed gases pass over of themselves when heated *in vacuo*; but neither argon, nor helium, nor their associates can be driven off in this manner. The absorption of argon by water, on the other hand, takes place with greater facility than that of nitrogen, about four volumes of argon being dissolved by 100 volumes of water at the ordinary temperature and pressure (almost the same as oxygen).

Thus argon must be regarded as a peculiar gas distinguished by its great chemical inactivity, but possessing perfectly defined physical properties, among which a typical spectrum must also be noted (see note 60). And as typical spectra chiefly belong to simple bodies,⁶³ argon is placed among their number, although the chief characteristics of simple bodies, namely, the independence and individuality of their corresponding compounds, are not exhibited by argon.⁶⁴ However, it is quite possible to imagine a class of elements which do not combine with hydrogen or oxygen to form acids or bases, just as many elements are known which do not combine with hydrogen, while fluorine does not combine with oxygen to form saline substances. If such be the case, we have the right to form a special **group of the argon elements**, including helium, He, neon, Ne, argon, Ar, krypton, Kr, and xenon Xe; not only because they accompany each other in the nitrogen of the atmosphere, and are perfectly analogous to each other in their inertness and incapacity for entering into combination in the ordinary way, or for forming compounds more or less resembling bases, acids, or salts, but

⁶³ In Chap. XIII. we shall see, however, that compound bodies have also their spectra, if they can be subjected to the necessary degree of incandescence.

⁶⁴ Neither are there any reasons for considering argon as a compound substance, although when it was first discovered (1894) I had my reasons for considering it a polymeride of nitrogen, N_3 , standing in the same relation to nitrogen, N_2 , as ozone, O_3 , does to oxygen, O_2 (see last edition of *Principles of Chemistry*), but formed with the evolution of heat (ozone is formed with the absorption of heat). If argon and its associates (helium, &c.) be regarded as individual chemical elements, then, owing to their incapacity to form saline compounds of the type RX_n (see Chap. XV.), they must be placed in a special, so to speak, zero group preceding the first group, the elements of which give RX , and forming a transition stage towards the halogens (group VII. giving hydrogen compounds of the type RX and oxygen compounds of the type RX_7). This view, which answers to what Ramsay stated to me personally (March 19, 1900) is in accordance with the fact that argon and its analogues contain one atom in their molecule, which gives the possibility of determining the atomic weight from the density, for the atomic weights of such elements referred to that of hydrogen (Chap. VII.) are approximately equal to twice the densities of the gases also referred to that of hydrogen. Thus if the density of argon is 19.8, its atomic weight must be near to 39.6. And the periodic law (Chap. XV.) requires that the order in which the elements stand according to their atomic weights should correspond with their properties, and therefore the atomic weights of argon and its analogues should be greater than the atomic weights of the halogens of

also because ⁶⁵ this group of argon elements is exactly similar (even in the values of the atomic weights) to the other most characteristic groups of the elements spoken of more fully in Chap. XV.

The analogues of argon have all been found, as already mentioned, in air; that is, in its nitrogen; but they also accompany nitrogen and argon in the above-named minerals, such as cleveite, and **Helium**, $\text{He}=4.0$, was first obtained by Ramsay in 1895 by heating cleveite with sulphuric acid. The history of helium, however, begins before its discovery was an accomplished fact, and it had even been named, for Lockyer, from observations on the spectrum of the solar protuberances (Chap. XIII.), foretold the existence of an element giving a bright pale yellow line (wave length 587.0 thousandths of a micron), and a feebler green line (wave length 508). Helium may be separated from argon, nitrogen, and the other argon gases, owing to its being lighter than any of them, and therefore passing through porous partitions in larger quantity. More-

group VII., but less than those of the alkali metals of group I. This is, if not quite, at all events very nearly confirmed by their *observed* densities.

	He	Ne	Ar	Kr	Xe
Density (H=1)	2.0	9.95	19.8	40.6	63.5

Therefore taking hydrogen = 1 (and we take it = 1.008) the atomic weights of these elements will be:

He = 4:	Ne = 19.9:	Ar = 39.6:	Kr = 81.2:	Xe = 127.0
helium	neon	argon	krypton	xenon

These values of the atomic weights of the halogens of group VII. and those of the alkali metals of group I. (taking H = 1) are:

Group VII.	F	Cl	Br	I
	18.9	35.2	79.4	125.9
I. Li	Na	K	Rb	Cs
7.0	22.9	38.9	84.8	132.0

All the analogues of argon (judging by their densities) have, therefore, greater atomic weights than the corresponding elements of group VII., and smaller atomic weights than those of the alkali metals (argon presents a slight discrepancy, as, judging from Cl and K, its atomic weight should be about 37, that is, its density should be 18.5 instead of 19.8. This leads one to think that argon still includes some other gas of high density in admixture with it). Moreover, we find that F, Cl, Br, and I exhibit a resemblance to each other similar to that shown by Li, Na, K, Rb, and Cs, or He, Ne, Ar, Kr, and Xe. The parallel goes still further, for the first members of all three groups have certain peculiarities, as we shall see later. These considerations support the idea of the elementary character of the analogues of argon, and indicate to us their position in regard to the other elements. Still, it is impossible to be quite sure of the true nature of these gases until some of their compounds (for instance, of the kind present in cleveite, fergusonite, &c.) have been obtained. Professor Ramsay himself first informed me (1900, see above) of the position occupied by the analogues of argon in the periodic system between the halogens and the metals of the alkalies; later Professor Ramsay published a paper on the subject, and in 1902 communications on the same subject were published by N. N. Beketoff, Piccini, and others. For my part, when I saw the above regularity, I became more inclined than before to regard argon and its analogues with their peculiar combination of properties as elementary substances standing, not in group VIII., as some think, but forming a special (zero) group.

⁶⁵ As explained in the preceding note

over it does not pass into a liquid state under the action of cold, even at the temperature produced by liquid hydrogen,⁶⁶ and if helium is present in admixture with the other argon gases it dissolves in them when they liquefy, but the solution parts with almost pure helium at -250° (in liquid hydrogen) in a vacuum. The density of helium is only twice that of hydrogen, so that it is the lightest of all gases except hydrogen. In other respects helium is exactly like argon.⁶⁷ **Neon**, $\text{Ne}=19.9$, which accompanies helium in air and has the density 9.95, differs in the free state from helium in the fact that it liquefies in the cold produced by liquid air, and remains liquid at the temperature of liquid hydrogen under a low pressure; it boils below -186° (that is, is more volatile than argon) and gives a spectrum with brilliant reddish-orange lines (650, 641). Among the liquefiable argon gases, two more gases occur in those portions of liquid air which evaporate with the greatest difficulty, namely, **Krypton**, $\text{Kr}=81.8$, and **Xenon**, $\text{X}=128$, discovered by Ramsay and Travers. They are also looked upon as simple bodies, but they boil at a higher temperature than argon. The spectrum of the former is greenish yellow (wave lengths of the most brilliant lines,⁶⁸ 558, 477, 474, and 450 thousandths of a micron), while that of the latter is blue (wave lengths 492, 481, 474, 467, 463). The density of krypton is 40.6 and that of xenon, 63.5; so that these gases are much heavier than all the other gases in the atmosphere (the density of CO_2 being, for example, 22). However, they are present in such minute quantities in the atmosphere that it requires great perseverance to extract even the smallest amount of such a gas as xenon, for only four volumes of it have been procured from 600 million volumes of air. The amount of krypton in air is much greater, but still far less than that of argon.

If these five argon gases be compared, they are all seen to be of very rare occurrence on the earth, to be chemically inactive, and to present a distinct sequence in the variation of their properties.

	He.	Ne	Ar	Kr	Xe
Density	1.98	9.95	19.96	40.88	64
Boiling-point: below	-262°	-239°	-187°	-152°	-109° ^{68a}

⁶⁶ At first it was thought that helium could be converted into a liquid at low temperatures, but now it appears that this is only true for impure helium.

⁶⁷ The ratio of the specific heats is about 1.66, as with argon. Helium, as an unliquefiable gas, is used in thermometers for determining the lowest possible temperatures.

⁶⁸ Similar green spectrum lines are observed in the spectrum of the aurora borealis.

^{68a} Since the spectrum lines of helium have been observed in the sun and in certain stars, and those of krypton and the others in the corona, zodiacal light, and aurora borealis, these gases may be assumed to enter into the composition of interplanetary space and to have some connection with the substance which forms 'ether.'

We will now consider the few remaining gases and vapours occurring in ordinary air.⁶⁹

The researches of Saussure (1806), Boussingault (1833), and especially of A. Gauthier (1899–1900) showed that the air, even at high altitudes, always contains about 0·02 per cent. (by volume) of **hydrogen** and a variable amount (more in cities and forests, less on mountains) of hydrocarbons, such as marsh gas, evolved in the decay of plants (Chapter VIII).^{69a} Their presence is shown by the fact that when air, which has been quite freed from water and carbonic anhydride, is passed over a long layer of red-hot copper oxide it again gives these substances (see note 22) in the proportion of 1 part by weight of hydrogen to generally less than 3 parts by weight of carbon, or with mountain air even ten times less; while marsh gas, CH_4 , which contains more hydrogen than any other known compound of carbon, contains 3 parts by weight of hydrogen to 1 part of carbon. As the hydrogen of the atmosphere may partly oxidise to form water, and must partly pass into the interplanetary space, owing to its diffusive properties (Chap. I., notes 34 and 35), it is evident that its presence in air cannot be explained unless constant sources for its formation exist in nature. According to A. Gauthier, such a source is found in rocks, like the granites, as these evolve hydrogen (in small quantity) when acted upon by aqueous vapour in a vacuum and when heated to redness with phosphoric anhydride. Therefore there is reason to think that the rock formations of the earth cause a constant flow of hydrogen to the atmosphere.⁷⁰

⁶⁹ Of course in special cases, when particular gases or vapours, for instance, SO_2 , H_2S , &c., are evolved, they may pass into the surrounding air, but they either undergo change or disperse.

^{69a} Besides the ten-thousandths (by volume) of hydrogen and hydrocarbons, Gauthier found small traces (especially in the air of towns), or some millionths by volume, of carbon monoxide, CO , as a product of imperfect combustion. It was determined by its reaction (at 60° – 80°) with iodic anhydride, I_2O_5 (previously calcined to drive off all moisture), which, as Ditte showed, gives iodine and carbonic anhydride, $\text{I}_2\text{O}_5 + 5\text{CO} = \text{I}_2 + 5\text{CO}_2$. The resultant iodine and carbonic anhydride are easily collected, the former by powdered copper and the latter by washing with caustic baryta, which absorbs the slightest traces of CO_2 from any gaseous mixture.

⁷⁰ The investigation of liquid air and the discovery of small amounts of hydrogen, argon, helium, &c., in it have been accomplished during the last few years by means of extensive and very careful researches, thus proving in a most instructive manner that more and more new objects may be found in all that surround us if we follow a method of careful research based upon the logical study of facts already known. I make this remark for the benefit of those beginners who may be discouraged by the vast stores of scientific research, and may imagine that there is nothing left for them to discover. But as a matter of fact there remains to be discovered far more than has as yet been made known. Newton rightly said that we have only become acquainted with the grains of sand on the shores of the infinite ocean of nature. These words of the great investigator are, I think, as true now after 200 years of indefatigable labour as they were then, for

The presence of **ammonia**, a compound of nitrogen and hydrogen, in the air is indicated by the fact that all acids exposed to the air absorb ammonia from it after a time. De Saussure observed that aluminium sulphate is partially converted by air into a double sulphate of ammonium and aluminium, the so-called ammonia alum. Quantitative determinations have shown that the amount of ammonia⁷¹ contained in air varies at different periods. However, it may be accepted that 100 cubic metres of air do not contain less than 1 or more than 5 milligrams of ammonia.⁷² The air in those places where animal substances undergoing change are accumulated, and especially that of stables, generally contains a much greater quantity of this gas. This is the reason of the peculiar pungent smell noticed in such places. Moreover, as we shall learn in the following chapter, ammonia combines with acids, and should therefore be found in air in the form of such combinations, since air contains carbonic and nitric acids.

The presence of **nitric acid** in air is proved without doubt by the fact that rain-water contains an appreciable amount of it.

Further (as already mentioned in Chap. IV.), air contains a small and variable amount of ozone and hydrogen peroxide and nitrous acid (and its ammonia salt), i.e., substances having a direct oxidising action (for instance, upon iodised starch-paper), but these are present in very small quantities⁷³ (Chap. IV.).

Besides substances in a gaseous or vaporous state,⁷⁴ there is always found a more or less considerable quantity of solid substances as **dust**, and also salts and organic matter not enumerated above. If a linen surface, moistened with an acid, be placed in perfectly pure air, the washings are found to contain sodium, calcium, iron, and potassium.⁷⁵ the few grains, or even stones, we have gathered have only revealed fresh depths in the unknown.

⁷¹ Schloesing studied the equilibrium of the ammonia of the atmosphere and of the rivers, seas, &c., and showed that the amount of the gas is interchangeable between them. The ratio between the amount of ammonia in a cubic metre of air and in a litre of water at $0^{\circ}=0.004$, at $10^{\circ}=0.010$, at $25^{\circ}=0.040$ to 1, and therefore in nature there is a state of equilibrium in the amount of ammonia in the atmosphere and waters.

⁷² It is remarkable that it occurs in greater quantity on mountains than in valleys (the same thing is observed with ozone and even CO_2).

⁷³ Though being formed in the air, these oxidising substances (N_2O_3 , ozone, and hydrogen peroxide) at the same time rapidly disappear from it by causing the oxidation of substances capable of being oxidised. Owing to this instability their amounts vary considerably, and, as would be expected, they are met with to an appreciable extent in pure air, whilst their amount decreases to zero in the air of cities and especially of dwellings, where there is a maximum of substances capable of oxidation and a minimum of conditions favouring the formation of such bodies.

⁷⁴ Amongst them we may mention iodine and alcohol, $\text{C}_2\text{H}_6\text{O}$, which Müntz found to be always present in air, soil, and water, although in minute traces only.

⁷⁵ A portion of the atmospheric dust is of cosmic origin: this is indisputably proved by the fact that it contains metallic iron, as do meteorites. Nordenskiöld found iron in

Linen moistened with an alkali absorbs carbonic, sulphuric, phosphoric, and hydrochloric acids. Further, the presence of organic substances in air has been proved by a similar experiment. If a glass globe be filled with ice and placed in a room where are a number of people, the presence of organic substances, such as albuminous bodies, may be detected in the water which condenses on the surface of the globe. It may be that the miasmata causing infection in marshy localities, hospitals, and in certain epidemic diseases, proceed from the presence of such substances in the air (and especially in water, which contains many micro-organisms), as well as from the presence of germs of lower organisms in the air in the form of a minute dust. Pasteur proved the existence of such germs in the air by the following experiment: He placed in a glass tube some gun-cotton (pyroxylin), which has the appearance of ordinary cotton and is soluble in a mixture of ether and alcohol, forming the so-called collodion. A current of air was passed through the tube for a long time, after which the gun-cotton was dissolved in a mixture of ether and alcohol. An insoluble residue was thus obtained which actually contained the germs of organisms, as was shown by microscopical observations, and by their capacity of developing under favourable conditions into organisms (mould, &c.). The presence of these germs determines the property possessed by air of bringing about the processes of putrefaction and fermentation—that is, the fundamental alteration of organic substances accompanied by an entire change in their properties. The appearance of lower organisms, both vegetable and animal, is always to be observed in these processes. Thus, for instance, in the process of fermentation, when, for example, wine is procured from the sweet juice of grapes, a sediment separates out which is known under the name of lees, and contains peculiar yeast organisms. Germs are required before these organisms can appear.⁷⁶ These germs are floating in the air, and fall therefrom into the sweet fermentable liquid. Finding themselves under favourable conditions, the germs develop into organisms, they are nourished at the expense of the organic substances present, and during their growth change and destroy these substances and bring about fermentation and putrefaction. This explains why, for instance, the juice of the grape when contained the dust covering snow, and Tissandier detected it in every kind of air, although naturally in very small quantities.

⁷⁶ The idea of the spontaneous growth of organisms in a suitable medium, although still upheld by many, has been discarded since the work of Pasteur and his followers (and to a certain extent of his predecessors), because it has been proved how, when, and whence (from the air, water, &c.) the germs appear, and that neither fermentation nor infectious diseases can take place without them; and chiefly because it has been shown that any change accompanied by the development of the organisms introduced may be brought about at will by the introduction of the germs into a suitable medium.

in the skin of the fruit, which allows access of the air but is impenetrable to the germs, does not ferment or change so long as the skin remains intact. It is for this reason also that animal substances when kept out of contact of air may be preserved for a great length of time. Preserved foods for long sea voyages are kept in this way.⁷⁷ It is hence evident that, however infinitesimal the quantity of germs carried in the atmosphere may be, they have an immense significance in nature.⁷⁸

Thus we see that air contains a great variety of substances. The nitrogen, which is found in it in the largest quantity, has the least influence on those processes which are accomplished by the action of air. The oxygen, which is met with in a lesser quantity than the nitrogen, takes, on the contrary, a very important part in a number of reactions: it supports combustion and respiration, it brings about decomposition and every process of slow oxidation. The part played by the moisture of air is well known; without it and its precipitations the earth would be a desert. The carbonic anhydride, which is met with in still smaller quantities, has an immense significance in nature, inasmuch as it serves for the nourishment of plants. The importance of the ammonia and nitric acid is very great, because they are the sources of the nitrogenous substances constituting an indispensable element in all living organisms. And, lastly, the infinitesimal quantity of germs also has a great significance in a number of processes. Thus it is not the quantitative but the qualitative relations of the component parts of the atmosphere which determine its importance in nature.⁷⁹

⁷⁷ In confirmation of the fact that putrefaction and fermentation depend on germs carried in the air, we may cite the circumstance that poisonous substances destroying the life of organisms prevent or hinder the appearance of the above processes. Air which has been heated to redness or passed through sulphuric acid no longer contains the germs of organisms (sterilisation), and loses the power of producing fermentation and putrefaction.

⁷⁸ Their presence in the air is naturally due to the diffusion of germs into the atmosphere, and owing to their microscopical dimensions; they hang, as it were, in the air by virtue of the large surface they possess compared with their weight. In Paris the amount of dust suspended in the air amounts to from 6 (after rain) to 23 grams per 1,000 cm. of air.

⁷⁹ We see similar cases everywhere. For example, the predominating mass of sand and clay in the soil takes scarcely any chemical part in the economy of the soil in respect to the nourishment of plants. The plants by their roots search for substances which are diffused in comparatively small quantities in the soil. If a large proportion of these nourishing substances is removed, then the plants will not develop in the soil, just as animals die in oxygen. There exists everywhere a medium in things, determined by equilibrium. The Russian proverb says, 'Too much salt or too little salt is alike an evil.' It is the same in political and social relations.

Air, being a mixture of various substances, may suffer considerable **changes** in consequence of incidental circumstances. It is particularly necessary to remark those changes in the composition of air which take place in dwellings and in various localities where human beings have to remain during a lengthy period of time. The respiration of human beings and animals alters the air.⁸⁰ A similar deterioration of air is produced by the influence of decomposing organic substances, and especially of substances burning in it, and then the amount of oxygen decreases while the proportion of noxious impurities increases.⁸¹ Hence it is necessary to have regard to the purification of the air of dwellings. The renewal of air, the replacing of respired by fresh air, is termed

⁸⁰ A man in breathing burns about 10 grams of carbon per hour—that is, he produces about 880 grams, or (as 1 cub.m. of carbonic anhydride weighs about 2,000 grams) about $\frac{5}{12}$ c.m. of carbonic anhydride. The air coming from the lungs contains 4 per cent. of carbonic anhydride by volume. The exhaled air acts as a direct poison, owing to the presence of this gas and other impurities.

⁸¹ For this reason candles, lamps, and gas change the composition of air almost in the same way as respiration. In the burning of 1 kilogram of stearin candles, 50 cubic metres of air are changed as by respiration—that is, 4 per cent. of carbonic anhydride will be formed in this volume of air. The respiration of animals and the exhalations from their skins and especially from their intestines and the transformations taking place in these bodies contaminate the air to a still greater extent, because they introduce into it other volatile substances besides carbonic anhydride. At the same time that carbonic anhydride is formed the amount of oxygen in the air decreases, and there is noticed the appearance of miasmata which occur in but small quantity, but which are noticeable in passing from fresh air into a confined space full of such adulterated air. The researches of Schmidt and Leblanc and others show that even when the percentage of oxygen in air is reduced, as a result of respiration, merely from 20·9 to 20·6, the air becomes noticeably less fit for respiration, and that the heavy feeling experienced in such air increases with a further diminution in the percentage of oxygen. It is difficult to remain for a few minutes in air containing only 17·2 per cent. of oxygen. These observations were chiefly obtained by observations on the air of mines at different depths below the surface. The air of theatres and buildings full of people also proves to contain a deficiency of oxygen: it was found on one occasion that at the end of a theatrical representation the air in the stalls contained 20·75 per cent. of oxygen, whilst that in the upper part of the theatre contained only 20·36 per cent. The amount of carbonic anhydride in the air may be taken as a measure of its purity (Pettenkofer). When it reaches 1 per cent. it is very difficult for human beings to remain long in such air, and it is necessary to set up a vigorous ventilation for the removal of the adulterated air. In order to keep the air in dwellings in a uniformly good state, it is necessary to introduce *at least* 10 cubic metres of fresh air per hour per person. We saw that a man exhales about five-twelfths of a cubic metre of carbonic anhydride per day. Accurate observations have shown that air containing 0·1 per cent. of exhaled carbonic anhydride (and consequently also a corresponding amount of the other substances evolved together with it) is not felt to be oppressive; and therefore the five-twelfths of a cubic metre of carbonic anhydride should be diluted with 420 cubic metres of fresh air if it be desired to have not more than 0·1 per cent. (by volume) of carbonic anhydride present. Hence a man requires 420 cubic metres of air per day, or 18 cubic metres per hour. With the introduction of only 10 cubic metres of fresh air per hour per person, the proportion of carbonic anhydride may reach 0·2 per cent., and the air will not then be of the requisite freshness.

‘ventilation,’⁸² and the removal of foreign and injurious admixtures from the air is called ‘disinfection.’⁸³ The accumulation of all kinds

⁸² The **ventilation** of inhabited buildings is most necessary, and is even indispensable in hospitals, schools, and similar buildings. In winter it is carried on by the so-called calorifiers or stoves heating the air before it enters. The best kind of calorifiers in this respect are those in which the fresh cold air is led through a series of flues heated by the hot gases coming from a stove. In ventilation, particularly during winter, care is taken that the incoming air shall be moist, because in winter the amount of moisture in the air is very small. Ventilation, besides introducing fresh air into a dwelling-place, must also withdraw the air already spoilt both by respiration and from other causes—that is, it is necessary to construct channels for the escape of the bad air, besides those for the introduction of fresh air. In ordinary dwelling-places, where not many people are congregated, the ventilation is maintained by natural means—by fires, crevices, windows, and various orifices in walls, doors, and windows. In mines, factories, and workrooms ventilation is of the greatest importance.

Animal vitality may, however, continue for a period of several minutes in air containing as much as 30 per cent. of carbonic anhydride if the remaining 70 per cent. consist of ordinary air; but respiration ceases after a certain time, and death may even ensue. The flame of a candle is very rapidly extinguished in an atmosphere containing from 5 to 6 per cent. of carbonic anhydride; but animal vitality can be sustained in it for a somewhat long time, although the effect of such air is exceedingly painful even to the lower animals. The presence of 1 per cent. of carbonic oxide is fatal even to cold-blooded animals. The air in the galleries of a mine where blasting has taken place is known to produce a state of insensibility resembling that produced by charcoal fumes. Deep wells and vaults not infrequently contain similar substances, and their atmosphere often causes suffocation. The atmosphere of such places cannot be tested by lowering a lighted candle into it, as these poisonous gases would not extinguish the flame. This method only suffices to indicate the amount of carbonic anhydride. If a candle keeps alight, it signifies that there is less than 6 per cent. of this gas. In doubtful cases it is best to lower a dog or other animal into the air to be tested. If CO_2 be very carefully added to air, the flame of a candle is not extinguished (although it becomes very much smaller) even when the gas is present to the extent of 12 per cent. Researches made by F. Clowes (1894) show that the flames ($\frac{3}{4}$ in. long) of different combustible substances are extinguished by the gradual addition of different percentages of nitrogen and carbonic acid to the air; the percentages sufficient to extinguish the flame being as follows (the percentage of oxygen present being given in parenthesis):

	per cent. of CO_2	per cent. of N_2
Absolute alcohol	14 (18.1)	21 (16.6)
Candle	14 (18.1)	22 (16.4)
Hydrogen	58 (8.8)	70 (6.3)
Coal gas	33 (14.1)	46 (11.3)
Carbonic oxide	24 (16.0)	28 (15.1)
Methane	10 (18.9)	17 (17.4)

The flames of all solid and liquid substances are extinguished by about the same percentage of CO_2 or N_2 , but the flames of different gases vary in this respect, and hydrogen continues to burn in mixtures which are far poorer in oxygen than those in which the flames of other combustible gases are extinguished; the flame of methane is the most easily extinguished. The percentage of nitrogen may be greater than that of carbonic anhydride. This, together with the fact that under the above circumstances the flame of a gas, before going out, becomes fainter and increases in size, indicates that the chief reason for the extinction of the flame is the fall in its temperature.

⁸³ Different so-called **disinfectants** purify the air and prevent the injurious action of

of impurities in the air of dwellings and cities is the reason why the air of mountains, forests, seas, and non-marshy localities covered with vegetation or snow is distinguished for its freshness and for its beneficial action.⁸⁴

certain of its components by changing or destroying them. Disinfection is especially necessary in those places where volatile substances are evolved into the air in considerable quantity, and where organic substances are decomposed; for instance, in hospitals, closets, &c. The numerous disinfectants employed are of the most varied nature. They may be divided into oxidising, antiseptic, and absorbent substances. To the oxidising substances used for disinfection belong chlorine and also various substances evolving it, because chlorine in the presence of water oxidises the majority of organic substances. This is why chlorine is used as a disinfectant for Siberian plagues. Further, to this class belong the permanganates of the alkalies and peroxide of hydrogen, substances readily oxidising matters dissolved in water. These salts are not volatile like chlorine, and therefore act much more slowly, and have a much more limited sphere of action. Antiseptic substances are those which convert organic substances into such as are little prone to change, and prevent putrefaction and fermentation. They most probably kill the germs of organisms occurring in miasmata. The most important of these substances are creosote and phenol (carbolic acid), which occur in tar and are used for preserving smoked meat. Phenol is a substance little soluble in water, volatile, oily, and having the characteristic smell of smoked objects. Its action on animals in considerable quantities is injurious, but in small quantities, used in the form of a weak solution, it prevents change in animal matter. The smell of urinals, which depends on the change of excremental matter, may be easily removed by means of chlorine or phenol. Salicylic acid, thymol, common tar and especially its solution in alkalies as proposed by Nensky, &c., have the same property. Absorbent substances are of no less importance, especially as preventives, than the preceding two classes of disinfectants, inasmuch as they are innocuous. They are those substances which absorb the odoriferous gases and vapours which are emitted during putrefaction, and which are chiefly ammonia, sulphuretted hydrogen, &c. To this class of disinfectants belong charcoal, certain salts of iron, gypsum, salts of magnesia, and similar substances, as well as peat, mould, and clay. Questions of disinfection and ventilation are among the most serious problems of everyday life and hygiene. These questions are so vast that we are here able to give only a short outline of their nature.

⁸⁴ As it is often necessary in making researches of different kinds (especially such as concern combustion, respiration, &c.) to make detailed calculations based on a knowledge of the composition of ordinary air by weight and volume, I think it well to sum up here the existing data on the composition of air. First of all the component parts of air must be divided into those which are constant and those which are variable or incidental (such as the products of smoke or respiration). Among the latter, moisture must be included, because its absolute quantity (for instance, the number of grams per cubic metre) varies considerably with the temperature and degree of dryness of the air. The following calculation relates to the constant components of the air, on the assumption that dry air contains about 23.12 per cent. of oxygen by weight (with a possible variation of not more than ± 0.05 per cent.), and that a litre of such air (under normal conditions, i.e., at 0° and 760 mm. and at latitude 45°) weighs about 1.293 gm. Then it must be remembered that although hydrogen, ammonia, &c., always enter into the composition of air, they occur in but small proportions (for instance, 0.02 per cent. by vol. or 0.0018 per cent. by weight of hydrogen), and act so slightly upon the weight of a given volume of air, and on all the calculations appertaining to it, that their influence may be neglected in comparison with that of the variations in the amounts of oxygen and nitrogen. These component parts should be included under the category of 'various other components,' just as the category 'argon' also includes its associates krypton, neon, xenon, and helium. Thus the composition of dry air is:

By volume per cent.	Weight of litre at 0° and 760 mm.	Per cubic metre at 0° and 760 mm.	By weight per cent.
Oxygen—20·91	1·429	129·8	23·12
Nitrogen—78·23	1·251	978·7	75·7
Argon— (&c.)—0·80	1·78	14·2	1·10
Carbonic anhydride—0·03	1·98	0·6	0·95
Various other components—0·03	0·32	0·1	0·01
Dry air 100·000	—	1292·4	100·00

The last cipher in each of the above numbers is of doubtful accuracy, as the observations are subject to possible errors and the composition of air varies (for argon Schloesing gives 0·935 per cent. by vol.). The amount of each component part and the weight of a cubic metre of air in different cases are easily calculated from what has been said in Chap. I., note 1, that is if we know the vapour pressure p mm. of the water vapour in the air, the barometric pressure P mm. and the temperature t° ; for instance if $P = 740$, $t = 20^{\circ}$ and $p = 10$ mm. (relative moisture 57·4 per cent.), then taking the weight of a litre of aqueous vapour (under normal conditions) as 0·8 gram, we find that the volume of the aqueous vapour stands to the volume of dry air in the ratio $p : P - p$ or $10 : 740 - 10$; i.e., that a litre of air will contain 13·5 c.c. of aqueous vapour and 986·5 c.c. (or millilitres) of dry air, and as the composition by volume of the latter is known we can find the amount by volume of all the remaining components. Knowing also that a litre of aqueous vapour under normal conditions weighs 0·8 gram, and that the coefficient of expansion of gases and vapours is 0·00367, it is easy to calculate the composition by weight and also the weight of a litre, recollecting, however, that the laws of gases and vapours (Boyle's, Dalton's, &c.) are only approximate, and cannot give absolutely accurate results.

CHAPTER VI

THE COMPOUNDS OF NITROGEN WITH HYDROGEN AND OXYGEN

IN the last chapter we saw that nitrogen does not directly (i.e., under

FIG. 48.—The dry distillation of bones on a large scale. The bones are heated in the vertical cylinders C (about $1\frac{1}{2}$ metre high and 30 centimetres in diameter). The products of distillation pass through the tubes T into the condenser B and receiver F. When the distillation is completed the trap H is opened, and the burnt bones are loaded into trucks V. The roof M is then opened and the cylinders are charged with a fresh quantity of bones. The ammonia water is preserved, and is used for the preparation of ammoniacal salts, as is shown in the following drawing.

ordinary conditions) combine with hydrogen or oxygen, but hydrogen and oxygen compounds of nitrogen are formed indirectly, and are even present in the atmosphere, water, and soil. Thus a mixture of nitrogen and hydrogen, in presence of hydrochloric acid gas, HCl , forms ammonium chloride, NH_4Cl , under the action of a series of electric sparks.¹ In ammonium chloride, HCl is combined with NH_3 ; consequently here we find nitrogen and hydrogen directly forming **ammonia**.² This is

the simplest typical compound of nitrogen, and therefore we shall begin with it. Almost all the **nitrogenous constituents of plants and**

¹ The ammonia in the air, water, and soil proceeds from the decomposition of the nitrogenous substances of plants and animals, and also probably from the reduction of nitrates. Ammonia is always formed in the rusting of iron. Its formation in this case depends in all probability either on the decomposition of water and on the action of the hydrogen, at the moment of its evolution, on the nitric acid contained in the air (Cloeze) or on the formation of ammonium nitrite, which takes place under many circumstances, and in its composition, NH_4NO_2 , is equal to nitrogen, N_2 + water, $2\text{H}_2\text{O}$. The evolution of vapours of ammonia compounds is sometimes observed in the vicinity of volcanoes. At a red heat nitrogen combines directly with boron, calcium, magnesium, and many other metals, and the compounds thus formed, when heated with a caustic alkali, or in the presence of water, give ammonia. These are examples of the indirect combination of nitrogen with hydrogen.

² If a silent discharge or a series of electric sparks is passed through ammonia gas, the latter is decomposed into nitrogen and hydrogen. This is a phenomenon of

animals when heated with an alkali evolve their nitrogen as ammonia. But even without the presence of an alkali the majority of nitrogenous substances, when decomposed or heated with a limited supply of air, evolve their nitrogen, if not entirely, at all events partially, in the form of ammonia. When animal substances such as skins, bones, flesh, hair, horns, &c., are heated without access of air in iron retorts, they undergo what is termed dry distillation. A portion of the resultant substances remains in the retort and forms a carbonaceous residue, whilst the other portion, in virtue of its volatility, escapes through the tube leading from the retort. The vapours given off, on cooling, form a liquid which separates into two layers: the one, which is oily, is composed of the so-called animal oils (*oleum animale*): the other, an aqueous layer, contains a solution of ammonium salts. If this solution be mixed with lime and heated, the lime takes up the elements of carbonic acid from the ammonium salts, and ammonia is evolved as a gas.³ In ancient times ammonium compounds were imported into

dissociation; that is, a series of sparks do not totally decompose the ammonia, but leave a certain portion undecomposed. One volume of nitrogen and three volumes of hydrogen are obtained by the decomposition of two volumes of ammonia. Ramsay and Young (1884) investigated the decomposition of NH_3 under the action of heat, and showed that at 500° , $1\frac{1}{2}$ per cent. is decomposed; at 600° , about 18 per cent.; and at 800° , 65 per cent.; but these results were hardly free from the influence of 'contact.' The action of a silent discharge on a mixture of nitrogen and hydrogen also gives ammonia, but not to completion.

The presence of free ammonia—that is, ammonia not combined with acids—in a gas or aqueous solution may be recognised by its characteristic smell. But many ammonia salts do not possess this smell. However, on the addition of an alkali (for instance, caustic lime, potash, or soda), they evolve ammonia gas, especially when heated. The presence of ammonia may be made visible by introducing a substance moistened with strong hydrochloric acid into its neighbourhood. A white cloud, or visible white vapour, then makes its appearance. This depends on the fact that both ammonia and hydrochloric acid are volatile, and on coming into contact with each other produce solid sal-ammoniac, NH_4Cl , which forms a cloud. This test is usually made by dipping a glass rod into hydrochloric acid and holding it over the vessel from which the ammonia is evolved. With small amounts of ammonia this test is, however, untrustworthy, as the white vapour is scarcely observable. In this case it is best to take paper moistened with mercurous nitrate, HgNO_3 . This paper turns black in the presence of ammonia owing to the formation of a black compound of ammonia with mercurous oxide. The smallest traces of ammonia (for instance, in river water) may be detected by means of the so-called *Nessler's reagent*, containing an alkaline solution of mercury in potassium iodide, which forms a brown precipitate ($\text{Hg}_2\text{NIH}_2\text{O}$) with the smallest quantities of ammonia. It will be useful here to give the thermo-chemical data (in thousands of heat units, according to Thomsen), or the quantities of heat *evolved* in the formation of ammonia and its compounds in quantities expressed by their formulæ. Thus, for instance, $(\text{N} + \text{H}_3)$ 26.7 indicates that 14 grams of nitrogen in combining with 3 grams of hydrogen develop sufficient heat to raise the temperature of 26.7 kilograms of water 1° . $(\text{NH}_3 + n\text{H}_2\text{O})$ 8.4 (heat of solution); $(\text{NH}_3, n\text{H}_2\text{O} + \text{HCl}, n\text{H}_2\text{O})$ 12.3; $(\text{N} + \text{H}_4 + \text{Cl})$ 90.6; $(\text{NH}_3 + \text{HCl})$ 41.9.

³ The same ammonia water is obtained, although in smaller quantities in proportion to the weight taken, in the dry distillation of plants and of coal, which consists of the remains of fossil plants. In all these cases the ammonia proceeds from the destruction

Europe from Egypt, where they were prepared from the soot obtained in the employment of camel's dung as fuel in the locality of the temple of Jupiter Ammon (in Libya), and therefore the salt obtained was called 'sal-ammoniacum,' from which the name of 'ammonia' is derived. At the present time ammonia is obtained almost exclusively, on a large scale, from the products of the dry distillation of coal. The ammoniacal

FIG. 49.—Method of abstracting ammonia, on a large scale, from ammonia water obtained at gas-works by the dry distillation of coal, or by the fermentation of urine, &c. This water is mixed with lime and poured into the boiler C'', and thence into C' and C consecutively. The last boiler is heated directly over a furnace, and hence no ammonia remains in solution after the liquid has been boiled in it. The liquid is therefore then thrown away. The ammonia vapour and steam pass from the boiler C, through the tube T, into the boiler C', and then into C'', so that in C' the solution becomes stronger than in C, and still stronger in C''. The boilers are furnished with stirrers A, A', and A'' to prevent the lime from settling. From C'' the ammonia and steam pass through the tube T'' into worm condensers surrounded with cold water, thence into the Woulfe's bottle P, where the solution of ammonia is collected, and finally the still uncondensed ammonia vapour is led into the flat vessel R, containing acid which absorbs the last traces of ammonia.

liquor obtained in the preparation of coal gas and coke (which contains ammonium salts, chiefly the carbonate in solution) is placed in a retort with lime and heated; the ammonia is then evolved together with steam.⁴ In the arts, only a small amount of ammonia is used in a free state, that is, in aqueous solution; the greater portion of it is converted into different salts having technical uses, especially

of the complex nitrogenous substances occurring in plants and animals. The ammonium salts employed in the arts are prepared by this method. The greater part of the ammonium salts are now prepared from the ammonia water obtained as a by-product in the dry distillation of coal in the manufacture of coke and illuminating gas.

⁴ The technical methods for the preparation of ammonia water, and for the extraction of ammonia from it, are to a certain extent explained in the figures accompanying the text.

sal-ammoniac, NH_4Cl , and ammonium sulphate, $(\text{NH}_4)_2\text{SO}_4$. They are saline substances which are formed on account of the capability of ammonia, NH_3 , of combining with all acids, HX , forming ammonium salts, NH_4X . Sal-ammoniac, NH_4Cl , is a compound of ammonia with hydrochloric acid. It is prepared by passing the vapours of ammonia and water, evolved, as above described, from ammoniacal liquor, into an aqueous solution of hydrochloric acid; on evaporating the solution, sal-ammoniac is obtained in the form of soluble crystals⁵ resembling common salt in appearance and properties. **Ammonia** may be very easily prepared from this **sal-ammoniac**, NH_4Cl , as from any other ammoniacal salt, by heating it with lime. Calcium hydroxide, CaH_2O_2 , being an alkali, takes up the acid forming calcium chloride and sets free the ammonia, according to the equation: $2\text{NH}_4\text{Cl} + \text{CaH}_2\text{O}_2 = 2\text{H}_2\text{O} + \text{CaCl}_2 + 2\text{NH}_3$. In this reaction the ammonia is evolved as a gas.⁶

It must be observed that all the complex nitrogenous substances of plants, animals, and soils are decomposed when heated with an excess of sulphuric acid, the whole of their nitrogen being converted into ammonium sulphate, from which it may be liberated by treatment with an excess of alkali. This reaction is so complete that it forms the basis of Kjeldahl's method for estimating the amount of nitrogen in its compounds.

Ammonia is a colourless **gas**, resembling, in its outward appearance, those with which we are already acquainted, but clearly distinguishable from any other gas by its very characteristic and pungent smell. It irritates the eyes, and it is positively impossible to inhale it. Animals die in it. Its density, referred to that of hydrogen, is 8.5; hence it is lighter than air. It belongs to the class of gases which are easily liquefied.⁷

⁵ Usually these crystals are sublimed by heating them in crucibles or pots, when the vapours of sal-ammoniac condense on the cold covers as a crust, in which form the salt is placed on the market.

⁶ In the laboratory ammonia may be prepared in a glass flask by mixing equal parts by weight of slaked lime and finely powdered sal-ammoniac, the neck of the flask being connected with an arrangement for drying the gas obtained. In this instance neither calcium chloride nor sulphuric acid can be used for drying the gas, since both these substances absorb ammonia, and therefore solid caustic potash, which is capable also of retaining the water, is employed. The gas-conducting tube leading from the desiccating apparatus is introduced into a mercury bath, if dry gaseous ammonia is required, because water cannot be employed in collecting ammonia gas. Ammonia was first obtained in this dry state by Priestley, and its composition was investigated by Berthollet at the end of the eighteenth century. Oxide of lead mixed with sal-ammoniac (Isambert) evolves ammonia with still greater ease than lime. The cause and process of the decomposition are almost the same: $2\text{PbO} + 2\text{NH}_4\text{Cl} = \text{Pb}_2\text{OCl}_2 + \text{H}_2\text{O} + 2\text{NH}_3$, lead oxychloride being (probably) formed.

⁷ This is evident from the fact that its absolute boiling-point lies at about $+130^\circ$ (Chap. II., note 29). It may therefore be liquefied by pressure alone at the ordinary, and

Faraday employed the following method for liquefying ammonia. Ammonia when passed over dry silver chloride, AgCl , is absorbed by it

even at much higher temperatures. The latent heat of evaporation of ammonia is about 300 units of heat; and hence liquid ammonia may be employed for the production of cold. Strong aqueous solutions of ammonia, which in parting with their ammonia act in a similar manner, are not infrequently employed for this purpose. Suppose a saturated solution of ammonia to be contained in a closed vessel furnished with a receiver. If the ammoniacal solution be heated, the ammonia, with a small quantity of water, will pass off from the solution, and in accumulating in the apparatus will produce a considerable pressure, and will therefore liquefy in the cooler portions of the apparatus. Hence liquid ammonia will be obtained in the receiver. The heating of the vessel containing the aqueous solution of ammonia is then stopped. After having been heated it contains only water, or a solution poor in ammonia. When once it begins to cool, the ammonia vapours commence dissolving in it, the space becomes rarefied, and a rapid vaporisation of the liquefied ammonia left in the receiver takes place. In evaporating in the receiver it will cause the temperature therein to fall considerably, and will itself pass into the aqueous solution. In the end, the same ammoniacal solution as was originally taken is re-

FIG. 50—Carré's apparatus. Described in text.

obtained. Thus, in this case, on heating one portion of the closed vessel, compression of the ammonia takes place, and on cooling, the liquid evaporates and so generates great cold. This is the principle of the simplest form of *Carré's ice-making machine*, shown in fig. 50. C is a vessel made of boiler plates into which the saturated solution of ammonia is poured; m is a tube conducting the ammonia vapour to the receiver A. All parts of the apparatus should be hermetically joined together, and should be able to withstand a pressure of ten atmospheres. The apparatus should be freed from air, which would otherwise hinder the liquefaction of the ammonia. The process is carried on as follows:—The apparatus is first so inclined that any liquid remaining in A may flow into C. The vessel C is then placed upon a stove F, and heated until the thermometer t indicates a temperature of 130°C . During this time the ammonia has been expelled from C, and has liquefied in A. In order to facilitate the liquefaction, the receiver A should be immersed in a tank of water R (see the left-hand drawing in fig. 50). When it may be supposed that the ammonia has been expelled, the fire is removed from under C, which in its turn is immersed in the tank of water R, as is represented in the right-hand drawing of

to a considerable extent, especially at low temperatures.⁸ The solid compound, $\text{AgCl}\cdot 3\text{NH}_3$, thus obtained is introduced into a thick bent tube (fig. 51), whose open end *c* is then fused up. The compound is then slightly heated at *a*, and the ammonia comes off, owing to the easy dissociation of the compound. The other end of the tube is immersed in a freezing mixture. The pressure of the gas coming off combined with the low temperature at one end of the tube, causes the ammonia evolved to condense into a liquid, in which form it collects at the cold end of the tube. If the heating be stopped, the silver chloride will again absorb the ammonia. In this manner one tube may serve for repeated experiments. Ammonia may always be liquefied by the ordinary methods—that is, by pumping dry ammonia gas into a refrigerated space. Liquefied ammonia is a colourless and very mobile liquid,⁹ whose specific gravity at 0° is 0.63 (E. Andr  eff). At the temperature given by a mixture of liquid carbonic anhydride and ether, liquid ammonia crystallises, and in this form its odour is feeble, because at so low a temperature its vapour pressure is very inconsiderable. The boiling-point (at 760 mm.) of liquid ammonia is about 34° , the melting-point about -78° , and the absolute (critical) boiling-point about $+130^\circ$.

FIG. 51.—The liquefaction of ammonia in a thick bent glass tube. A compound of chloride of silver and ammonia is placed in the end *a*, and the end *c* is then sealed up.

Ammonia, containing, as it does, a large proportion of hydrogen, is fig. 50. The liquefied ammonia then evaporates, and passes over into the water in C. This causes the temperature of A to fall considerably. The substance to be refrigerated is placed in a vessel G, in the cylindrical space inside the receiver A. The heating and also the refrigeration are kept on for about half an hour, and with an apparatus of ordinary dimensions (containing about two litres of ammonia solution), five kilograms of ice are produced by the consumption of one kilogram of coal. In industrial works larger and more complicated types of Carr  's machines are employed.

⁸ Below 15° (according to Isambert), the compound $\text{AgCl}\cdot 3\text{NH}_3$ is formed, and above 20° the compound $2\text{AgCl}\cdot 3\text{NH}_3$. The pressure of the ammonia evolved from the latter substance is equal to the atmospheric pressure at 68° , whilst for $\text{AgCl}\cdot 3\text{NH}_3$ the same happens at about 20° ; hence, at higher temperatures, the pressure is greater than that of the atmosphere, whilst at lower temperatures the ammonia is absorbed and forms this compound. Consequently, all the phenomena of dissociation are here clearly to be observed. Joannis and Croisier (1894) made investigations with AgBr , AgI , AgCN , and AgNO_3 , and found that they all give definite compounds with NH_3 ; for instance, $\text{AgBr}\cdot 3\text{NH}_3$; $2\text{AgBr}\cdot 3\text{NH}_3$ and $\text{AgBr}\cdot 2\text{NH}_3$; they are all colourless solid substances which decompose under the atmospheric pressure at $+3.5^\circ$, $+34^\circ$, and $+51^\circ$ respectively.

⁹ The liquefaction of ammonia may be accomplished without increase of pressure by means of freezing mixtures producing temperatures below -35° . It may even take place in the severe frosts of a Russian winter. The application of liquid ammonia as a motive power for engines forms a problem which has to a certain extent been solved by the French engineer Tellier and others. Liquid ammonia resembles water in many respects; its specific heat is 1.02 (Ellean); the latent heat of evaporation at -30° is 330 cal. (pressure 1.15 atmosphere), at $0^\circ = 316$ (pressure 4.21 atmospheres), at $+30^\circ = 300$ cal. (pressure 11.62 atmospheres).

capable of combustion ; it does not, however, burn steadily, and sometimes not at all, in ordinary atmospheric air (the temperature not being sufficiently high). In pure oxygen it burns with a greenish-yellow flame,¹⁰ forming water, whilst the nitrogen set free gives partly oxygen compounds, that is, oxides of nitrogen, and partly escapes in an uncombined form. The decomposition of ammonia into hydrogen and nitrogen not only takes place at a red heat and under the action of electric sparks, but also under the influence of many oxidising substances ; for instance, by passing ammonia through a tube containing red-hot copper oxide. The water thus formed may be collected by substances absorbing it, and the nitrogen may be measured in the gaseous state, and thus the composition of ammonia determined. In this manner it is found that ammonia contains very nearly 3 parts by weight of hydrogen to 14 parts by weight of nitrogen ; whilst 3 vols. of hydrogen and 1 vol. of nitrogen form 2 vols of ammonia.¹¹

Ammonia is capable of combining with a number of substances, forming, like water, compounds of various degrees of stability. It is more **soluble** than any of the gases yet described, both in water and in many aqueous solutions. We have already seen, in the first chapter, that one volume of water, at the ordinary temperature, dissolves about 700 vols. of ammonia gas. If a piece of ice be placed in ammonia gas it melts and absorbs the gas with great rapidity. The great solubility of ammonia enables it to be kept ready for use in the form of an aqueous solution,¹² which is known commercially as **spirits of hartshorn**.

¹⁰ The combustion of ammonia in oxygen may be easily demonstrated by means of incandescent platinum. A small quantity of an aqueous solution of ammonia, containing about 20 per cent. of the gas, is poured into a wide-mouthed beaker of about one litre capacity. A gas-conducting tube about 10 mm. in diameter, and supplying oxygen, is immersed in the aqueous solution of ammonia. But before introducing the gas, an incandescent platinum spiral is placed in the beaker ; in the presence of the platinum the ammonia is oxidised and burns, whilst the platinum wire becomes still more incandescent. The solution of ammonia is heated and oxygen passed through the solution. The oxygen, as it bubbles off from the ammonia solution, carries with it a part of the ammonia, and this mixture explodes on coming into contact with the incandescent platinum. This is followed by a certain cooling effect owing to the combustion ceasing ; but after a short interval this is renewed, so that one feeble explosion follows another. During the period of oxidation without explosion, white vapours of ammonium nitrite and red-brown vapours of oxides of nitrogen make their appearance, while during the explosion there is complete combustion, and consequently water and nitrogen are formed.

¹¹ This may be verified by their densities. Nitrogen is 14 times denser than hydrogen, and ammonia, $8\frac{1}{2}$ times. If 3 volumes of hydrogen with 1 volume of nitrogen gave 4 volumes of ammonia, then these 4 volumes would weigh 17 times as much as 1 volume of hydrogen ; consequently 1 volume of ammonia would be $4\frac{1}{4}$ times heavier than the same volume of hydrogen. But if these 4 volumes only give 2 volumes of ammonia, the latter will be $8\frac{1}{2}$ times as dense as hydrogen, which is found to be actually the case.

¹² Aqueous solutions of ammonia are lighter than water, and at 15° (taking water at 4° as 10,000) their specific gravity, s , as dependent on p , the percentage amount (by weight)

Ammonia water is continually evolving ammoniacal vapour, and so has the characteristic smell of ammonia itself, and is therefore employed for making smelling salts. It is a very characteristic and important

of ammonia, is given by the expression: $s = 9,992 - 42.5p + 0.21p^2$; for instance, with 10 per cent., $s = 9,588$. If t represents the temperature between the limits of $+10^\circ$ and $+20^\circ$, then the expression $(15 - t)(1.5 + 0.14p)$ must be added to the above formula for the specific gravity. Solutions containing more than 24 per cent. of the gas have not been sufficiently investigated with respect to the variation of their specific gravity. It is, however, easy to obtain more concentrated solutions, and at 0° solutions approaching $\text{NH}_3, \text{H}_2\text{O}$ (48.6 per cent. NH_3) in their composition, and of sp. gr. 0.85, may be prepared. But such solutions give up much of their ammonia at the ordinary temperature, so that more than 24 per cent. of NH_3 is rarely contained in solution. Ammonia solutions containing a considerable amount of ammonia give at temperatures far below 0° (for instance, an 8 per cent. solution at -14° and the strongest solutions at -48°) ice-like crystals which seem to contain ammonia. The whole of the ammonia may be expelled from a solution by heating, even at a comparatively low temperature; hence on heating aqueous solutions containing ammonia, a very strong solution of ammonia is obtained in the distillate. Alcohol, ether, and many other liquids are also capable of dissolving

FIG. 52.—Apparatus for preparing solutions of ammonia.

ammonia. Solutions of ammonia, when exposed to the atmosphere, give off a part of their ammonia in accordance with the laws of the solutions of gases in liquids, which we have already considered. But the ammoniacal solutions at the same time absorb carbonic anhydride from the air, and ammonium carbonate remains in the solution.

Solutions of ammonia are required both for laboratory and factory operations, and have therefore to be frequently prepared. For this purpose the arrangement shown in fig. 52 is employed in the laboratory. In works the same arrangement is used, only on a larger scale (with earthenware or metallic vessels). The gas is prepared in a flask A, whence it is led through a series of Woulfe's bottles, B, C, D, E. The gas is dissolved in B, but the solution soon becomes saturated, and a purer (washed) ammonia passes over into the following vessels, in the last of which only a pure solution is obtained. The bent funnel tube G in the flask preserves the apparatus from the possibility both of the pressure of the gas evolved in it becoming too great (when the gas escapes through it into

fact that ammonia has an alkaline reaction, and colours litmus paper blue, just like caustic potash or lime; it is therefore sometimes called **caustic ammonia** (volatile alkali). Acids may be saturated by ammonia water or gas in exactly the same way as by any other alkali. In this process **ammonia combines directly with acids**, and this forms the most characteristic chemical reaction of this substance. If sulphuric, nitric, acetic, or any other acid is brought into contact with ammonia, it absorbs it, and in so doing evolves a large amount of heat and forms a compound having all the properties of a salt. Thus, for example, sulphuric acid, H_2SO_4 , in absorbing ammonia, forms (on evaporating the solution) one or both of two salts, according to the relative quantities of ammonia and acid. One salt is formed from $\text{NH}_3 + \text{H}_2\text{SO}_4$, and consequently has the composition NH_4SO_4 , and the other is formed from $2\text{NH}_3 + \text{H}_2\text{SO}_4$, and its composition is therefore $\text{N}_2\text{H}_6\text{SO}_4$. The former has an acid

the air), and also from the pressure accidentally falling too low (for instance, owing to a cooling effect, or from the reaction stopping). If this takes place, the air passes into the retort, otherwise the liquid from B would be drawn into A. The safety tubes s_1 , s_2 , &c.,

FIG. 53.—Tischenko's apparatus for washing or absorbing gases. In the form shown in the right-hand figure, solids such as fused calcium chloride, potash, &c. may be employed.

in each Woulfe's bottle, open at both ends and immersed in the liquid, serve for the same purpose. Without them, in case of an accidental stoppage in the evolution of so soluble a gas as ammonia, the solution would be sucked from one vessel to another; for instance, from E into D, &c. In order to see clearly the necessity for *safety tubes* in a gas apparatus, it must be remembered that the *gaseous pressure* in the interior of the arrangement must exceed the atmospheric pressure by the sum of the heights of the columns of liquid through which the gas has to pass.

Instead of setting up each time such a cumbersome and breakable apparatus as the above, various ready-made forms are now employed which greatly simplify the matter. Among such, Prof. Tischenko's apparatus, shown in fig. 53, is distinguished for its simplicity and regular action. It is composed of a glass jar furnished with a glass partition passing down the middle and having one or more holes at the bottom. A gas-conducting tube extends from the upper portion of each side of the jar, and the top is provided with a stoppered opening for pouring in the liquid used for washing the gas. If the liquid be introduced in such quantity as not quite to fill either half of the jar, but sufficient to cover the holes at the bottom of the partition, then the gas will be able to pass in either direction without forcing the liquid out of the jar. If, for instance, the pressure be greater on the right-hand side than the left, then the liquid will pass from the right to the left, and the gas will rise in bubbles through the column of liquid. If the pressure be reversed the same thing takes place in the opposite direction. A series of such jars may be advantageously used in the preparation of saturated solutions of ammonia.

reaction and the latter a neutral reaction, and they are called respectively acid ammonium sulphate (ammonium hydrogen sulphate) and normal ammonium sulphate or simply ammonium sulphate. Similar salts are formed by the action of all other acids; but certain of them are able to form normal ammonium salts only, whilst others give both acid and normal ammonium salts. This depends on the nature of the acid and not on the ammonia, as we shall afterwards see. Ammonium salts are very similar in appearance and in many of their properties to metallic salts; for instance, sodium chloride or table salt, NaCl , resembles sal-ammoniac, or ammonium chloride, NH_4Cl , not only in its outward appearance but even in crystalline form, in its property of giving precipitates with silver salts, in its solubility in water, and in its power of evolving hydrochloric acid when heated with sulphuric acid—in a word, a most perfect analogy is to be remarked in an entire series of reactions. An analogy in composition is seen if sal-ammoniac, NH_4Cl , be compared with table salt, NaCl ; or ammonium hydrogen sulphate, NH_4HSO_4 , with sodium hydrogen sulphate, NaHSO_4 ; or ammonium nitrate, NH_4NO_3 , with sodium nitrate, NaNO_3 , &c.¹³ It is seen, on comparing the above compounds, that the part which sodium takes in the sodium salts is played in ammonium salts by a group, NH_4 , which is called **ammonium**. If table salt be called ‘sodium chloride,’ then sal-ammoniac should be and is called ‘ammonium chloride.’

The hypothesis that ammoniacal salts correspond with a complex metal ammonium was enunciated by the famous Swedish chemist Berzelius, after a proposition put forward by Ampère. The analogy

¹³ The analogy between the ammonium and sodium salts might seem to be destroyed by the fact that the latter are formed from the alkali or oxide and an acid, with the separation of water, whilst the ammonium salts are directly formed from ammonia and an acid without the separation of water; but the analogy is restored if we compare soda to ammonia water, and liken caustic soda to a compound of ammonia with water. Then the very preparation of ammonium salts from such a hydrate of ammonia will completely resemble the preparation of sodium salts from soda. We may cite as an example the action of hydrochloric acid on both substances.

Just as in soda, so also in ammonia hydrate, the hydroxyl or aqueous radicle OH is replaced by chlorine. The analogy between NH_4 and Na and H is moreover exhibited by the fact that anhydrous peroxide of hydrogen directly absorbs ammonia gas (H_2O_2 is taken in the form of an ethereal solution) and forms a peroxide compound, NH_4HO_2 (cubical crystals insoluble in ether) like H_2O_2 or Na_2O_2 . Moissan in his researches on Weyl's compounds (see following note), for instance, NH_3Na , considers that free ammonium may be regarded as ammonia hydride, NH_3H , that is, as an analogue of these compounds.

between ammonium and metals is probable, owing to the fact that mercury is able to form an amalgam with ammonium similar to those which it forms with sodium and many other metals. The only difference between **ammonium amalgam** and sodium amalgam consists in the instability of the ammonium, which easily decomposes into ammonia and hydrogen.¹⁴ Ammonium amalgam may be prepared from sodium amalgam. If the latter be shaken up with a strong solution of sal-ammoniac the mercury swells up violently and loses its mobility whilst preserving its metallic appearance. In so doing the mercury dissolves ammonium—that is, the sodium in the mercury is replaced by the ammonium, which it replaces in the sal-ammoniac, forming sodium chloride, $\text{NH}_4\text{Cl} + \text{HgNa} = \text{NaCl} + \text{HgNH}_4$. Naturally the formation of ammonium amalgam does not absolutely prove the existence of ammonium itself in a separate state; but it shows the possibility of this substance existing, and its analogy with the metals,

¹⁴ By subjecting sodium to the action of ammonia at the ordinary temperature and under considerable pressures, Weyl (1864) obtained a liquid which was subsequently investigated by Joannis (1889), who confirmed Weyl's results. At 0° and the atmospheric pressure the composition of this substance is $\text{Na} + 5.3\text{NH}_3$. The removal (at 0°) of ammonia from the liquid gives a solid copper-red body having the composition NH_3Na . The determination of the molecular weight of this substance by the fall of the pressure of liquid ammonia gave the composition $\text{N}_2\text{H}_6\text{Na}_2$. It is therefore free ammonium in which one H is replaced by Na. Compounds with potassium, lithium, calcium, &c. proved to have analogous compositions. Dry NH_3 is absorbed by lithium at $+70^\circ$, forming a blue liquid, and it also gives similar liquids with sodium and potassium at -20° , whilst with metallic calcium at $+20^\circ$ it forms a solid compound, Ca_4NH_3 . When heated, all these compounds decompose into ammonia and the metal, or into an amide NH_2R and H_2 (Moissan, Chap. XIV., note 62). By the decomposition of NH_3Na at the ordinary temperature, Joannis (1891) obtained hydrogen and sodium amide, NH_2Na , in small colourless crystals soluble in water. The addition of liquid ammonia to metallic sodium and a saturated solution of sodium chloride gives $\text{NH}_2\text{Na}_2\text{Cl}$, that is, sal-ammoniac in which H_2 is replaced by Na_2 .

Ammonium amalgam was originally obtained in exactly the same way as sodium amalgam (Davy); namely, a piece of sal-ammoniac was taken and moistened with water (in order to render it a conductor of electricity). A cavity was made in it, into which mercury was poured, and it was laid on a sheet of platinum connected with the positive pole of a galvanic battery, the negative pole of which was put into connection with the mercury. On passing a current the mercury increased considerably in volume, and became plastic, while preserving its metallic appearance, just as would be the case were the sal-ammoniac replaced by a lump of a salt of sodium or of one of a number of other metals. Moissan (1901) prepared amalgams with the aid of liquid ammonia and low temperatures. The amalgam of sodium does not act upon liquid ammonia, but dry iodide of ammonium reacts, forming—without the evolution of gas—a liquid amalgam of ammonium which solidifies into a compact mass when cooled to -80° . If it be warmed (after washing and drying) it becomes liquid at -40° , and then effervesces and swells up owing to the formation of gases, which were found to contain hydrogen and ammonia, $2\text{NH}_3 + \text{H}_2$. All efforts to obtain the ammonium itself, for instance, by the reaction $2\text{NH}_3\text{Li} + \text{H}_2\text{S} = \text{Li}_2\text{S} + 2\text{NH}_4$ at low temperatures (to -70°) were unsuccessful, and only gave a mixture of NH_3 and H_2 .

because only metals dissolve in mercury.¹⁵ Ammonium amalgam crystallises in cubes, three times heavier than water; it is stable only in the cold, and particularly so at very low temperatures. It begins to decompose at the ordinary temperature, evolving ammonia and hydrogen in the proportion of two volumes of ammonia to one volume of hydrogen, $\text{NH}_4 = \text{NH}_3 + \text{H}$. Under the action of water, ammonium amalgam gives hydrogen and ammonia water, just as sodium amalgam gives hydrogen and sodium hydroxide; and therefore, in accordance with the ammonium theory, ammonia water or caustic ammonia must be looked on as containing ammonium hydroxide, NH_4OH ,¹⁶ just as an aqueous solution of caustic soda contains NaOH . The ammonium hydroxide, like ammonium itself, is an unstable substance, which readily dissociates and can only exist in a free state at low temperatures.¹⁷ Ordinary solutions of ammonia may be looked upon as the products of the dissociation of this hydroxide, inasmuch as $\text{NH}_4\text{OH} = \text{NH}_3 + \text{H}_2\text{O}$. In its chemical reactions caustic ammonia (and in general, solutions of NH_3 in water) is exactly similar to caustic soda, NaHO ; thus it neutralises acids, enters into double saline decompositions (for instance, a salt MX gives the reaction, $\text{NH}_4\text{OH} + \text{MX} = \text{NH}_4\text{X} + \text{MOH}$), &c., only with this difference, that this alkali can be entirely and readily volatilised.

All ammoniacal salts **decompose at a red heat** into ammonia and an acid, which, on cooling in contact with each other, recombine. If the acid be non-volatile, the ammoniacal salt, when heated, evolves the ammonia, leaving the non-volatile acid behind; if the acid be volatile, then, on heating, both the acid and ammonia volatilise together, and on cooling recombine into the salt which originally served for the formation of their vapours.¹⁸

¹⁵ We may mention, however, that under certain conditions hydrogen is also capable of forming an amalgam resembling the amalgam of ammonium. If an amalgam of zinc is shaken up with an aqueous solution of platinum chloride, without access of air, a spongy mass is formed which easily decomposes, with evolution of hydrogen.

¹⁶ We saw above (note 12) that the solubility of ammonia in water at low temperatures attains to the molecular ratio, $\text{NH}_3 + \text{H}_2\text{O}$, in which these substances are contained in caustic ammonia; and it may perhaps be possible, at exceedingly low temperatures, to obtain ammonium hydroxide, NH_4HO , in a solid form. Regarding solutions as dissociated definite compounds, we should see a confirmation of this view in the property shown by ammonia of being extremely soluble in water, and in so doing of approaching to the limit NH_4HO .

¹⁷ In confirmation of the truth of this conclusion we may cite the fact that there exist, in a free state and as comparatively stable compounds, a series of alkaline hydroxides, NR_4HO , which are perfectly analogous to ammonium hydroxide, and present a striking resemblance to it and to sodium hydroxide, with the only difference that the hydrogen in NH_4HO is replaced by complex groups, $\text{R} = \text{CH}_3$, C_2H_5 , &c., for instance $\text{N}(\text{CH}_3)_4\text{HO}$. Details will be found in works on organic chemistry.

¹⁸ The fact that ammoniacal salts are decomposed when ignited, and not simply sublimed, may be proved by a direct experiment with sal-ammoniac, NH_4Cl , which in a

Ammonia is capable of combining not only with acids, but also with many salts, as was seen from its forming definite compounds, $\text{AgCl}, 3\text{NH}_3$ and $2\text{AgCl}, 3\text{NH}_3$ (mentioned above), with silver chloride. Ammonia is absorbed with evolution of heat by various oxygen salts of the metals, and also by the chlorine, iodine, and bromine compounds of many metals. Certain of these compounds part with their ammonia when left exposed to the air, but others only do so at a red heat; many give up their ammonia when dissolved, whilst others dissolve without decomposition, and when their solutions are evaporated, separate unchanged. All these facts merely indicate that ammoniacal, like aqueous, compounds dissociate with greater or less facility.¹⁹ Certain metallic oxides also absorb ammonia and are dissolved by ammonia water. This is the case, for instance, with the oxides of zinc, nickel, copper, and many others, the majority of the compounds thus formed being unstable. The property of ammonia of combining with various oxides explains its action on certain metals, for instance, on copper in the presence of air.^{19a}

The similarity between the relations of ammonia and of water to salts and other substances is more especially marked in those cases in which the salt is capable of combining with both ammonia and water. Take, for example, copper sulphate, CuSO_4 , which, as we saw in Chapter I., gives with water blue crystals, $\text{CuSO}_4, 5\text{H}_2\text{O}$; but the anhydrous salt also absorbs dry ammonia in the same molecular proportions, forming a blue substance, $\text{CuSO}_4, 5\text{NH}_3$, and therefore the ammonia combining with salts may be termed **ammonia of crystallisation**.

Many **products** of direct or indirect **substitution** correspond to ammonia, its compounds with water and the ammonium salts. Certain

state of vapour is decomposed into ammonia, NH_3 , and hydrochloric acid, HCl , as will be explained in the following chapter. The readiness with which ammonium salts decompose is seen from the fact that a solution of ammonium oxalate is decomposed with evolution of ammonia even at -1° . Dilute solutions of ammonium salts, when boiled, give aqueous vapour having an alkaline reaction owing to the presence of free ammonia given off from the salt.

¹⁹ As we have seen in note 8, Isambert studied the dissociation of ammoniacal compounds, and showed that at low temperatures many salts are able to combine with a still greater amount of ammonia, which proves an entire analogy with hydrates; and as in this case it is easy to isolate the definite compounds, and as also the least possible pressure of ammonia is greater than that of water, the ammoniacal compounds present a great and peculiar interest, as a means of explaining the nature of aqueous solutions and as a confirmation of the hypothesis of the formation of definite compounds in them. For these reasons we shall frequently refer to these compounds in the further exposition of this work.

^{19a} Chap. V., note 2. This is the reason why copper vessels cannot be used for holding ammonia. Iron is not acted on by it. As zinc evolves hydrogen from ammonia (in aqueous solution) it may act like copper; but the affinity is small in this case, so that the oxygen affinity must also be taken into account. Copper alloys may be cleaned (the superficial coating of oxides removed) with a solution of ammonia.

of the elements, for instance, sodium, zinc, chlorine, &c., directly displace a portion of the hydrogen from NH_3 and take its place. The displaced hydrogen then appears either in the free state or combined with the simple body. If metallic sodium be heated in an atmosphere of dry ammonia it will displace a portion of the hydrogen in the ammonia and form sodium amide, NaNH_2 , according to the equation: $\text{NH}_3 + \text{Na} = \text{NaNH}_2 + \text{H}$. Chlorine acts in essentially the same way, forming ClNH_2 , but the hydrogen evolved, owing to its great affinity for chlorine, gives HCl , and in general the reaction is more complicated (see Chap. XI.), although fundamentally it is the same as in the case of sodium. Certain metallic compounds resembling ammonia in their composition and reactions, and in which the hydrogen is replaced by the metal, are formed directly by heating the metal in nitrogen. Thus lithium and magnesium readily absorb nitrogen when heated, forming nitrides, NLi_3 and N_2Mg_3 , which give ammonia with water (for instance, $\text{N}_2\text{Mg}_3 + 6\text{H}_2\text{O} = 3\text{MgH}_2\text{O}_2 + 2\text{NH}_3$). This shows that they, like sodium amide, are analogous to ammonia, and have the same composition and structure, with the difference that all the hydrogen is replaced by a metal, just as the metallic oxides correspond to water and may be regarded as products of substitution of the hydrogen in water by metals. But the hydrocarbon products of substitution of the hydrogen in ammonia present even greater interest. They have the composition NH_2R , NHR_2 , and NR_3 , where R is a hydrocarbon group (or residue), such as CH_3 , C_2H_5 , C_6H_5 , &c. These compounds, which are described fully in organic chemistry, are especially instructive because they preserve in themselves the faculty of ammonia for combining with acids and forming salts, and thus resemble ammonia completely in their chemical characters also. In nature such nitrogenous hydrocarbon derivatives of ammonia are met with in plants and animals, and are known as alkaloids owing to their capacity of combining with acids like ammonia; such, for instance, are quinine, nicotine, &c.²⁰

²⁰ The practical applications of ammonia are very varied. The use of ammonia as a stimulant, in the form of the so-called 'smelling salts' or of spirits of hartshorn, in cases of faintness, &c., is known to everyone. The volatile carbonate of ammonium, or a mixture of an ammonium salt with an alkali, is also employed for this purpose. Ammonia also produces a well-known stimulating effect when rubbed on the skin, for which reason it is sometimes employed for external applications. Thus, for instance, the well-known volatile salve is prepared from any liquid oil by shaking up with a solution of ammonia. A portion of the oil is thus transformed into a soapy substance. The solubility of greasy substances in ammonia, which proceeds from the formation both of emulsions and soaps, explains its use in extracting grease-spots. It is also employed as an external application for stings from insects and for poisonous snake-bites, and in general in medicine. It is also remarkable that in cases of drunkenness a few drops of ammonia in water taken internally rapidly renders a person sober. A large quantity of ammonia is used in dyeing, either for the solution of certain dyes—for example, carmine—or for

We shall now pass on to the consideration of the other compounds of nitrogen with hydrogen, and also of those with oxygen.

But in order to grasp the relation between ammonia and the other compounds of nitrogen it is necessary to recognise the general **law of substitution**, which is applicable to all cases of substitution between elements,^{20a} and to show therefore what may be the conditions of substitution between oxygen and hydrogen as component parts of water. The law of substitution may be deduced from mechanical principles, if the molecule be conceived as a system of elementary atoms occurring in a certain chemical and mechanical equilibrium. By likening the molecule to a system of bodies in a state of motion—for instance, to the sum total of the sun, planets, and satellites, existing in conditions of mobile equilibrium—we should expect the action of one part in this system to be equal and opposite to the other, according to Newton's third law of mechanics. Hence, given a molecule of a compound, for instance, H_2O , NH_3 , NaCl , HCl , &c., its two parts must, in a chemical sense, represent two things somewhat alike in force and properties, and therefore *every two parts into which a molecule of a compound may be divided are capable of replacing each other*.²¹ In order that the

changing the tints of others, or else for neutralising the action of acids. It is also employed in the manufacture of artificial pearls. For this purpose the small scales of a peculiar small fish are mixed with ammonia, and the liquid so obtained is blown into small hollow glass beads shaped like pearls.

In nature and the arts, however, ammonium salts, and not free ammonia, are most frequently employed. It is in this form that a portion of that **nitrogen** which is necessary for the formation of albuminous substances **is supplied to plants**. In this way a large quantity of ammonium sulphate is now employed as a fertilising substance. But the same effect may be produced by nitre or by animal refuse, which in decomposing gives ammonia. For this reason an ammoniacal (hydrogen) compound which may be introduced into the soil in the spring will be converted into a nitrate (oxygen salt) in the summer.

^{20a} When the element chlorine, as we shall afterwards more fully learn, replaces hydrogen, the reaction by which such an exchange is accomplished proceeds as a substitution, $\text{AH} + \text{Cl}_2 = \text{ACl} + \text{HCl}$, so that two substances, AH and chlorine, react on each other and two substances, ACl and HCl , are formed; and, further, two molecules react on each other, and two others are formed. Such reactions proceed very easily, but the substitution of one element, A , by another, X , does not always proceed with such ease, clearness or simplicity. The substitution between oxygen and hydrogen is very rarely accomplished by the direct action of the free elements, but the substitution between these elements, one for another, forms the most common case of oxidation or reduction. In speaking of the law of substitution, I have in view the substitution of the elements one by another, and not the direct reaction of substitution. The law of substitution determines the cycle of the combinations of a given element if a few of its compounds (for instance, the hydrogen compounds) be known. A development of the conceptions of the law of substitution may be found in my lecture given at the Royal Institution in London, 1889 (two lectures read in London. See 2nd edition of *Principles of Chemistry*).

²¹ It is evident from the essence of the matter that affinity must play a certain part in substitution, that is to say, that although chlorine, for instance, forms NaCl with

application of the law should become clear it is evident that among compounds the most stable should be chosen. We shall therefore take hydrochloric acid and water as the most stable compounds of hydrogen.^{21a} According to the above law of substitution, if the elements H and Cl are able to form a molecule, HCl, and a stable one, they are able to replace each other. And, indeed, we shall afterwards see (Chap. XI.) that in a number of instances substitution between hydrogen and chlorine can take place. Given RH, then RCl is possible, because HCl exists and is stable. The molecule of water, H₂O, may be divided in two ways, because it contains three atoms: into H and (HO) on the one hand, and into H₂ and O on the other. Consequently, being given RH, its substitution products will be R(HO) according to the first form, and R₂O according to the second; being given RH₂, its corresponding substitution products will be RH(OH), R(OH)₂, RO, (RH)₂O, &c. The group (OH) is the same **hydroxyl or aqueous radicle** which we have already mentioned in the third chapter as a component part of hydroxides and alkalies—for instance, Na(OH), Ca(OH)₂, &c. It is evident, judging from H(HO) and HCl, that (OH) can be substituted by Cl, because both are replaceable by H; and this is of common occurrence in chemistry, because metallic chlorides—for example, NaCl and NH₄Cl—correspond with hydroxides of the alkalis, Na(OH) or NH₄(OH). In hydrocarbons—for instance, C₂H₆—the hydrogen is replaceable by chlorine and by hydroxyl. Thus ordinary alcohol is C₂H₅(OH), in which one atom of H is replaced by (OH), that is, C₂H₅(OH). It is evident that the replacement of hydrogen by hydroxyl forms essentially the phenomenon of oxidation, because RH gives R(OH), or RHO. Hydrogen peroxide may

sodium, and therefore Cl can replace Na, yet this does not take place in every case. The law indicates the possibility of such a substitution taking place, and, what is still more important, it foretells the relative amounts of the substituting groups. Two atoms of hydrogen are replaced, judging from the composition of water, not by two atoms, but by one atom, of oxygen. The greater the complexity of the molecule the more difficult will it naturally be to obtain the products of substitution of all its subdivisions. It should further be remarked that in its above form the law of substitution simultaneously generalises the principles of such phenomena as metalepsis (see, in Chap. XI., the substitution of hydrogen by chlorine), oxidation, and homology (Chap. VIII.), which are as a rule (especially under the influence of the electrical and the dualistic conceptions) considered separately and independently of each other. The ordinary common instances of substitution of like by like are that quantities separately equal to some third are equal to each other; from which it is evident that if MX and RX exist then M can replace R, and *vice versa*.

^{21a} If hydrogen peroxide be taken as a starting-point, then still higher forms of oxidation than those corresponding with water should be looked for. They should possess the properties of hydrogen peroxide, especially that of parting with their oxygen with extreme ease (even by contact). Such compounds are known. Pernitric, persulphuric, and similar acids present these properties, as we shall see when describing them.

in this sense be regarded as water in which the hydrogen is replaced by hydroxyl; $\text{H}(\text{OH})$ gives $(\text{OH})_2$ or H_2O_2 . The other form of substitution—namely, that of O in the place of H_2 —is also a common chemical phenomenon. Thus alcohol, $\text{C}_2\text{H}_6\text{O}$, or $\text{C}_2\text{H}_5(\text{OH})$, when oxidising in the air, gives acetic acid, $\text{C}_2\text{H}_4\text{O}_2$, or $\text{C}_2\text{H}_3\text{O}(\text{OH})$, in which H_2 is replaced by O.

In the further course of this work we shall have frequent occasion to refer to the law of substitution for explaining many chemical phenomena and relations.

We shall now apply these conceptions to ammonia in order to see its relation to other compounds of nitrogen. It is evident that many substances should be obtainable from ammonia, NH_3 , or aqueous ammonia, $\text{NH}_4(\text{OH})$, by replacing their hydrogen by hydroxyl, or H_2 by oxygen. And such is the case. The extreme cases of substitution will be obtained on the one hand when we imagine the substitution of hydrogen in ammonia, NH_3 , by hydroxyl, so that $\text{NH}_2(\text{OH})$ is obtained, and on the other hand when we imagine that all the hydrogen in $\text{NH}_4(\text{OH})$ is replaced by oxygen, so that $\text{NO}_2(\text{OH})$ is formed. Both these possible extreme cases of the application of the law of substitution are evidently products of oxidation, for $\text{NH}_2(\text{OH}) = \text{NH}_3 + \text{O}$ and $2\text{NO}_2(\text{OH}) = 2\text{NH}_3 + 4\text{O}_2 + 2\text{H}_2\text{O}$, and they are both known as independent substances. The first, $\text{NH}_2(\text{OH})$, is called **hydroxylamine**, because substances containing the ammonia residue, NH_2 , are called amides or amines, and the residue itself amide, and the aqueous residue OH , as we already know, is called hydroxyl, and here these two are combined together. The second of the above substitution products, the highest oxidation compound, $\text{NO}_2(\text{OH})$, is nothing else but nitric acid, which corresponds to the anhydride, N_2O_5 , and salts NMO_3 . And as intermediate substitution products can be placed between these two extreme cases, we see that, starting from ammonia and its compound with water, we are enabled by the law of substitution to understand the relations of all the known compounds of nitrogen, hydrogen, and oxygen. It is simplest to start with caustic ammonia and substitution by hydroxyl.

The *first* product of this substitution will be $\text{NH}_3(\text{OH})_2 = \text{NH}_5\text{O}_2$. The separation of H_2O from it will give the above **hydroxylamine**, $\text{NH}_2(\text{OH})$. This substance was obtained as a salt, i.e., combined with an acid, in 1865 by Lossen as a product of the deoxidation (by the action of nascent hydrogen, SO_2 , and other reducing agents) of nitric acid. The salt formation is determined by the fact that hydroxylamine still contains a large proportion of hydrogen in combination with the nitrogen, so that the substance obtained is able, like ammonia, to

form salts with acids.²² But the formation of hydroxylamine, $\text{NH}_2(\text{OH}) = \text{NH}_3\text{O}$, indicates the possibility of the formation of two other compounds of nitrogen: N_2H_4 and NH , that is, of free amide $(\text{NH}_2)(\text{NH}_2) = \text{N}_2\text{H}_4$ and free imide NH (equivalent to $\text{NH}_3\text{O} - \text{H}_2\text{O}$), in which, as hydrogen compounds similar to ammonia, one would also expect to find a faculty for combining with acids. The possibility of the existence of free amide

²² The compound of hydroxylamine with hydrochloric acid has the composition $\text{NH}_2(\text{OH})\text{HCl} = \text{NH}_4\text{ClO}$, being, as it were, oxidised sal-ammoniac. It was prepared by Lossen in 1866 by the action of tin and hydrochloric acid in the presence of water on a substance called ethyl nitrate, the hydrogen liberated from the hydrochloric acid by the tin acting upon the elements of nitric acid—

Thus in this case the nitric acid is deoxidised, not directly into nitrogen, but into hydroxylamine. On mixing nitric acid with water and either sulphuric or hydrochloric acid, cooling the solution and subjecting it to the action of an electric current, using a mercury or amalgamated lead cathode, the nitric acid is almost completely reduced to hydroxylamine (Tafel, 1902). Hydroxylamine is also formed by passing nitric oxide, NO , into a mixture of tin and hydrochloric acid—that is, by the action of the hydrogen evolved on the nitric oxide, $\text{NO} + 3\text{H} + \text{HCl} = \text{NH}_4\text{OCl}$ —and in many other reactions. According to Lossen's method, a mixture of 30 parts of ethyl nitrate, 120 parts of tin, and 40 parts of a solution of hydrochloric acid of sp. gr. 1.06 is made, and after a certain time the reaction commences spontaneously. When the reaction has ceased the tin is separated by means of hydrogen sulphide and the solution evaporated, a large amount of sal-ammoniac being thus obtained (owing to the further action of hydrogen on the hydroxylamine compound, from which it takes up oxygen and forms water); a solution ultimately remains containing the hydroxylamine salt, which is dissolved in anhydrous alcohol and purified by the addition of platinum chloride, which precipitates any ammonium salt still remaining in the solution. After concentrating the alcoholic solution, the hydroxylamine hydrochloride separates in crystals. This substance melts at about 150° , and in so doing decomposes into nitrogen, hydrogen chloride, water, and sal-ammoniac. A sulphuric acid compound of hydroxylamine may be obtained by mixing a solution of the above salt with sulphuric acid; like the hydrochloride, it is soluble in water. Hydroxylamine, then, like ammonia itself, forms a series of salts in which one acid may be substituted for another. It might be expected that, by mixing a strong solution of a hydroxylamine salt with a solution of a caustic alkali, hydroxylamine itself would be liberated, just as an ammonium salt under these circumstances evolves ammonia; but the liberated hydroxylamine is immediately decomposed with the formation of nitrogen and ammonia (and probably nitrous oxide), $3\text{NH}_3\text{O} = \text{NH}_3 + 3\text{H}_2\text{O} + \text{N}_2$. Dilute solutions give the same reaction, although very slowly, but by decomposing a solution of the sulphate with barium hydroxide a certain amount of hydroxylamine is obtained in solution (it is partly decomposed). Like ammonia, hydroxylamine in aqueous solution precipitates basic hydrates, and it deoxidises the oxides of copper, silver, and other metals. Free hydroxylamine was obtained by Lobry de Bruyn (1891) and is a solid, colourless, crystalline substance (sp. gr. 1.935), without odour, and melting at $+33^\circ$. It is highly hygroscopic and readily distils under a low pressure (it is purified in this way), but decomposes with explosion when heated at the ordinary pressure. It is almost insoluble in ordinary solvents like chloroform, benzene, acetic ether, and carbon bisulphide. Its aqueous solutions, containing up to 60 per cent. (sp. gr. 1.15 at 20°), are tolerably stable, and may be kept for many weeks without undergoing any change. Lobry de Bruyn used the hydrochloric acid salt to prepare pure hydroxylamine. The salt was first

is in accordance with the law of substitution, because if ammonia be expressed as $(\text{NH}_2)\text{H}$, the group NH_2 should be able to replace hydrogen, and this exchange would result in the formation of amide $(\text{NH}_2)\text{NH}_2 = \text{N}_2\text{H}_4$. This substance was obtained by Curtius (1887), and was named **hydrazine**, N_2H_4 .^{22a} It forms a liquid boiling at about 113° , and

treated with sodium methylate, (CH_3NaO) , after which methyl alcohol was added to the mixture. The precipitated sodium chloride was separated from the solution by filtration. (The methyl alcohol is added to prevent the precipitated chloride of sodium from coating the insoluble hydrochloride of hydroxylamine.) Under the action of NaHO , hydroxylamine gives NH_3 and NHO_2 or N_2O , while it forms nitric acid (Kolotoff, 1893) under the action of oxidising agents. It is obtained in a great number of reactions; for instance, by the action of tin on dilute nitric acid and by the action of zinc on ethyl nitrate and dilute hydrochloric acid. The relation between hydroxylamine, $\text{NH}_2(\text{OH})$, and nitrous acid, $\text{NO}(\text{OH})$, which is so clear in the sense of the law of substitutions, becomes a reality in those cases in which reducing agents act on salts of nitrous acid. Thus Raschig (1888) proposed the following method for the preparation of hydroxylamine sulphate. A mixture of strong solutions of potassium nitrite, KNO_2 , and hydroxide, KHO , in molecular proportions, is prepared and cooled. An excess of sulphurous anhydride is then passed into the mixture and the solution boiled for a long time. A mixture of the sulphates of potassium and hydroxylamine is thus obtained: $\text{KNO}_2 + \text{KHO} + 2\text{SO}_2 + 2\text{H}_2\text{O} = \text{NH}_2(\text{OH})\cdot\text{H}_2\text{SO}_4 + \text{K}_2\text{SO}_4$, and these may be separated from each other by crystallisation.

^{22a} Free **amidogen** or **hydrazine**, N_2H_4 , or 2NH_2 , was prepared by Curtius (1887) by means of ethyl diazoacetate, or triazoacetic acid. Curtius and Jay (1889) showed that triazoacetic acid, $\text{CHN}_2\cdot\text{COOH}$ (the formula should be tripled), when heated with water or a mineral acid, gives (quantitatively) oxalic acid and amidogen (hydrazine), $\text{CHN}_2\cdot\text{COOH} + 2\text{H}_2\text{O} = \text{C}_2\text{O}_2(\text{OH})_2 + \text{N}_2\text{H}_4$ —i.e., expressed empirically, the oxygen of the water replaces the nitrogen of the azoacetic acid. The amidogen is thus obtained in the form of a salt. With acids, amidogen forms very stable salts of the two types $\text{N}_2\text{H}_4\cdot\text{HX}$ and $\text{N}_2\text{H}_4\cdot\text{H}_2\text{X}_2$; as, for example, with HCl , H_2SO_4 , &c. These salts are easily crystallised; in acid solutions they act as powerful reducing agents, evolving nitrogen; when ignited they are decomposed into ammoniacal salts, nitrogen, and hydrogen; with nitrites they evolve nitrogen. The sulphate $\text{N}_2\text{H}_4\cdot\text{H}_2\text{SO}_4$ is sparingly soluble in cold water (3 parts in 100 of water), but is very soluble in hot; its specific gravity is 1.378 and it fuses at 254° with decomposition. The hydrochloride $\text{N}_2\text{H}_4\cdot 2\text{HCl}$ crystallises in octahedra, is very soluble in water, but not in alcohol; it fuses at 198° , evolving hydrogen chloride and forming the salt $\text{N}_2\text{H}_4\cdot\text{HCl}$; when rapidly heated it decomposes with an explosion; with platinic chloride it immediately evolves nitrogen, forming platinous chloride. By the action of alkalis the salts $\text{N}_2\text{H}_4\cdot 2\text{HX}$ give **hydrate of amidogen**, $\text{N}_2\text{H}_4\cdot\text{H}_2\text{O}$, which is a fuming liquid (specific gravity 1.03), solidifying at about 10° and boiling at 199° , almost without odour, and whose aqueous solution corrodes glass and indiarubber, has an alkaline taste and poisonous properties. With oxide of barium the hydrate gives anhydrous hydrazine as a liquid (sp. gr. 1.01) boiling at 113° (but it is best to distil it under a low pressure because it readily decomposes), and solidifying at about $+1^\circ$. The reducing properties of the hydrate are clearly seen from the fact that it reduces the metals platinum and silver from their solutions. With mercuric oxide it explodes. Iodic acid HIO_3 (and also its salts, even the insoluble barium salt BaI_2O_6) oxidises the salts of hydrazine at the ordinary temperature, and is entirely converted into hydriodic acid, with the evolution of free nitrogen (Ditte); for instance, $\text{BaI}_2\text{O}_6 + 3\text{N}_2\text{H}_4\cdot\text{H}_2\text{SO}_4 = 2\text{HI} + 2\text{H}_2\text{SO}_4 + \text{BaSO}_4 + 6\text{H}_2\text{O} + 3\text{N}_2$ (this reaction is so complete that the amount of barium may be determined by the volume of nitrogen evolved; it was proposed by Rigler as an analytical method). It reacts directly with the aldehydes RO , forming N_2R_2 and water; for example, with benzaldehydes it gives the very stable insoluble *benzalazine*, $(\text{C}_6\text{H}_5\text{CHN})_2$, of a yellow colour. We may add that hydrazine often forms double

capable of giving a stable hydrate $\text{N}_2\text{H}_4\cdot\text{H}_2\text{O}$, which may be regarded as caustic ammonia, NH_4OH , in which H is replaced by NH_2 . This hydrate is distinctly alkaline. Hydrazine is also formed by reducing hyponitrous acid, $\text{N}_2(\text{OH})_2$, with ammonium sulphide, $\text{N}_2\text{H}_2\text{O}_2 + 3\text{H}_2 = \text{N}_2\text{H}_4 + 2\text{H}_2\text{O}$. We shall afterwards become acquainted with this acid, because, like amide, it forms one of the intermediate substances between ammonia and nitric acid, and so far such intermediary products have been almost exclusively obtained from more highly oxidised products by a method of reduction, and not by the oxidation of more highly hydrogenated compounds. The free amide NH (or maybe N_nH_n), equivalent to hydroxylamine less water, has not yet been obtained separately, and if it be at any time prepared, it will be as a substance which easily decomposes into nitrogen and hydrogen.²³

The *second* product of the substitution of hydrogen by hydroxyl, in caustic (aqueous) ammonia, $\text{NH}_2(\text{OH})_3 = \text{NH}_5\text{O}_3$, should by the abstraction of water give NH_3O_2 and NHO . This latter is hyponitrous acid, which appears, however, in the form of a polymeride, $\text{N}_2\text{H}_2\text{O}_2$, described further on. But as it still contains hydrogen and oxygen, it is to be expected that it should part with water, and give the nitrous oxide described later.

The *third* product of substitution, $\text{NH}(\text{HO})_4 = \text{NH}_5\text{O}_4$, when deprived

salts; for example, $\text{MgSO}_4\cdot\text{N}_2\text{H}_4\cdot\text{H}_2\text{SO}_4$ or $\text{KCl}\cdot\text{N}_2\text{H}_4\cdot\text{HCl}$, and that it is also formed by the action of nitrous acid upon aldehyde ammonia. The products of the substitution of the hydrogen in hydrazine by hydrocarbon groups R ($\text{R} = \text{CH}_3, \text{C}_2\text{H}_5, \text{C}_6\text{H}_5$, &c.) were obtained before hydrazine itself; for example, NHRNH_2 , NR_2NH_2 , and $(\text{NRH})_2$.

The heat of formation of hydrated hydrazine, $-9\cdot5$ cals., from its elements was deduced from the heat of combustion, $+127\cdot7$ cals., determined by burning $\text{N}_2\text{H}_4\cdot\text{H}_2\text{SO}_4$ in a calorimetric bomb. Thus hydrazine is an endothermal compound: its passage into ammonia by combination with hydrogen is accompanied by the evolution of $51\cdot5$ cals. In the presence of an acid these figures become greater by $+14\cdot4$ cals. Hence the direct converse transformation of ammonia into hydrazine is impossible. As regards the passage of hydroxylamine into hydrazine, it would be accompanied in aqueous solution by an evolution of heat ($+21\cdot5$ cals.).

Amidogen must be regarded as a compound which stands in the same relation to ammonia as hydrogen peroxide to water. As was clearly to be expected, water, $\text{H}(\text{OH})$, gives, according to the law of substitution, $(\text{OH})(\text{OH})$ —that is, peroxide of hydrogen. So also ammonia, $\text{H}(\text{NH}_2)$, forms hydrazine, $(\text{NH}_2)(\text{NH}_2)$ —that is, the free radicle of ammonia, NH_2 , or amidogen. In the case of phosphorus a similar substance, as we shall afterwards see, has long been known under the name of liquid phosphoretted hydrogen, P_2H_4 .

²³ **Imide**, NH , has not been obtained in a free state, but its hydrochloric acid salt, NH_2HCl , has apparently been obtained (1890) by Maumené by igniting the double bichloride of platinum and ammonium chloride, $\text{PtCl}_2\cdot\text{NH}_4\text{Cl} = \text{Pt} + 2\text{HCl} + \text{NH}_2\text{HCl}$. It is soluble in water, and crystallises from its solution in hexagonal rhombic prisms. It gives a double salt with FeCl_3 of the composition $\text{FeCl}_3\cdot 3\text{NHHCl}$. The salt NH_2HCl is similar (isomeric) to the first possible product of the metalepsis of ammonia, NH_2Cl , although it can hardly resemble it in any of its properties.

of water, should yield nitrous acid (treated of later), NHO_2 , and its orthohydrate, $\text{N}(\text{OH})_3$, and by the total abstraction of the elements of water,

nitrous anhydride, N_2O_3 , which is also described in the following pages.

The *fourth* and last product of substitution, $\text{N}(\text{HO})_5$, less water, gives orthonitric acid, NH_3O_4 ,²⁴ and the most highly oxidised product of nitrogen, nitric acid, NHO_3 , and its anhydride, N_2O_5 :²⁵ $\text{NHO}_3 + \text{NHO}_3 = \text{H}_2\text{O} + \text{N}_2\text{O}_5$. And as it is supposed in the above equations that two molecules of hydrate are taken, it follows that intermediate oxides of nitrogen, N_2O_2 and N_2O_4 , or their polymerides, NO and NO_2 , may also be looked for. All these bodies are known and are described in what follows.

We shall, however, first show by two examples that in the first place the passage of ammonia into the oxygen compounds of nitrogen up to nitric acid, as well as the converse preparation of ammonia (and consequently of the intermediate compounds also) from nitric acid, are reactions which proceed directly and easily under many circumstances,²⁶

²⁴ Phosphorus (Chap. XIX.) gives the hydride PH_3 , corresponding with ammonia, NH_3 , and forms phosphorous acid, PH_3O_3 , which is analogous to nitrous acid, just as phosphoric acid is to nitric acid; but phosphoric (or, better, orthophosphoric) acid, PH_3O_4 , is capable of giving up water yielding pyro- and meta-phosphoric acids. The latter is equal to the ortho-acid minus water = PHO_3 , and therefore nitric acid, NHO_3 , is really meta-nitric acid. So also nitrous acid, HNO_2 , is meta-nitrous (anhydrous) acid, and thus the ortho-acid is $\text{NH}_3\text{O}_3 = \text{N}(\text{OH})_3$. Hence for nitric acid we should expect to find, besides the ordinary or meta-nitric acid, $\text{HNO}_3 (= \frac{1}{2}\text{N}_2\text{O}_5\text{H}_2\text{O})$, and ortho-nitric acid, $\text{H}_3\text{NO}_4 (= \frac{1}{2}\text{N}_2\text{O}_5, 3\text{H}_2\text{O})$, an intermediate pyro-nitric acid, $\text{N}_2\text{H}_4\text{O}_7$, corresponding with pyrophosphoric acid, $\text{P}_2\text{H}_4\text{O}_7$. We shall see (for instance, in Chap. XVI., note 21) that in nitric acid there is indeed an inclination of the ordinary salts (of the meta-acid) MNO_3 , to combine with bases M_2O , and to approximate to the composition of ortho-compounds which are equivalent to the meta-compound plus a base ($\text{MNO}_3 + \text{M}_2\text{O} = \text{M}_3\text{NO}_4$).

²⁵ Nitric acid corresponds with the anhydride N_2O_5 , which will afterwards be described, and which must be regarded as the highest saline oxide of nitrogen, just as is Na_2O (and the hydroxide NaHO) in the case of sodium, although sodium forms a peroxide, possessing the property of parting with its oxygen with the same ease as hydrogen peroxide, if not on heating, at all events in reactions—for instance, with acids. So also nitric acid has its corresponding peroxide, which may be called **pernitric acid**. Its composition is not well known, but is probably NHO_4 , so that its corresponding anhydride would be N_2O_7 . It is formed by the action of a silent discharge on a mixture of nitrogen and oxygen, a portion of its oxygen being hence similar to that in ozone. The instability of this substance (obtained by Hautefeuille, Chappuis, and Berthelot), which readily splits up with formation of nitric peroxide, and its resemblance to persulphuric acid, which we shall afterwards describe, will permit our passing over the consideration of the little that is further known concerning it.

²⁶ In reality it appears up to the present that the process of oxidation leads to the formation of nitric and nitrous acids, but not to the formation of the intermediate hydrogen compounds which so far have only been obtained by a method of reduction from higher degrees of oxidation. The action of a galvanic current on solutions of nitric acid, in the

and in the second place that the above general principle of substitution gives the possibility of understanding many, at first sight, unexpected and complex relations and transformations, such as the preparation of hydrazoic acid, HN_3 . In nature the matter is complicated by a number of influences and circumstances, but in the law the relations are presented in their simplest aspect.

It is easy to prove the possibility of the oxidation of ammonia into nitric acid by passing a mixture of ammonia and air over heated spongy platinum. This causes the oxidation of the ammonia, giving nitric acid, which partially combines with the excess of ammonia.

The converse transformation of nitric acid into ammonia is effected by the action of hydrogen at the moment of its evolution.²⁷ Thus metallic aluminium, evolving hydrogen from a solution of caustic soda, is able to completely convert nitric acid added to the mixture (as a salt, because the alkali gives a salt with the nitric acid) into ammonia, $\text{NHO}_3 + 8\text{H} = \text{NH}_3 + 3\text{H}_2\text{O}$. And as, judging from what was said above,

ammonia and nitric acid are the extreme compounds of nitrogen with hydrogen and oxygen, and all the other compounds of these elements may be regarded as intermediate compounds, so the passage of NH_3 to HNO_3 , and the reverse, clearly show that all the hydrogen and oxygen

presence of H_2SO_4 or HCl at the cathode, especially if the latter consist of mercury or an amalgamated metal, leads entirely to the formation of the hydroxylamine salt (Tafel, 1902); but as a rule reduction leads to the formation of ammonia, especially if the cathode be of copper.

²⁷ The formation of ammonia is observed in many cases of oxidation by means of nitric acid. This substance is even formed in the action of nitric acid on tin, especially if dilute acid be employed in the cold. A still more considerable amount of ammonia is obtained if, in the action of nitric acid, there are conditions directly tending to the evolution of hydrogen, which then reduces the acid to ammonia; for instance, in the action of zinc on a mixture of nitric and sulphuric acids. But hydrogen gas itself can in presence of platinum and by the aid of heat convert the oxide of nitrogen, for instance, NO , into ammonia:

FIG. 54.—Conversion of ammonia into nitric acid. Air is driven out of the bottle B (by the stream of water from *r*) into C, where it mixes with the ammonia evolved from an aqueous solution in A. The mixed gases pass from C through the heated tube D containing spongy platinum. The nitric acid formed is collected in water in the vessel E.

compounds of nitrogen form one natural series. This sequence of compounds becomes particularly distinct when considered under the light of the law of substitutions.

The same law gives the possibility of foreseeing the relations of trinitride of hydrogen, HN_3 , to the members of this series.

In 1890, Curtius, in Germany, obtained this substance as a very volatile (at $+37^\circ$), soluble, and very explosive liquid having the distinctive properties of an acid, dissolving zinc, aluminium, &c., with the evolution of hydrogen, and giving, like hydrochloric acid, salts; for example, a sodium salt, NaN_3 ; an ammonium salt, $\text{NH}_4\text{N}_3 = \text{N}_4\text{H}_4$; a barium salt, $\text{Ba}(\text{N}_3)_2$, &c. He therefore named it **hydrazoic acid**, HN_3 .^{27a} The extraordinary composition of the compound (ammonia,

^{27a} Curtius started with benzoylhydrazine, $\text{C}_6\text{H}_5\text{CONHNH}_2$ (hydrazine; see note 20a) (this substance is obtained by the action of hydrated hydrazine on the compound ether of benzoic acid). Benzoylhydrazine, under the action of nitrous acid, gives benzoylazoimide and water:

Benzoylazoimide when treated with sodium alcoholate gives the sodium salt of hydrazoic acid:

The addition of ether to the resultant solution precipitates the NaN_3 , and this salt, when treated with sulphuric acid, gives gaseous hydrazoic acid, HN_3 . It has an acrid smell, and is easily soluble in water. The aqueous solution exhibits a strongly acid reaction and dissolves metals, giving the corresponding salts. With hydrazoic acid, gaseous ammonia forms a white cloud, consisting of the ammonium salt, NH_4N_3 , which separates out from an alcoholic solution in the form of white lustrous scales. The salts of hydrazoic acid are obtained by reactions of substitution with the sodium or ammonium salts. In this manner Curtius obtained and studied the salts of silver (AgN_3), lead (PbN_6), and barium (BaN_6). With hydrazine, N_2H_4 , hydrazoic acid forms saline compounds in the composition of which there are one or two molecules of N_3H per one of hydrazine; e.g., N_5H_5 and N_8H_6 . The first, which was obtained in an almost pure form, crystallises from an aqueous solution in dense, volatile, lustrous prisms (up to 1 in. long), melting at 50° , and deliquescing in the air; from a solution in boiling alcohol it separates out in bright crystalline plates. This salt, N_5H_5 , has the same empirical composition, N_4H_4 , as imide, but its molecular weight and structure are different. Curtius also obtained (1893) hydrazoic acid by passing the vapour of N_2O_3 (evolved by the action of HNO_3 on As_2O_3) into a solution of hydrazine, N_2H_4 . Similarly Angeli, by acting upon a saturated solution of silver nitrite with a strong solution of hydrazine, obtained the explosive, AgN_3 , in the form of a precipitate, and this reaction, which is based upon the equation: $\text{N}_2\text{H}_4 + \text{NHO}_2 = \text{HN}_3 + 2\text{H}_2\text{O}$, proceeds so easily that it forms an experiment for the lecture table. The amide of potassium, NH_2K (obtained by the action of dry NH_3 on heated potassium), gives the potassium salt when acted upon by nitrous oxide, $\text{NH}_2\text{K} + \text{N}_2\text{O} = \text{N}_3\text{K} + \text{H}_2\text{O}$. This is the most convenient method for obtaining the potassium salt of hydrazoic acid, and therefore the acid itself. A thermal investigation of hydrazoic acid by Berthelot and Matignon gave for the heat of solution of the ammonium salt, $\text{N}_3\text{H}_4\text{N}_3$ (1 gram. in 100 parts of water) the value -708 cals. and for the heat of neutralisation by barium hydrate $+10.0$ cals. and by ammonia $+8.2$ cals. The heat of combustion of N_4H_4 ($+163.8$ cals. at a constant vol.) gives the heat of formation of the salt N_4H_4 (solid) as -25.3 cals. and (solution) -32.3 cals.; this explains the explosive nature of this compound. In its heat of forma-

NH_3 , contains one N atom and three H atoms ; in HN_3 , on the contrary, there are three N atoms and one H atom), the ready decomposition of its salts with explosion, and above all its distinctly acid character (an aqueous solution shows a strong acid reaction to litmus), not only indicated the importance of this unexpected discovery, but at first gave rise to some perplexity as to the nature of the substance obtained, for the relations in which HN_3 stood to other simple compounds of nitrogen which had long been known was not at all evident, and the scientific spirit requires that there should be a distinct bond between every innovation, every fresh discovery, and that which is already firmly established and known ; for upon this basis is founded that apparently paradoxical union in science of a conservative stability with an irresistible and never-ceasing improvement. This missing connection between the newly discovered hydrazoic acid, HN_3 , and the long known ammonia, NH_3 , and nitric acid, HNO_3 , may be found in the law of substitution, starting from the well-known properties and composition of nitric acid and ammonia, as I mentioned in the 'Journal of the Russian Physico-Chemical Society' (1890). The essence of the matter lies in the fact that to the hydrate of ammonium, or caustic ammonia, NH_4OH , there should correspond, according to the law of substitution, an ortho-nitric acid, $\text{H}_3\text{NO}_4 = \text{NO}(\text{OH})_3$, which equals $\text{NH}_4(\text{OH})$ with the substitution in it of (a) two atoms of hydrogen by oxygen ($\text{O}-\text{H}_2$) and (b) two atoms of hydrogen by the aqueous radicle ($\text{H}-\text{OH}$). The analogue of nitric acid, phosphoric acid, gives corresponding ortho- and meta-acids, PH_3O_4 and PHO_3 , with great ease, as we shall afterwards see (Chap. XIX.). The existence of an ortho-nitric acid, NH_3O_4 , is to be expected also from other analogies (Chapter XV.). Ordinary or meta-nitric acid is merely this ortho-nitric acid minus water. To ortho-nitric acid there should correspond the ammoniacal salts : mono-substituted, $\text{H}_2\text{NH}_4\text{NO}_4$; bi-substituted, $\text{H}(\text{NH}_4)_2\text{NO}_4$; and tri-substituted, $(\text{NH}_4)_3\text{NO}_4$. These salts, containing as they do hydrogen and oxygen, like many similar ammoniacal salts (see, for instance, Chapter IX.—Cyanides), are able to part with them in the form of water. Then from the first salt we have : $\text{H}_2\text{NH}_4\text{NO}_4 - 4\text{H}_2\text{O} = \text{N}_2\text{O}$ —nitrous oxide, and from the second, $\text{H}(\text{NH}_4)_2\text{NO}_4 - 4\text{H}_2\text{O} = \text{HN}_3$ —hydronitrous acid, and from the third, $(\text{NH}_4)_3\text{NO}_4 - 4\text{H}_2\text{O} = \text{N}_4\text{H}_4$ —the ammonium salt of the same acid. The composition of HN_3 should be thus understood, whilst its acid properties are explained by the fact that the water ($4\text{H}_2\text{O}$) from

tion from its elements, $\text{N}_3\text{H} = -62.6$ cals., this compound differs from all the hydrogen compounds of nitrogen in having a maximum absorption of heat, which explains its instability.

$\text{H}(\text{NH}_4)_2\text{NO}_4$ is formed at the expense of the hydrogen of the ammonium and the oxygen of the nitric acid, so that there remains the hydrogen of nitric acid, which may be replaced by metals and so give salts. Moreover, nitrogen undoubtedly belongs to the category of metalloids which give acids, like S, Cl, C, P, and therefore, under the influence of three of its atoms, one atom of hydrogen acquires those properties which it has in acids, just as in HCN (hydrocyanic acid) the hydrogen has received these properties under the influence of the carbon and nitrogen (and HN_3 may be regarded as HCN, where C has been replaced by N_2). Moreover, besides explaining the composition and acid properties of HN_3 , the above method gives the possibility of foretelling the closeness of the bond between hydrazoic acid and nitrous oxide, for $\text{N}_2\text{O} + \text{NH}_3 = \text{HN}_3 + \text{H}_2\text{O}$. This reaction, which was foreseen from the above considerations, was accomplished by Wislicenus (1892), who synthesised the sodium salt by taking the amide of sodium, NH_2Na (obtained by heating Na in a current of NH_3), and acting upon it (when heated) with nitrous oxide, N_2O , the reaction being: $2\text{NH}_2\text{Na} + \text{N}_2\text{O} = \text{NaN}_3 + \text{NaHO} + \text{NH}_3$. The resultant salt, NaN_3 , gives hydrazoic acid when acted upon by sulphuric acid, $\text{NaN}_3 + \text{H}_2\text{SO}_4 = \text{NaHSO}_4 + \text{HN}_3$. The latter gives, with the corresponding solutions of their salts, the insoluble (and readily explosive) salts of silver, AgN_3 (insoluble, like AgCl or AgCN), and lead, $\text{Pb}(\text{N}_3)_2$.

Thus the law of substitution in the above form renders it possible to connect the various compounds of nitrogen with hydrogen and oxygen by a more intimate bond.

The compounds of nitrogen with oxygen also present an excellent example of the law of multiple proportions, because they contain, for every 14 parts by weight of nitrogen, 8, 16, 24, 32, and 40 parts by weight respectively of oxygen. The compositions of these compounds are as follows:—

N_2O , nitrous oxide; hydrate NHO .

N_2O_2 , nitric oxide, NO .

N_2O_3 , nitrous anhydride; hydrate NHO_2 .

N_2O_4 , peroxide of nitrogen, NO_2 .

N_2O_5 , nitric anhydride; hydrate NHO_3 .

Of these compounds,²⁸ nitrous and nitric oxides, peroxide of nitrogen, and nitric acid, NHO_3 are characterised as being the most stable. *The lower oxides, when coming into contact with the higher, may give the intermediate forms, for instance, NO and NO_2 form N_2O_3 ; and the*

²⁸ According to the thermochemical determinations of Favre, Thomsen, and more especially of Berthelot, it follows that, in the formation of quantities of the oxides of nitrogen expressed by their formulæ, if gaseous nitrogen and oxygen be taken as

intermediate oxides may, in splitting up, give a higher and lower oxide, e.g., N_2O_4 gives N_2O_3 and N_2O , or, in the presence of water, their hydrates.

We have already seen that, under certain conditions, nitrogen combines with oxygen, and we know also that ammonia may be oxidised. In these cases various oxidation products of nitrogen are formed, but in the presence of water and an excess of oxygen they always give nitric acid. Nitric acid, as corresponding with the highest oxide, is able, on deoxidation, to give the lower oxides; it is the only nitrogen acid whose salts occur somewhat widely distributed in nature, and it has many technical uses, for which reason we shall begin with it.

Nitric acid, NHO_3 , is likewise known as aqua fortis. In a free state it is only met with in small quantities in nature, in the air and in rain-water after storms; but even in the atmosphere nitric acid does not long remain free, but combines with ammonia, traces of which are always found in air. On falling on the soil and into running water, &c., the nitric acid comes everywhere into contact with bases (or their salts), which readily act on it, so that it is converted into the nitrates of these bases. Hence nitric acid is always met with in nature in the form of salts. The soluble salts of nitric acid are called **nitres**. This name is derived from the Latin *sal nitri*. The potassium salt, KNO_3 , is common or prismatic nitre, and the sodium salt, $NaNO_3$, Chili salt-petre, or cubic nitre. Nitres are formed in the soil when a nitrogenous substance is slowly oxidised, in the presence of an alkali, by means of the oxygen of the atmosphere. In nature there are very frequent

the starting-points, and if the compounds formed be also gaseous, the following amounts of heat, expressed in thousands of heat units, are *absorbed* (hence a minus sign):—

N_2O	N_2O_2	N_2O_3	N_2O_4	N_2O_5
−21	−43	−22	−5	−1
−22	+21	+17	+4	

The differences are given in the lower line. For example, if N_2 , or 28 grams of nitrogen, combine with O—that is, with 16 grams of oxygen—21,000 units of heat will be absorbed, that is, sufficient heat to raise 21,000 grams of water through 1° . Naturally, direct observations are impossible in this case; but if charcoal, phosphorus, or similar substances are burned both in nitrous oxide and in oxygen, and the heat evolved observed in both cases, then the difference (more heat will be evolved in burning in nitrous oxide) gives the figures required. If N_2O_2 , by combining with O_2 , gives N_2O_4 , then, as is seen from the table, heat should be *developed* to the extent of 38,000 units, i.e., $NO + O = 19,000$ units of heat. The differences given in the table show that the maximum absorption of heat corresponds with nitric oxide, from which the higher oxides are formed with evolution of heat. If liquid nitric acid, NHO_3 , is to be decomposed into $N + O_3 + H$, 41,000 heat units will be required; that is, an evolution of heat takes place in its formation from the gases. It should be observed that the formation of ammonia, NH_3 , from the gases $N + H_3$ evolves 12·2 thousand heat units, so that free nitrogen has a greater tendency to combine with hydrogen than with oxygen.

instances of such oxidation. For this reason certain soils and rubbish heaps—for instance, lime rubbish (in the presence of a base—lime)—contain a more or less considerable amount of nitre. One of these nitres—sodium nitrate—is extracted from the earth in large quantities in Chili, where it was probably formed by the oxidation of animal refuse. This kind of nitre is employed in practice for the manufacture of nitric acid and the other oxygen compounds of nitrogen. Nitric acid is obtained from **Chili saltpetre** *by heating* it with **sulphuric acid**. The hydrogen of the sulphuric acid replaces the sodium in the nitre. The sulphuric acid then forms either an acid salt, NaHSO_4 , or a normal salt, Na_2SO_4 , whilst nitric acid is formed from the nitre and volatilised. The decomposition is expressed by the equation: (1) $\text{NaNO}_3 + \text{H}_2\text{SO}_4 = \text{HNO}_3 + \text{NaHSO}_4$, if the acid salt is formed, or by (2) $2\text{NaNO}_3 + \text{H}_2\text{SO}_4 = \text{Na}_2\text{SO}_4 + 2\text{HNO}_3$, if the normal sodium sulphate is formed. With an excess of sulphuric acid, at a moderate heat (up to 200°), and at the commencement of the reaction, the decomposition proceeds according to the first equation; and on further heating (to 230°) with a sufficient amount of nitre, according to the second, because the acid salt NaHSO_4 itself acts like an acid (its hydrogen being replaceable as in acids), according to the equation: $\text{NaNO}_3 + \text{NaHSO}_4 = \text{Na}_2\text{SO}_4 + \text{HNO}_3$.

The sulphuric acid, as it is said, here displaces the nitric acid from its compound with the base.²⁹ Thus, in the reaction of sulphuric acid on nitre there is formed a non-volatile salt of sulphuric acid, which remains together with an excess of this acid in the distilling apparatus,

²⁹ This often gives rise to the supposition that sulphuric acid possesses a considerable degree of affinity or energy compared with that of nitric acid, but we shall afterwards see that the conception of the relative degree of affinity of acids and bases is, in many cases, exceedingly inaccurate and need not be accepted so long as it is possible to explain the observed phenomena without admitting any supposition whatsoever of the degree of the force of affinity, because the latter cannot be measured. The action of sulphuric acid upon nitre may be explained by the simple fact that the resultant nitric acid is volatile. The nitric acid is the only one of all the substances partaking in the reaction which is able to pass into vapour, the others being non-volatile, or, more strictly speaking, exceedingly difficultly volatile substances. Let us imagine that the sulphuric acid is only able to set free a small quantity of nitric acid from its salt, and this will suffice to explain the decomposition of the whole of the nitre by the sulphuric acid, because when the nitric acid is separated it is formed into vapour on heating, and passes away from the sphere of action of the remaining substances; then the free sulphuric acid will liberate a further small quantity of nitric acid, and so on until it drives off the entire quantity. It is evident from this explanation that it is essential that the sulphuric acid should be in excess (although not greatly) throughout the reaction; according to the equation expressing the reaction, 98 parts of sulphuric acid are required per 85 parts of Chili saltpetre; but if this proportion be maintained in practice the nitric acid will not all be disengaged by the sulphuric acid; an excess of the latter must be taken, and as a rule 80 parts of Chili saltpetre are taken per 98 parts of acid, so that a portion of the latter remains free to the very end of the reaction.

and nitric acid, which is converted into vapour, and may be condensed, because it is a liquid and volatile substance. On a small scale, this reaction may be carried on in a glass retort with a glass condenser. On a large scale, in chemical works, the process is exactly similar, but

FIG. 55.—Method of preparing nitric acid on a large scale. A cast-iron retort, C, is fixed in the furnace, and heated by the fire, B. The flame and products of combustion are at first led along the flue, M (in order to heat the receivers), and afterwards into L. The retort is charged with Chili saltpetre and sulphuric acid, and the cover luted on with clay and gypsum. A clay tube *a*, is fixed into the neck of the retort (in order to prevent the nitric acid from corroding the cast iron), and a bent glass tube, D, luted on to it. This tube carries the vapours into a series of earthenware receivers, E. Nitric acid mixed with sulphuric acid collects in the first. The purest nitric acid is procured from the second, whilst that which condenses in the third receiver contains hydrochloric acid, and that in the fourth nitrous oxide. Water is poured into the last receiver in order to condense the residual vapours.

iron retorts are employed for holding the mixture of nitre and sulphuric acid, and earthenware three-necked bottles are used instead of a condenser,³⁰ as shown in fig. 55.

³⁰ It must be observed that sulphuric acid, at least when undiluted (60° Baumé), corrodes cast iron with difficulty, so that it may be heated in cast-iron retorts. Nevertheless, both sulphuric and nitric acids have a certain action on cast iron, so that the acid obtained will contain traces of iron. In practice sodium nitrate (Chili saltpetre) is usually employed, as it is cheaper, but in the laboratory it is best to take potassium nitrate, because it is purer and does not froth up so much as sodium nitrate when heated with sulphuric acid. In the action of an excess of sulphuric acid on nitre and nitric acid a portion of the latter is decomposed, forming lower oxides of nitrogen, which are dissolved in the nitric acid. A portion of the sulphuric acid itself is also carried over as spray by the vapours of the nitric acid. Hence sulphuric acid occurs as an impurity in commercial nitric acid. A certain amount of hydrochloric acid will also be found to be present in it, because sodium chloride is generally found as an impurity in nitre, and under the action of sulphuric acid it forms hydrochloric acid. Commercial acid further contains a considerable excess of water above that necessary for the formation of the hydrate, because water is first poured into the earthenware vessels employed for condensing the nitric acid in order to facilitate its cooling and condensation. Further, the

The nitric acid obtained generally contains water. It is extremely difficult to deprive it of all the admixed water without destroying a portion of the acid itself and partially converting it into lower oxides, because in the absence of excess of water it is very unstable. When rapidly distilled a portion is decomposed, giving free oxygen and lower oxides of nitrogen, which, together with the water, remain in solution with the nitric acid. It is therefore necessary to work with great care in order to obtain a pure hydrate of nitric acid, HNO_3 , and to mix the nitric acid obtained from nitre, as above described, with sulphuric acid, which takes up the water, and to distil it at the lowest possible temperature—that is, by lowering the pressure and by placing the retort holding the mixture in a water or oil bath and carefully heating it. The first portion of the nitric acid thus distilled boils at 86° , has a specific gravity at 15° of 1.526, and solidifies at -50° ; it is very unstable at higher temperatures. This is the normal hydrate, HNO_3 , which corresponds with the salts, NMO_3 , of nitric acid. When diluted with water, nitric acid presents a higher boiling-point, not only as compared with that of the nitric acid itself, but also with that of water; so that if very dilute nitric acid be distilled, the first portions passing over will consist of almost pure water, until the boiling-point in the vapours reaches 121° . At this temperature a compound of nitric acid with water, containing about 70 per cent. of nitric acid,³¹ distils over; its specific gravity at 15° is 1.421. If the

acid of composition HNO_3 decomposes with great ease, with the evolution of oxides of nitrogen. Thus the commercial acid contains a large number of impurities, and is frequently purified in the following manner:—Lead nitrate is first added to the acid as it forms non-volatile and almost insoluble (precipitated) substances with the free sulphuric and hydrochloric acids, according to the equations: $\text{Pb}(\text{NO}_3)_2 + 2\text{HCl} = \text{PbCl}_2 + 2\text{HNO}_3$ and $\text{Pb}(\text{NO}_3)_2 + \text{H}_2\text{SO}_4 = \text{PbSO}_4 + 2\text{HNO}_3$. Potassium chromate is then added to the impure nitric acid, by which means oxygen is liberated from the chromic acid, and this oxygen, at the moment of its evolution, oxidises the lower oxides of nitrogen and converts them into nitric acid. A pure nitric acid, containing no impurities other than water, may then be obtained by carefully distilling (under a low pressure) the acid, treated as above described, and particularly if only the middle portions of the distillate are collected. Such acid should give no precipitate, either with a solution of barium chloride (a precipitate shows the presence of sulphuric acid) or with a solution of silver nitrate (a precipitate shows the presence of hydrochloric acid), nor should it, after being diluted with water, give a coloration with starch containing potassium iodide (a coloration shows the admixture of other oxides of nitrogen). The oxides of nitrogen may be most easily removed from impure nitric acid by heating it for some time with a small quantity of pure charcoal. By the action of nitric acid on the charcoal carbonic anhydride is evolved, and this carries off the lower oxides of nitrogen. On re-distilling, pure acid is obtained. The oxides of nitrogen occurring in solution may also be removed by passing air through the nitric acid.

³¹ Dalton, Smith, Bineau, and others considered that the hydrate of nitric acid of constant boiling-point (see Chap. I., note 60) was the compound $2\text{HNO}_3, 3\text{H}_2\text{O}$, but Roscoe showed that its composition changes with a variation of the pressure and temperature under which the distillation proceeds. Thus, at a pressure of 1 atmosphere the solution

solution contain less than 25 per cent. of water, then, the specific gravity of the solution being above 1.44, HNO_3 evaporates off and fumes in the air, forming the above hydrate, whose vapour pressure is less than that of water. Such solutions form *fuming nitric acid*. On distillation this gives monohydrated acid,³² HNO_3 , which is a hydrate boiling at 121° , so that it is obtained from both weak and strong solutions. Fuming nitric acid, under the action not only of organic substances, but even of heat, loses a portion of its oxygen, forming lower oxides of nitrogen, which impart a *reddish-brown colour* to it; ³³ the pure acid is colourless.

of constant boiling-point contains 68.6 per cent., and at one-tenth of an atmosphere 66.8 per cent. of the acid. Judging from what has been said concerning solutions of hydrochloric acid, and from the variation of specific gravity, I think that the comparatively large decrease in the pressure of the vapours depends on the formation of a hydrate, $\text{NHO}_3, 2\text{H}_2\text{O}$ (=53.6 per cent.) Such a hydrate may be expressed by $\text{N}(\text{HO})_5$, that is, as $\text{NH}_4(\text{HO})$, in which all the equivalents of hydrogen are replaced by hydroxyl. The constant boiling-point will then be the temperature of decomposition of this hydrate.

The variation of the specific gravity at 15° from water ($p=0$) to the hydrate $\text{NHO}_3, 5\text{H}_2\text{O}$ (41.2 per cent. HNO_3) is expressed by $s = 9992 + 57.4p + 0.16p^2$, if water = 10,000 at 4° . For example, when $p=30$ per cent., $s=11,860$. For more concentrated solutions, the presence must be assumed of at least the above-mentioned hydrate, $\text{HNO}_3, 2\text{H}_2\text{O}$, of which the specific gravity $s = 9570 + 84.18p - 0.240p^2$; but perhaps (the results of observations of the specific gravity of the solutions not being in sufficient agreement to warrant a conclusion) the hydrate $\text{HNO}_3, 3\text{H}_2\text{O}$ should be recognised, as is indicated by many nitrates (Al, Mg, Co, &c.), which crystallise with this amount of water of crystallisation. From $\text{HNO}_3, 2\text{H}_2\text{O}$ to HNO_3 the specific gravity of the solutions (at 15°) is given by: $s = 10,652 + 62.08p - 0.160p^2$. The hydrate $\text{HNO}_3, 2\text{H}_2\text{O}$ is recognised by Berthelot on the basis of the thermo-chemical data for solutions of nitric acid, because on approaching to this composition there is a rapid change in the amount of heat evolved by mixing nitric acid with water. Pickering (1892) by refrigeration obtained the crystalline hydrates: $\text{HNO}_3, \text{H}_2\text{O}$, melting at -37° and $\text{HNO}_3, 3\text{H}_2\text{O}$, melting at -18° . A more detailed study of the reactions of hydrated nitric acid would no doubt show, on approaching these hydrates, the existence of change in the process and rapidity of reaction.

³² The normal hydrate HNO_3 , corresponding with the ordinary salts, may be termed the monohydrated acid, because the anhydride N_2O_5 forms with water this normal nitric acid. In this sense the hydrate $\text{HNO}_3, 2\text{H}_2\text{O}$ is the pentahydrated acid: $\text{N}_2\text{O}_5 + 5\text{H}_2\text{O}$.

³³ For technical and laboratory purposes recourse is frequently had to *red fuming nitric acid*—that is, the normal nitric acid, HNO_3 , or strong solutions of it (containing less than $1\frac{1}{2}\text{H}_2\text{O}$), containing lower oxides of nitrogen, NO_2 and N_2O_3 , in solution. This acid is prepared by decomposing nitre with half its weight of strong sulphuric acid, or by distilling nitric acid with an excess of sulphuric acid. The normal nitric acid is first obtained, but partially decomposes, and gives the lower oxidation products of nitrogen, which are dissolved by the nitric acid, to which they impart its usual brown or reddish colour. This acid fumes in the air, from which it attracts moisture, forming a less volatile hydrate. If carbonic anhydride be passed through the reddish-brown fuming nitric acid for a long period of time, especially if assisted by a moderate heat, it expels all the lower oxides, and leaves a colourless acid free from these oxides. It is necessary, in the preparation of the red acid, that the receivers should be kept quite cool, because it is only when cold that nitric acid is able to dissolve a large proportion of the oxides of nitrogen. The strong red fuming acid has a specific gravity 1.56 at 20° , and

Nitric acid, as an **acid hydrate**, enters into reactions of double decomposition with bases, basic hydrates (alkalies), and salts. In these cases salts of nitric acid are obtained. An alkali and nitric acid give water and a salt; for instance, with lime, $\text{CaO} + 2\text{HNO}_3 = \text{Ca}(\text{NO}_3)_2 + \text{H}_2\text{O}$.³⁴ The composition of the ordinary salts of nitric acid may be expressed by the general formula $\text{M}(\text{NO}_3)_n$, where M indicates a metal replacing the hydrogen in one or several (n) molecules of nitric acid. We shall find afterwards that the atoms M of metals are equivalent to one (K, Na, Ag) atom of hydrogen, or two (Ca, Mg, Ba), or three (Al, In), or, in general, n atoms of hydrogen. **The salts of nitric acid** are especially characterised by being all **soluble in water**.³⁵ Owing to the property common to all these salts of entering into double decompositions and also to the volatility of nitric acid, they evolve nitric acid when heated with sulphuric acid. They are all, like the acid itself, capable of evolving oxygen when heated, and consequently of acting as oxidising substances; thus, for instance, they deflagrate with ignited carbon, which burns at the expense of the oxygen of the salt, and forms gaseous products of combustion.³⁶

has a suffocating smell of the oxides of nitrogen. When the red acid is mixed with water it turns green, and then bluish, and with an excess of water ultimately becomes colourless. This is owing to the fact that the oxides of nitrogen in the presence of water and nitric acid undergo change, and give coloured solutions.

Marchlewsky (1892) showed that the green solutions contain (besides HNO_3) HNO_2 and N_2O_4 , whilst the blue solutions contain only HNO_2 (see note 48).

The action of red fuming nitric acid (or a mixture of it with sulphuric acid) is in many cases very powerful and rapid, and sometimes quite different from that of pure nitric acid. Thus iron becomes covered with a coating of oxides, and is insoluble in acids; it becomes, as it is said, passive. Also chromic acid (and potassium dichromate) gives oxide of chromium with this red acid, which is thus deoxidised. This is owing to the presence of the lower oxides of nitrogen, which are capable of being oxidised—that is, of passing into nitric acid like the higher oxides. But, generally, the action of fuming nitric acid, both red and colourless, is powerfully oxidising.

³⁴ Hydrogen is not evolved in the action of nitric acid (especially strong) on metals, even with those metals which evolve hydrogen under the action of other acids. This is because at the moment of its separation the hydrogen reduces the nitric acid, with formation of the lower oxides of nitrogen, as we shall see later.

³⁵ Certain basic salts of nitric acid, however (for example, the basic salt of bismuth), are insoluble in water, but, on the other hand, all the normal salts are soluble; this is an exceptional phenomenon among acids, all the ordinary acids forming insoluble salts with one or another base. Thus, of sulphuric acid the salts of barium, lead, &c., of hydrochloric acid the salts of silver, &c., are insoluble in water. However, the normal salts of acetic and certain other acids are all soluble.

³⁶ **Ammonium nitrate**, NH_4NO_3 , is easily obtained by adding a solution of ammonia or of ammonium carbonate to nitric acid until it becomes neutral. On evaporating this solution, crystals of the salt are formed which contain no water of crystallisation. It crystallises in prisms like those formed by common nitre, and has a refreshing taste; 100 parts of water at t° dissolve $54 + 0.61 t$ parts by weight of the salt. It is soluble in alcohol, melts at 160° , and is decomposed at about 180° , forming water and nitrous oxide, $\text{NH}_4\text{NO}_3 = 2\text{H}_2\text{O} + \text{N}_2\text{O}$. If ammonium nitrate is mixed with sulphuric acid, and the

Nitric acid also enters into double decompositions with a number of hydrocarbons, which possess no alkaline characters and do not react with other acids. Under these circumstances the nitric acid gives water and a new substance termed a **nitro-compound**. The chemical character of the nitro-compound is the same as that of the original substance; for example, if an indifferent substance be taken, the nitro-compound obtained from it will also be indifferent; whilst if an acid be taken, an acid will be obtained.^{36a} Benzene, C_6H_6 , for instance, acts according to the equation: $C_6H_6 + HNO_3 = H_2O + C_6H_5NO_2$, nitrobenzene being produced. The substance taken, C_6H_6 , is a liquid hydrocarbon which has a faint tarry smell, boils at 80° , and is lighter than water; the action of nitric acid yields nitrobenzene, which is a substance boiling at about 210° , heavier than water, and having an almond-like odour: it is employed in large quantities for the preparation of aniline and aniline dyes.³⁷ As the

mixture heated to about the boiling-point of water, nitric acid is evolved, and ammonium hydrogen sulphate remains in solution; but if the mixture be heated rapidly to 160° , nitrous oxide will be evolved. In the first case the sulphuric acid takes up ammonia, and in the second place water. Ammonium nitrate is employed in practice for the artificial production of cold, because in dissolving in water it lowers the temperature very considerably. For this purpose it is best to take equal parts by weight of the salt and water. The salt must first be reduced to a powder and then rapidly stirred up in the water, when the temperature will fall from $+15^\circ$ to -10° , so that the water freezes.

Ammonium nitrate absorbs ammonia, with which it forms unstable compounds resembling compounds containing water of crystallisation [Divers (1872), Raoult (1873)]. At -10° , $NH_4NO_3 \cdot 2NH_3$ is formed; it is a liquid of sp. gr. 1.15, which loses all its ammonia under the influence of heat. At $+28^\circ$, $NH_4NO_3 \cdot NH_3$ is formed as a solid which easily parts with its ammonia when heated, especially in solution.

Troost (1882) investigated the dissociation pressures of the compounds formed, and came to the conclusion that a definite compound corresponding to the formula $2NH_4NO_3 \cdot 3NH_3$ is formed, because the pressure of dissociation remains constant in the decomposition of such a compound at 0° . V. Kouriloff (1893), however, considers that the constancy of the pressure of the ammonia evolved is due to the decomposition of a saturated solution, and not of a definite compound. During decomposition the system is composed of a liquid and a solid, and the pressure only becomes constant from the moment the solid begins to precipitate. The composition $2NH_4NO_3 \cdot 3NH_3$ corresponds with a saturated solution at 0° , and the solubility of NH_4NO_3 in NH_3 increases with a rise of temperature.

^{36a} This is explained by saying that in true nitro-compounds the residue of nitric acid NO_2 takes the place of the hydrogen in the hydrocarbon group. For example, if C_6H_5OH be given, then $C_6H_4(NO_2)OH$ will be a true nitro-compound having the radical properties of C_6H_5OH . If, on the other hand, the NO_2 replace the hydrogen of the aqueous radicle ($C_6H_5ONO_2$), the chemical character is changed, as in the passage of KOH into $KONO_2$ (nitre) (see note 37 and Organic Chemistry).

³⁷ The compound ethers of nitric acid in which the hydrogen of the aqueous radicle (OH) is replaced by the residue of nitric acid (NO_2) are frequently called nitro-compounds. But in their chemical character they differ from true nitro-compounds (for details see Organic Chemistry) and do not burn like them. The action of nitric acid on cellulose, $C_6H_{10}O_5$, is an example. This substance, which forms the outer coating of all plant cells, occurs in an almost pure state in cotton, in common writing

nitro-compounds contain both combustible elements (hydrogen and carbon), as well as oxygen in unstable combination with nitrogen, in the form of the radicle NO_2 of nitric acid, they decompose, when ignited or even when struck, with an explosion, owing to the pressure of the vapours and gases formed—free nitrogen, carbonic anhydride, CO_2 , carbonic oxide CO , and aqueous vapour. In the explosion of nitro-compounds ^{37a}

paper, and in flax, &c.; under the action of nitric acid it yields water and nitrocellulose (like water and KNO_3 from KHO), which, although it has the same appearance as the cotton originally taken, differs from it entirely in properties. It explodes when struck, bursts into flame very easily under the action of sparks, and acts like gunpowder, whence its name of pyroxylin, or gun-cotton. The composition of gun-cotton is $\text{C}_6\text{H}_7\text{N}_3\text{O}_{11} = \text{C}_6\text{H}_{10}\text{O}_5 + 3\text{NHO}_3 - 3\text{H}_2\text{O}$. The proportion of the group NO_2 in nitrocellulose may be decreased by limiting the action of the nitric acid, compounds being then obtained with different properties; for instance the (impure) well-known *collodion cotton*, containing from 11 to 12 per cent. of nitrogen, and *pyro-collodion* (Mendeléeff, 1890), containing from 12.5 to 12.4 per cent. of nitrogen. Both these products are soluble in a mixture of alcohol and ether (in collodion a portion of the substance is soluble in alcohol), and the solution when evaporated gives a transparent film, which is insoluble in water. A solution of collodion is employed in medicine for covering wounds, and in wet-plate photography for giving on glass an even coating of a substance into which the various reagents employed in the process are introduced. The composition of pyro-collodion, $\text{C}_{30}\text{H}_{38}(\text{NO}_2)_{12}\text{O}_{25}$ (i.e. a product of the substitution of 12 atoms of hydrogen by the residue of nitric acid NO_2 in $5\text{C}_6\text{H}_{10}\text{O}_5$), is such that when exploded the whole of its hydrogen is capable of forming water and all its carbon, carbon monoxide, CO , occupying a larger volume than would be occupied by the CO_2 formed from the same amount of oxygen (because $\text{CO}_2 = 2$ vols. and $\text{CO} = 2$ vols., and consequently $2\text{CO} = 4$ vols.). Therefore the normal (in the absence of subsidiary reactions) decomposition of pyro-collodion is expressed by the equation: $\text{C}_{30}\text{H}_{38}(\text{NO}_2)_{12}\text{O}_{25} = 30\text{CO} + 19\text{H}_2\text{O} + 6\text{N}_2$. As the form of nitrocellulose which evolves the greatest quantity (by volume) of vapours and gases (from a given weight of nitrocellulose), pyro-collodion presents one of the most convenient smokeless powders for artillery, all the more so because experiments made at the Russian Admiralty Research Laboratory (see the Admiralty Magazine for 1895) show that properly prepared ribbons of this powder burn when exploded in successive layers (which is required in firing guns to prevent them from bursting), and that it may be kept for an indefinite period if well washed in water, notwithstanding that it contains 58 per cent. of oxygen.

^{37a} The property possessed by nitroglycerin (occurring in dynamite), nitrocellulose, and the other nitro-compounds, of burning with an explosion, and their employment for smokeless powder and as explosives in general, is explained in the same way as the deflagration and explosion of a mixture of nitre and charcoal; in both cases the elements of the nitric acid occurring in the compound are decomposed, the oxygen in burning uniting with the carbon, and the nitrogen being set free; thus a very large volume of gaseous substances (nitrogen and oxides of carbon) is rapidly formed from the solid substances originally taken. These gases occupy an incomparably larger volume than the original substance, and therefore produce a powerful pressure and explosion. It is evident from their power of exploding with the development of heat (that is, in decomposing, not with the absorption of energy, as is generally the case, but with the evolution of energy), that the nitro-compounds form stores of energy which are readily set free, and that consequently their elements occur in a state of particularly energetic motion, which is especially strong in the group NO_2 ; this group is common to all nitro-compounds, and all the oxygen compounds of nitrogen are unstable, easily decomposable, and (note 28) absorb heat in their formation. On the other hand, the nitro-compounds are instructive as an example and proof of the fact that the elements and groups forming compounds are united in definite order in the molecules of a compound. A blow, con-

much heat is evolved, as in the combustion of gunpowder or detonating gas, and the force of explosion in a closed space is great, because from a solid or liquid nitro-compound occupying a small space there are

FIG. 56.—The method of decomposition of nitrous anhydride, also applicable to the other oxides of nitrogen, and to their analysis. NO_2 is generated from nitrate of lead in the retort A. Nitric acid and other less volatile products are condensed in B. The tube CC contains copper, and is heated from below. Undecomposed volatile products (if any are formed) are condensed in D, which is cooled. If the decomposition is incomplete, brown fumes make their appearance in this receiver. The gaseous nitrogen is collected in the cylinder E.

formed only vapours and gases, the pressure of which is great, not merely on account of the small space in which they are formed, but

cussion, or rise of temperature is necessary to bring the combustible elements C and H into the most intimate contact with NO_2 , and to distribute the elements in a new order in new compounds.

As regards the composition of the nitro-compounds, it will be seen that the hydrogen of a given substance is replaced by the complex group NO_2 of the nitric acid. The same is observed in the passage of alkalis into nitrates, so that the reactions of substitution of nitric acid—that is, the formation of salts and nitro-compounds—may be expressed in the following manner. In these cases the hydrogen is replaced by the so-called **radicle of nitric acid** NO_2 , as is evident from the following table:—

{ Caustic potash	KHO .	{ Glycerin	$\text{C}_3\text{H}_5\text{H}_3\text{O}_3$.
{ Nitre	$\text{K}(\text{NO}_2)\text{O}$.	{ Nitroglycerin	$\text{C}_3\text{H}_5(\text{NO}_2)_3\text{O}_3$.
{ Hydrate of lime	CaH_2O_2 .	{ Phenol	$\text{C}_6\text{H}_5\text{OH}$.
{ Calcium nitrate	$\text{Ca}(\text{NO}_2)_2\text{O}_2$.	{ Picric acid	$\text{C}_6\text{H}_2(\text{NO}_2)_3\text{OH}$, &c.

The difference between the salts formed by nitric acid and the nitro-compounds consists in the fact that nitric acid is very easily separated from the salts of nitric acid by means of sulphuric acid (that is, by a method of double saline decomposition), whilst nitric acid is not displaced by sulphuric acid from true nitro-compounds; for instance, nitrobenzene, $\text{C}_6\text{H}_5\text{NO}_2$. As nitro-compounds are formed exclusively from hydrocarbons, they are described with them in organic chemistry.

The group NO_2 of nitro-compounds in many cases (like all the oxidised compounds of nitrogen) passes into the ammonia group or the ammonia radicle NH_2 . This requires the action of reducing substances evolving hydrogen: $\text{RNO}_2 + 6\text{H} = \text{RNH}_2 + 2\text{H}_2\text{O}$. Thus Zinin converted nitrobenzene, $\text{C}_6\text{H}_5\text{NO}_2$, into aniline, $\text{C}_6\text{H}_5\text{NH}_2$, by the action of hydrogen sulphide.

Admitting the existence of the group NO_2 , as replacing hydrogen in various compounds, nitric acid may be considered as water in which half the hydrogen is replaced by the radicle of nitric acid. In this sense nitric acid is nitro-water, $(\text{NO}_2)\text{OH}$, and its anhydride dinitro-water, $(\text{NO}_2)_2\text{O}$. In nitric acid the radicle of nitric acid is

owing also to the high temperature corresponding to the decomposition (explosive combustion) of the nitro-compound.³⁸

If the vapour of nitric acid is passed through an even moderately heated glass tube, the formation of dark-brown fumes of the lower oxides of nitrogen and the separation of free oxygen may be observed, $2\text{NHO}_3 = \text{H}_2\text{O} + 2\text{NO}_2 + \text{O}$. Even light produces a similar decomposition, but not a complete one. The decomposition is complete at a white heat, when nitrogen is formed: $2\text{NHO}_3 = \text{H}_2\text{O} + \text{N}_2 + \text{O}_5$. Hence it is easily understood that nitric acid may part with its oxygen to a number of substances capable of being oxidised.³⁹ It is consequently

combined with hydroxyl, just as in nitrobenzene it is combined with the radicle of benzene.

It should here be remarked that the group NO_3 may be recognised in the salts of nitric acid, because the salts have the composition $\text{M}(\text{NO}_3)_n$, just as the metallic chlorides have the composition MCl_n . But the group NO_3 does not form any other compounds beyond the salts, and therefore it should be considered as hydroxyl, HO , in which H is replaced by NO_2 .

³⁸ The nitro-compounds play a very important part in mining and artillery. Detailed accounts of them must be looked for in special works, among which the works of A. R. Shuliachenko and T. M. Chelltsoff occupy an important place in the Russian literature on this subject, although historically the scientific works of Abel in England and Berthelot in France stand pre-eminent. The latter elucidated much in connection with explosive compounds by a series of both experimental and theoretical researches. Among explosives particularly important places from a practical point of view are occupied by ordinary or black gunpowder (Chap. XIII., note 16), fulminating mercury (Chap. XVI., note 26), the different forms of gun-cotton (Chap. VI., note 37), and nitro-glycerin (Chap. VIII., note 45, and Chap. XII., note 33). The latter when mixed with solid pulverulent substances, like magnesia, tripoli, &c., forms dynamite, which is so largely used in quarries and mines, in driving tunnels, &c. We may add that the simplest true nitro-compound, that is, marsh gas, CH_4 , in which all the hydrogens are replaced by NO_2 groups, $\text{C}(\text{NO}_2)_4$ has been obtained by L. N. Shishkoff, as well as nitroform, $\text{CH}(\text{NO}_2)_3$.

³⁹ Nitric acid may be completely decomposed by passing its vapour over highly incandescent copper, because the oxides of nitrogen first formed give up their oxygen to the

FIG. 57.—Decomposition of nitrous oxide by sodium.

red-hot metallic copper, so that water and nitrogen gas alone are obtained. This forms a means for determining the composition both of nitric acid and of all the other compounds of nitrogen with oxygen, because by collecting the gaseous nitrogen formed it is possible from its volume to calculate its weight, and consequently its amount in a given quantity of a nitrogenous substance; and by weighing the copper before and after the decomposition it is possible to determine the amount of oxygen by the in-

crease in weight. The complete decomposition of nitric acid is also accomplished by passing a mixture of hydrogen and nitric acid vapours through a red-hot tube. Sodium

an **oxidising agent**. Charcoal, as we have already seen, burns in nitric acid; phosphorus, sulphur, iodine, and the majority of metals also decompose nitric acid, some on heating and others even at the ordinary temperature: the substances taken are oxidised and the nitric acid is deoxidised, yielding compounds containing less oxygen.

A few metals, such as gold and platinum, do not act on nitric acid, but the majority decompose it; in so doing, an oxide of the metal is formed, which, if it has the character of a base, acts on the remaining nitric acid; hence, with the majority of metals, the result of the reaction is usually not an oxide of the metal, but the corresponding salt of nitric acid, and, at the same time, one of the lower oxides of nitrogen. The resulting salts of the metals are soluble, and hence it is said that nitric acid *dissolves* nearly all metals.⁴⁰ This is termed the *solution* of metals by acids, although it is not a case of simple solution, but a complex chemical change of the substances taken. When treated with this acid, those metals whose oxides do not combine with nitric acid yield the oxide itself, and not a salt; for example, tin acts in this manner on nitric acid, forming a hydrated oxide, SnH_2O_3 , which is obtained in the form of a white powder: $\text{Sn} + 4\text{HNO}_3 = \text{H}_2\text{SnO}_3 + 4\text{NO}_2 + \text{H}_2\text{O}$. Silver is able to take up still more oxygen, and to convert a large proportion of nitric acid into nitrous anhydride: $4\text{Ag} + 6\text{HNO}_3 = 4\text{AgNO}_3 + \text{N}_2\text{O}_3 + 3\text{H}_2\text{O}$. Copper takes up still more oxygen from nitric acid, converting it into nitric oxide, and, by the action of zinc, nitric acid is able to give up a still further quantity of oxygen, forming nitrous oxide: $4\text{Zn} + 10\text{HNO}_3 = 4\text{Zn}(\text{NO}_3)_2 + \text{N}_2\text{O} + 5\text{H}_2\text{O}$.⁴¹ Sometimes, and especially

also decomposes the oxides of nitrogen at a red heat, taking up all the oxygen. This method is sometimes used for determining the composition of the oxides of nitrogen.

⁴⁰ The application of this acid for etching copper or steel in engraving is based on this fact. The copper is covered with a coating of wax, resin, &c. (etching ground), on which nitric acid does not act, and which is afterwards removed in certain parts with a needle, and the whole then washed in nitric acid. The parts coated remain untouched whilst the uncovered portions are eaten into by the acid. Copper plates for etchings, aquatints, &c., are prepared in this manner.

⁴¹ The formation of such complex equations as the above often presents some difficulty to the beginner. It should be observed that if the reacting and resultant substances be known, it is easy to form an equation for the reaction. Thus, if we wish to form an equation expressing the fact that nitric acid acting on zinc gives nitrous oxide, N_2O , and zinc nitrate, $\text{Zn}(\text{NO}_3)_2$, we must reason as follows:—Nitric acid contains hydrogen, whilst the salt and nitrous oxide do not; hence water is formed, and therefore it is as though anhydrous nitric acid, N_2O_5 , were acting. For its conversion into nitrous oxide it parts with four equivalents of oxygen, and hence it is able to oxidise four equivalents of zinc and thus convert them into zinc oxide, ZnO . These four equivalents of zinc oxide require for their conversion into the salt four more equivalents of nitric anhydride; consequently five equivalents in all of the latter are required, or ten equivalents of nitric acid. Thus in order to express the reaction in whole numbers of equivalents ten equivalents of nitric acid are necessary and four equivalents of zinc. It must not be forgotten, however, that there are very few such reactions which can be entirely expressed

with dilute solutions of nitric acid, the deoxidation proceeds as far as the formation of hydroxylamine and ammonia, and in some cases it leads to the formation of nitrogen itself. The formation of one or other nitrogenous substance from nitric acid is determined not only by the nature of the reacting substances, but also by the relative masses of water and nitric acid, and also by the temperature and pressure, that is, by the sum total of the conditions of reaction; and as in a given mixture even these conditions vary (the temperature and the relative masses vary), it not unfrequently happens that a mixture of different deoxidation products of nitric acid is formed.

Thus the action of nitric acid on metals consists in their being oxidised, whilst the acid itself is converted, according to the temperature, the concentration in which it is taken, the nature of the metal, &c., into lower oxides, ammonia, or even into nitrogen.⁴² Many compounds are oxidised by nitric acid like metals and other elements; for instance, lower oxides are converted into higher oxides. Thus, arsenious acid is converted into arsenic acid, suboxide of iron into oxide, sulphurous acid

by simple equations. The majority of equations of reactions only express the chief and ultimate products of reaction, and thus none of the three preceding equations express all that actually occurs in the action of metals on nitric acid. In no one of them is one oxide of nitrogen alone formed, but always several, either together or consecutively—according to the temperature and strength of the acid. And this is easily intelligible. The resulting oxide is itself capable of acting on metals and of being deoxidised, and in the presence of the nitric acid it may change the acid and be itself changed. The equations given must be looked on as a systematic expression of the main features of the reactions, or as a limit towards which they tend, but to which they only attain in the absence of disturbing influences.

⁴² Montemartini endeavours to show that the products evolved in the action of nitric acid upon metals (and their amount) are in direct connection with both the concentration of the acid and the capacity of the metals to decompose water. Those metals which only decompose water at a high temperature give, under the action of nitric acid, NO_2 , N_2O_4 , and NO ; whilst those metals which decompose water at a lower temperature give, besides the above products, N_2O , N , and NH_3 ; and, lastly, the metals which decompose water at the ordinary temperature also evolve hydrogen. Nitric acid diluted with a large quantity of water does not oxidise copper, but it oxidises tin; dilute nitric acid also does not oxidise either silver or mercury; but, on the addition of nitrous acid, even dilute acid acts on the above metals. This naturally depends on the less stability of nitrous acid, and on the fact that after the commencement of the action the nitric acid is itself converted into nitrous acid, which continues to act on the silver and mercury. Veley (Oxford, 1891) made detailed researches on the action of nitric acid upon Cu , Hg , and Bi , and showed that nitric acid of 30 per cent. strength does not act upon these metals at the ordinary temperature if nitrous acid (traces of which are destroyed by urea) and oxidising agents such as H_2O_2 , KClO_3 , &c. are entirely absent; but in the presence of even a small amount of nitrous acid the metals form nitrites, which, with HNO_3 , form nitrates and the oxides of nitrogen, which re-form the nitrous acid necessary for starting the reaction, because the reaction, $2\text{NO} + \text{HNO}_3 + \text{H}_2\text{O} = 3\text{HNO}_2$, is reversible. The above metals are quickly dissolved in a 1 per cent. solution of nitrous acid. Moreover, Veley observed that nitric acid is partially converted into nitrous acid by gaseous hydrogen in the presence of the nitrates of Cu and Pb .

into sulphuric acid, the sulphides of the metals, M_2S , into sulphates, M_2SO_4 , &c.; in a word, nitric acid brings about oxidation, its oxygen being taken up and transferred to many other substances. Certain substances are oxidised by strong nitric acid so rapidly and with so great an evolution of heat that they deflagrate and burst into flame. Thus turpentine, $C_{10}H_{16}$, bursts into flame when poured into fuming nitric acid. In virtue of its oxidising property, nitric acid *removes the hydrogen* from many substances. Thus it decomposes hydriodic acid, separating the iodine and forming water; and if fuming nitric acid be poured into a flask containing gaseous hydriodic acid, a rapid reaction takes place, accompanied by flame and the separation of violet vapours of iodine and brown fumes of oxides of nitrogen.⁴³

As nitric acid is very easily decomposed with the separation of oxygen, it was for a long time supposed that it was not capable of forming the corresponding **nitric anhydride**, N_2O_5 ; but first of all, Deville, and subsequently Weber and others, discovered the methods of its formation. Deville obtained nitric anhydride by decomposing silver nitrate by chlorine at a moderate heat. Chlorine acts on the above salt at a temperature of 95° ($2AgNO_3 + Cl_2 = 2AgCl + N_2O_5 + O$), and when once the reaction is started, it continues by itself without further heating. Brown fumes are given off, which are condensed in a tube surrounded by a freezing-mixture. A portion condenses in this tube and a portion remains in the gaseous state; the latter contains free oxygen. A crystalline mass and a liquid substance are obtained in the tube; the liquid is poured off, and a current of dry carbonic acid gas passed through the apparatus in order to remove all traces of volatile substances (liquid oxides of nitrogen) adhering to the crystals of nitric anhydride. These form a voluminous mass of rhombic crystals (density 1.64), which are sometimes of rather large size; they melt at about 30° and distil at about 47° . In distilling, a portion of the substance is

⁴³ When nitric acid acts on many organic substances it often happens that not only is hydrogen removed from them, but also oxygen introduced; thus, for example, nitric acid converts toluene, C_7H_8 , into benzoic acid, $C_7H_6O_2$. In certain cases, also, a portion of the carbon contained in an organic substance burns at the expense of the oxygen of the nitric acid. So, for instance, phthalic acid, $C_8H_6O_4$, is obtained from naphthalene, $C_{10}H_8$. Thus the action of nitric acid on the hydrocarbons is often most complex; not only does nitration take place, but also separation of carbon, displacement of hydrogen, and combination of oxygen. There are few organic substances which can withstand the action of nitric acid, and it causes fundamental changes in a number of them. It leaves a yellow stain on the skin, and in large quantity causes a wound and entirely eats away the membranes of the body. The tissues of plants are eaten into with the greatest ease by strong nitric acid in just the same manner. One of the most durable blue vegetable dyes employed in dyeing tissues is *indigo*; yet it is readily *converted into a yellow substance* by the action of nitric acid, and small traces of free nitric acid may be recognised by this means.

decomposed. With water these crystals give nitric acid. Nitric anhydride is also obtained by the action of phosphoric anhydride, P_2O_5 , on cold pure nitric acid (below 0°). During the very careful distillation of equal parts by weight of these two substances a portion of the acid decomposes, giving a liquid compound, $H_2O, 2N_2O_5 = N_2O_5, 2HNO_3$, whilst the greater part of the nitric acid gives the anhydride according to the equation: $2HNO_3 + P_2O_5 = 2PHO_3 + N_2O_5$. On heating, nitric anhydride decomposes either with an explosion, or gradually, into nitric peroxide and oxygen: $N_2O_5 = N_2O_4 + O$.

Nitrogen peroxide, N_2O_4 , and **nitrogen dioxide**, NO_2 , express one and the same composition, but they should be distinguished like ordinary oxygen and ozone, although in this case their mutual conversion is more easily effected and takes place on vaporisation; also, O_3 loses heat on passing into O_2 , whilst N_2O_4 absorbs heat in forming NO_2 .

Nitric acid in acting on tin and on many organic substances (for example starch) yields brown vapours, consisting of a mixture of N_2O_3 and NO_2 . A purer product is obtained by the decomposition of lead nitrate by heat, $Pb(NO_3)_2 = 2NO_2 + O + PbO$, when non-volatile lead oxide, oxygen gas, and nitrogen dioxide are formed. The latter condenses, in a well-cooled vessel, to a brown liquid, which boils at about 22° . The purest peroxide of nitrogen, solidifying at -9° , is obtained by mixing dry oxygen in a freezing-mixture with twice its volume of dry nitric oxide, NO , when transparent prisms of nitrogen peroxide are formed in the receiver: they melt into a colourless liquid at about -10° . When the temperature of the receiver is above -9° , the crystals melt,⁴⁴ and at 0° give a reddish-yellow liquid, like that obtained in the decomposition of lead nitrate. The vapours of nitrogen peroxide have a characteristic odour, and at the ordinary temperature are of a dark-brown colour, but at lower temperatures the colour of the vapour is much fainter. When heated, especially above 50° , the colour becomes a very dark brown, so that the vapours almost lose their transparency.

The causes of these peculiarities of nitrogen peroxide were not clearly understood until Deville and Troost determined the density and dissociation of the vapour of this substance at different temperatures, and showed that the density varies. If the density is referred to that

⁴⁴ According to certain investigations, if a brown liquid is formed from the melted crystals by heating above -9° , then they no longer solidify at -10° , probably because a certain amount of N_2O_3 (and oxygen) is formed, and the liquid does not solidify, even at -30° , or it may be that the passage from $2NO_2$ into N_2O_4 is not so easily accomplished as the passage from N_2O_4 into $2NO_2$.

Liquid nitrogen peroxide (that is, a mixture of NO_2 and N_2O_4) is employed in admixture with hydrocarbons as an explosive.

of hydrogen at the same temperature and pressure, it is found to vary from 38 at the boiling-point, or about 27° , to 23 at 135° , after which the density remains constant up to those high temperatures at which the oxides of nitrogen are decomposed. As on the basis of the laws enunciated in the following chapter, the density 23 corresponds with the compound NO_2 (because the weight corresponding with this molecular formula is 46, and the density referred to hydrogen as unity is equal, as we shall presently see, to half the molecular weight); at temperatures above 135° the existence of nitrogen dioxide only must be recognised. It is this gas which is of a brown colour. At a lower temperature it forms nitrogen peroxide, N_2O_4 , whose molecular weight, and therefore density, is twice that of the dioxide. This substance, which is polymeric with nitrogen dioxide, as ozone is polymeric with oxygen, and has twice as great a vapour density (46 referred to hydrogen), is formed in greater quantity the lower the temperature, and crystallises at -10° . The reasons both of the variation of the colour of the gas (N_2O_4 gives colourless and transparent vapours, whilst those of NO_2 are brown and opaque) and the variation of the vapour density with the variation of temperature are thus made quite clear; and as at the boiling-point a density 38 was obtained, at that temperature the vapours consist of a mixture of 79 parts by weight of N_2O_4 with 21 parts by weight of NO_2 .⁴⁵ It is evident that a decomposition here takes place, the peculiarity of which consists in the fact that the product of decomposition, NO_2 , is polymerised (i.e. becomes denser, combines with itself) at a lower temperature; that is, the reaction

is a reversible reaction, and consequently the whole phenomenon represents a **dissociation** in a homogeneous gaseous medium, where the original substance, N_2O_4 , and the resultant, NO_2 , are both gases. The *measure of dissociation* will be expressed if we find the proportion of the quantity of the substance decomposed to the whole amount of the substance. At the boiling-point, therefore, the measure of the decomposition of nitrogen peroxide will be 21 per cent.; at 135° it = 1, and at 10° it = 0, the N_2O_4 then being not decomposable. Consequently the limits of dissociation at the atmospheric pressure are -10° and 135° .⁴⁶ Within the limits of these temperatures the

⁴⁵ Because if x equal the amount by weight of N_2O_4 , its volume will = $x/46$, and the amount of NO_2 will = $100 - x$, and consequently its volume will = $(100 - x)/23$. But the mixture, having a density 38, will weigh 100; consequently its volume will = $100/38$. Hence $x/46 + (100 - x)/23 = 100/38$, or $x = 79.0$.

⁴⁶ The phenomena and laws of dissociation, which we shall consider only in particular instances, are discussed in detail in works on theoretical chemistry. Nevertheless, in

vapours of nitrogen peroxide have not a constant density; but, on the other hand, above and below these limits, definite substances exist. Thus, above 135° , N_2O_4 has ceased to exist and NO_2 alone remains. It is evident that at the ordinary temperature there is a partially dissociated system or a mixture of nitrogen peroxide, N_2O_4 , and nitrogen dioxide, NO_2 . In the brown liquid boiling at 22° probably a portion of the N_2O_4 has already passed into NO_2 , and it is only the colourless liquid and crystalline substance at -10° that can be considered as pure nitrogen peroxide.⁴⁷

The above explains the action of nitrogen peroxide on water at low temperatures. N_2O_4 then acts on water like a mixture of the anhydrides of nitrous and nitric acids. The first, N_2O_3 , may be looked upon as water in which each of the two atoms of hydrogen is replaced by the radicle NO , while in the second each hydrogen is replaced by the radicle NO_2 , belonging to nitric acid; and in nitrogen peroxide one atom of the hydrogen of water is replaced by NO and the other by NO_2 , as is seen from the formulæ—

or $\text{H}_2\text{O} ; \text{N}_2\text{O}_3 ; \text{N}_2\text{O}_4 ; \text{N}_2\text{O}_5.$

In fact, nitrogen peroxide at low temperatures gives with water (ice) both nitric, HNO_3 , and nitrous, HNO_2 , acids. The latter, as we shall

respect to nitrogen peroxide, as an historically important example of dissociation in a homogeneous gaseous medium, we will cite the results of the careful investigations (1885–1886) of E. and L. Natanson, who determined the densities under various conditions of temperature and pressure. The degree of dissociation, expressed as above (it may also be expressed otherwise—for example, by the ratio of the quantity of substance decomposed to that unaltered), proves to increase at all temperatures as the pressure diminishes, which would be expected for a homogeneous gaseous medium, as a decreasing pressure aids the formation of the lightest product of dissociation (that having the least density or largest volume). Thus in the Natansons' experiments the degree of dissociation at 0° increases from 10 per cent. to 30 per cent., with a decrease of pressure of from 251 to 38 mm.; at 49.7° it increases from 49 per cent. to 93 per cent. with a fall of pressure of from 498 to 27 mm., and at 100° it increases from 89.2 per cent. to 99.7 per cent. with a fall of pressure from 732.5 to 11.7 mm. At 130° and 150° the decomposition is complete—that is, only NO_2 remains at the low pressures (less than the atmospheric) at which the Natansons made their determinations; but it is probable that at higher pressures (of several atmospheres) molecules of N_2O_4 would still be formed, and it would be exceedingly interesting to trace the phenomena under the conditions both of very considerable pressures and of relatively large volumes.

⁴⁷ Liquid nitrogen peroxide is said by Geuther to boil at 22° – 26° , and to have a sp. gr. = 1.494 at 0° and 1.474 at 15° . It is evident that, in the liquid as in the gaseous state, the variation of density with the temperature depends not only on physical, but also on chemical changes, as the amount of N_2O_4 decreases and the amount of NO_2 increases as the temperature rises, and they (as polymeric substances) should have different densities, just as is the case, for instance, with the hydrocarbons C_5H_{10} and $\text{C}_{10}\text{H}_{20}$.

It may not be superfluous to mention here that the measurement of the specific heat

afterwards see, splits up into water and the anhydride, N_2O_3 . If, however, warm water acts on nitrogen peroxide, only nitric acid and monoxide of nitrogen are formed: $3\text{NO}_2 + \text{H}_2\text{O} = \text{NO} + 2\text{HNO}_3$.

Although NO_2 is not decomposed into N and O even at 500° , still in many cases it acts as an oxidising agent. Thus, for instance, it oxidises mercury, converting it into mercurous nitrate, $2\text{NO}_2 + \text{Hg} = \text{HgNO}_3 + \text{NO}$, being itself deoxidised into nitric oxide, into which the dioxide passes in many other instances, and from which it is easily formed.⁴⁸

Nitrous anhydride, N_2O_3 , corresponds⁴⁹ with nitrous acid, NHO_2 , which forms a series of salts, the nitrites—for example, the sodium salt NaNO_2 ,^{49a} the ammonium salt $(\text{NH}_4)\text{NO}_2$,⁵⁰ the silver salt AgNO_2 ,⁵¹ &c. Neither the anhydride nor the hydrate of the acid is

of a mixture of the vapours of N_2O_4 and NO_2 enabled Berthelot to determine that the transformation of 2NO_2 into N_2O_4 is accompanied by the evolution of about 13,000 units of heat, and as the reaction proceeds with equal facility in either direction, it will be exothermal in the one direction and endothermal in the other; and this clearly demonstrates the possibility of reactions taking place in either direction, although, as a rule, reactions evolving heat proceed with the greater ease.

⁴⁸ Nitric acid of sp. gr. 1.51 in dissolving nitrogen peroxide becomes brown, whilst nitric acid of sp. gr. 1.32 is coloured greenish blue, and acid of sp. gr. less than 1.15 remains colourless after absorbing nitrogen peroxide (note 33).

⁴⁹ Nitrogen peroxide as a mixed substance has no corresponding independent salts, but Sabatier and Senderens (1892) showed that, under certain conditions, NO_2 combines directly with some metals—for instance, copper and cobalt—forming Cu_2NO_2 and CoNO_2 as dark brown powders, which do not, however, exhibit the reactions of salts. Thus by passing gaseous nitrogen dioxide over freshly reduced (from the oxidised compounds by heating with hydrogen) copper at 25° – 30° , Cu_2NO_2 is directly formed. With water it partly gives off NO_2 and partly forms nitrite of copper, leaving metallic copper and its suboxide. The nature of these compounds has not yet been sufficiently investigated.

^{49a} This sodium salt, NaNO_2 , is the most largely used in the arts, as it reacts with the amides of certain colouring matters forming dyes for tissues. It is called ‘nitrite,’ and is prepared in the same way as KNO_2 (see further on).

⁵⁰ Ammonium nitrite may be easily obtained in solution by a method of double decomposition (for instance, of the barium salt with ammonium sulphate) similar to that employed for the other salts of nitrous acid, but it decomposes with great ease when evaporated, with evolution of gaseous nitrogen, as already mentioned (Chap. V.). If the solution, however, is evaporated at the ordinary temperature under the receiver of an air-pump, a solid saline mass is obtained, which is easily decomposed when heated. The dry salt even decomposes with an explosion when struck, or when heated to about 70° : $\text{NH}_4\text{NO}_2 = 2\text{H}_2\text{O} + \text{N}_2$. It is also formed by the action of aqueous ammonia on a mixture of nitric oxide and oxygen, or by the action of ozone on ammonia, and in many other instances. Sørensen (1894) prepared NH_4NO_2 by the action of a mixture of N_2O_3 and other oxides of nitrogen on lumps of ammonium carbonate, extracting the nitrite of ammonium formed with absolute alcohol, and precipitating it from this solution by ether. This salt is crystalline, dissolves in water with absorption of heat, and attracts moisture from the air. In order to preserve the salt it should be covered with a layer of pure dry ether.

⁵¹ Silver nitrite, AgNO_2 , is obtained as a very slightly soluble substance, which is precipitated, on mixing solutions of silver nitrate, AgNO_3 , and potassium nitrite, KNO_2 . It

known in a perfectly pure state. The anhydride has only been obtained as a very unstable substance, and has not yet been fully investigated; and on attempting to obtain the acid NHO_2 from its salts, it always gives water and the anhydride, whilst the latter, as an intermediate oxide, partially or wholly splits up into $\text{NO} + \text{NO}_2$. But the salts of nitrous acid are distinguished for their great stability. Potassium nitrate, KNO_3 , may be converted into potassium nitrite by depriving it of a portion of its oxygen; for instance, by fusing it (at not too high a temperature) with metals such as lead, $\text{KNO}_3 + \text{Pb} = \text{KNO}_2 + \text{PbO}$.^{51a} The resultant salt is soluble in water, whilst the oxide of lead is insoluble. With sulphuric and other acids the solution of potassium nitrite⁵² immediately evolves a brown gas, nitrous anhydride: $2\text{KNO}_2 + \text{H}_2\text{SO}_4 = \text{K}_2\text{SO}_4 + \text{N}_2\text{O}_3 + \text{H}_2\text{O}$. The same gas (N_2O_3) is obtained by passing nitric oxide at 0° through liquid nitrogen tetroxide,⁵³ or by heating starch with nitric acid of sp. gr. 1.3. At a very low temperature it condenses into a blue liquid boiling at about 0° ,⁵⁴ but then partially decomposing into $\text{NO} + \text{NO}_2$. Nitrous anhydride possesses a remarkable capacity for oxidising. Ignited bodies burn in it; nitric acid absorbs it, and then acquires the property of acting on silver and other metals, even when diluted (see note 42). **Potassium iodide** is oxidised by this gas just as it is by ozone (and by peroxide of hydrogen, chromic and other acids, but not by dilute nitric acid or sulphuric acid), with the **separation of iodine**. This iodine may be

is soluble in a large volume of water, and this is taken advantage of to free it from silver oxide, which is also present in the precipitate, owing to the fact that potassium nitrite always contains a certain amount of oxide, which with water gives the hydroxide, forming oxide of silver with silver nitrate. The solution of silver nitrite gives, by double decomposition with metallic chlorides (for instance, barium chloride), insoluble silver chloride and the nitrite of the metal taken (in this case, barium nitrite, $\text{Ba}(\text{NO}_2)_2$).

^{51a} Leroy (1889) obtained KNO_2 by mixing powdered KNO_3 with BaS , igniting the mixture in a crucible and washing the fused salts; BaSO_4 is then left as an insoluble residue, and KNO_2 passes into solution: $4\text{KNO}_3 + \text{BaS} = 4\text{KNO}_2 + \text{BaSO}_4$.

⁵² Probably potassium nitrite, KNO_2 , when strongly heated, especially with metallic oxides, evolves N and O , and yields potassium oxide, K_2O , because nitre is liable to such a decomposition; but it has, as yet, been but little investigated.

⁵³ The reaction $\text{N}_2\text{O}_3 = \text{NO}_2 + \text{NO}$ is probably reversible, i.e. resembles the conversion of N_2O_4 into NO_2 . The brown colour of the fumes of N_2O_3 is due to the formation of NO_2 .

If nitrogen peroxide is cooled to -20° , and half its weight of water added to it drop by drop, the tetroxide is decomposed, as we have already stated, into nitrous and nitric acids; the former does not then remain as a hydrate, but straightway passes into the anhydride, and hence if the resultant liquid be slightly warmed vapours of nitrous anhydride, N_2O_3 , are evolved, and condense into a blue liquid, as was shown by Fritzsche. This method of preparing nitrous anhydride apparently gives the purest product, but it easily dissociates, forming NO and NO_2 (and therefore also nitric acid, if water is present).

⁵⁴ According to Thorpe, N_2O_3 boils at $+18^\circ$. Geuther gives the boiling-point as $+3.5^\circ$, and the sp. gr. at 0° as 1.449.

recognised (Chapter IV.) by its turning starch blue. Very small traces of nitrites may be easily detected by this method. If, for example, starch and potassium iodide are added to a solution of potassium nitrite (at first there will be no change, there being no free nitrous acid), and then sulphuric acid, the nitrous acid (or its anhydride) set free liberates iodine, which produces a blue colour with the starch. Nitric acid does not act in this manner, but in the presence of zinc the coloration takes place, which proves the formation of nitrous acid in the deoxidation of nitric acid.⁵⁵ Nitrous acid acts directly on ammonia, forming nitrogen and water, $\text{HNO}_2 + \text{NH}_3 = \text{N}_2 + 2\text{H}_2\text{O}$.⁵⁶

As nitrous anhydride easily splits up into $\text{NO}_2 + \text{NO}$, so, like NO_2 , with warm water it gives nitric acid and nitric oxide, according to the equation: $3\text{N}_2\text{O}_3 + \text{H}_2\text{O} = 4\text{NO} + 2\text{HNO}_3$.

Being in a lower degree of oxidation than nitric acid, nitrous acid and its anhydride are oxidised in solution by many oxidising substances—for example, by potassium permanganate—into nitric acid.⁵⁷

Nitric oxide, NO.—This permanent gas⁵⁸ (that is unliquefiable by pressure without the aid of cold) may be obtained by the deoxidation of any of the above-described compounds of nitrogen with oxygen. The deoxidation of nitric acid by metals is the usual method employed for its preparation. Dilute nitric acid (sp. gr. 1.18 but not stronger, as then N_2O_3 and NO_2 are produced) is poured into a flask containing

⁵⁵ In its oxidising action nitrous anhydride gives nitric oxide, $\text{N}_2\text{O}_3 = 2\text{NO} + \text{O}$. Thus its analogy to ozone becomes still more marked, because in ozone it is only one-third of the oxygen that acts in oxidising; from O_3 there is obtained O , which acts as an oxidiser, and common oxygen O_2 . In a physical aspect the relation between N_2O_3 and O_3 is revealed in the fact that both substances are of a blue colour when in the liquid state.

⁵⁶ This reaction is taken advantage of for converting the amides, NH_2R (where R is an element or a complex group), into hydroxides, RHO . In this case $\text{NH}_2\text{R} + \text{HNO}_2$ forms $2\text{N} + \text{H}_2\text{O} + \text{RHO}$; H_2N is replaced by HO , the radicle of ammonia by the radicle of water. This reaction is employed for transforming many nitrogenous organic substances having the properties of amides into their corresponding hydroxides. Thus aniline, $\text{C}_6\text{H}_5\text{NH}_2$, which is obtained from nitrobenzene, $\text{C}_6\text{H}_5\text{NO}_2$ (note 37), is converted by nitrous anhydride into phenol, $\text{C}_6\text{H}_5\text{OH}$, which occurs in the creosote extracted from coal tar. Thus the H of the benzene is successively replaced by NO_2 , NH_2 , and HO ; this method is suitable for other cases also. With the acid amides of the aromatic series of hydrocarbons, nitrous acid gives highly coloured diazo-compounds.

⁵⁷ The action of a solution of potassium permanganate, KMnO_4 , on nitrous acid in the presence of sulphuric acid is determined by the fact that the higher oxide of manganese, Mn_2O_7 , contained in the permanganate is converted into the lower oxide, MnO , which as a base forms manganese sulphate, MnSO_4 , while the oxygen serves for the oxidation of HNO_2 into HNO_3 . As the solution of the permanganate is of a red colour, whilst that of manganese sulphate is almost colourless, this reaction is clearly seen, and may be employed for the detection and determination of nitrous acid and its salts.

⁵⁸ The absolute boiling-point = -93° (see Chap. II., note 29). The liquefied gas boils at -142° , and the melting-point is -152° .

metallic copper.⁵⁹ The reaction commences at the ordinary temperature. Mercury and silver also give nitric oxide with nitric acid. In these reactions with metals one portion of the nitric acid is employed in the oxidation of the metal, whilst the other, and by far the greater, portion combines with the metallic oxide so obtained, with formation of the nitrate corresponding with the metal taken. The first action of the copper on the nitric acid is thus expressed by the equation :

The second reaction consists in the formation of copper nitrate—

Adding these two equations together we obtain :

Nitric oxide is a colourless gas which is only slightly soluble in water ($\frac{1}{20}$ of a volume at the ordinary temperature). Reactions of double decomposition in which nitric oxide readily takes part are not known—that is to say, it is an indifferent, not a saline, oxide. Like the other oxides of nitrogen, it is decomposed into its elements at a red heat (starting from 900° , 60 per cent. of it forms N_2 and $2\text{N}_2\text{O}_3$ at 1200° , but complete decomposition into N_2 and O_2 only takes place at the melting-point of platinum; Emich, 1892). The most characteristic property of nitric oxide is its capacity for directly and easily combining with oxygen (with evolution of heat). With **oxygen** it forms **nitrous anhydride** and **nitrogen peroxide** : $2\text{NO} + \text{O} = \text{N}_2\text{O}_3$; $2\text{NO} + \text{O}_2 = 2\text{NO}_2$.

⁵⁹ Kammerer proposed preparing nitric oxide, NO, by pouring a solution of sodium nitrate over copper shavings and adding sulphuric acid drop by drop. The oxidation of ferrous salts by nitric acid also gives NO. One part of strong hydrochloric acid is taken and iron is dissolved in it (FeCl_2), and then an equal quantity of hydrochloric acid and also nitre are added to the solution. On heating, nitric oxide is evolved. In the presence of an excess of sulphuric acid and mercury the conversion of nitric acid into nitric oxide is complete (that is, the reaction proceeds to the end, and the nitric oxide is obtained without other products), and upon this is founded one of the methods for determining nitric acid (in nitrometers of various kinds, described in text-books of analytical chemistry), as the amount of NO can be easily and accurately measured volumetrically. The amount of nitrogen in gun-cotton, for instance, is determined by dissolving it in sulphuric acid. Nitrous acid acts in the same manner. Upon this property Emich (1892) founds his method for preparing pure NO. He pours mercury into a flask, and then covers it with sulphuric acid, in which a certain amount of NaNO_2 or other substance corresponding to HNO_2 or HNO_3 has been dissolved. The evolution of NO proceeds at the ordinary temperature, becoming more rapid as the surface of the mercury is increased (if the flask is shaken, the reaction proceeds very rapidly). If the gas is passed over KHO, it is obtained quite pure, because KHO does not act upon NO at the ordinary temperature (if heated, KNO_2 and N_2O or N_2 are formed).

If nitric oxide is mixed with oxygen and immediately shaken up with caustic potash, it is almost entirely converted into potassium nitrite; whilst after a certain time, when the formation of N_2O_4 has already commenced, a mixture of potassium nitrite and nitrate is obtained. If oxygen is passed into a bell-jar filled with nitric oxide, brown fumes of N_2O_3 and N_2O_2 are formed, even in the absence of moisture; in presence of water these give, as we already know, nitric acid and nitric oxide, so that with excess of water and oxygen the whole of the nitric oxide is easily and directly converted into nitric acid. This reaction of the re-formation of nitric acid from nitric oxide, air, and water, $2\text{NO} + \text{H}_2\text{O} + \text{O}_3 = 2\text{HNO}_3$, is frequently made use of in practice. The experiment showing the conversion of nitric oxide into nitric acid is very striking and instructive. As the intermixture of the oxygen with the oxide of nitrogen proceeds, the nitric acid formed dissolves in water, and if an excess of oxygen has not been added, the whole of the gas (nitric oxide), being converted into HNO_3 , is absorbed, and the water entirely fills the bell-jar previously containing the gas.⁶⁰ It is evident that nitric oxide⁶¹ in combining with oxygen has a strong tendency to give the higher types of nitrogen compounds, which we see in nitric acid, HNO_3 or $\text{NO}_2(\text{OH})$, in nitric anhydride, N_2O_5 or $(\text{NO}_2)_2\text{O}$, and in ammonium chloride, NH_4Cl . If X stand for an atom of hydrogen, or its equivalents, chlorine, hydroxyl, &c., and if O, which is, according to the law of substitution, equivalent to H_2 , be indicated by X_2 , then the three compounds of nitrogen above named should be considered as compounds of the type or form NX_5 . For example, in nitric acid

⁶⁰ This transformation of the permanent gases, nitric oxide and oxygen, into liquid nitric acid in the presence of water, and with the evolution of heat, presents a most striking instance of liquefaction produced by the action of chemical forces. The latter perform with ease the work which physical (cooling) and mechanical (pressure) forces effect only with difficulty. In this the motion, which is so distinctively the property of the gaseous molecules, is apparently destroyed.

⁶¹ Nitric oxide is capable of entering into many characteristic combinations; it is absorbed by the solutions of many acids—for instance, tartaric, acetic, phosphoric, sulphuric—and metallic chlorides (for example, SbCl_5 , BiCl_3 , &c., with which it forms definite compounds; Besson 1889), and also by the solutions of many salts, especially those formed by suboxide of iron (for instance, ferrous sulphate). In this case a brown compound is formed which is exceedingly unstable, like all the analogous compounds of nitric oxide. Ammonia is obtained by the action of a caustic alkali on the resultant compound, because the oxygen of the nitric oxide and water are transferred to the ferrous oxide, forming ferric oxide, whilst the nitrogen combines with the hydrogen of the water. According to the investigations of Gay (1885), the compound is formed with the evolution of a large quantity of heat, and is easily dissociated, like a solution of ammonia in water. If the presence of a radicle NO_2 , of the composition of nitrogen peroxide, must be recognised in the compounds of nitric acid, then a radicle NO , having the composition of nitric oxide, may be admitted in compounds of nitrous acid. The compounds in which the radicle NO is recognised are called *nitroso-compounds*. These substances are described in Prof. Bunge's work (Kief, 1868).

$X_5 = O_2 + (OH)$, where $O_2 = X_4$, and $OH = X$; whilst nitric oxide is a compound of the form NX_2 . Hence this lower form, like lower forms in general, strives by combination to attain to the higher forms proper to the compounds of a given element. NX_2 passes consecutively into NX_3 —namely, into N_2O_3 and NHO_2 — NX_4 (for instance, NO_2) and NX_5 .^{61a}

As the decomposition of nitric oxide begins at temperatures above 900° , **many substances burn in it**; thus, ignited phosphorus continues to burn in nitric oxide, but sulphur and charcoal are extinguished in it. This is due to the fact that the heat evolved in the combustion of these two substances is insufficient for the decomposition of the nitric oxide, whilst the heat developed by burning phosphorus suffices to produce this decomposition. That nitric oxide really supports combustion, owing to its being decomposed by the action of heat, is proved by the fact that strongly ignited charcoal continues to burn in the same nitric oxide⁶² in which a feebly incandescent piece of charcoal is extinguished.

The compounds of nitrogen with oxygen, which we have so far considered, may all be prepared from nitric oxide, and may themselves be converted into it. Thus nitric oxide stands in intimate connection with them.⁶³ The passage of nitric oxide into the higher degrees of

^{61a} In this example we see an instance of variable atomicity, of which we shall have further occasion to speak, especially in Chap. X., note 1.

⁶² A mixture of nitric oxide and hydrogen is inflammable. If a mixture of the two gases be passed over spongy platinum the nitrogen and hydrogen even combine, forming ammonia. A mixture of nitric oxide with many combustible vapours and gases is very inflammable. A very characteristic flame is obtained on burning a mixture of nitric oxide and the vapour of the combustible carbon bisulphide, CS_2 . The latter substance is very volatile, so that it is sufficient to pass the nitric oxide through a layer of the carbon bisulphide (for instance, in a Woulfe's bottle) in order that the gas escaping should contain a considerable amount of the vapours of this substance. This mixture continues to burn when ignited, and the flame emits a large quantity of the so-called ultra-violet rays, which are capable of inducing chemical combinations and decompositions, and therefore the flame may be employed in photography in the absence of sufficient daylight (magnesium light and electric light have the same property). There are many gases (for instance, ammonia) which when mixed with nitric oxide explode in a eudiometer.

⁶³ The oxides of nitrogen naturally do not proceed directly from oxygen and nitrogen by contact alone, because their formation is accompanied by the absorption of a large quantity of heat, for (see note 29) about 21,500 heat units are absorbed when 16 parts of oxygen and 14 parts of nitrogen combine; consequently the decomposition of nitric oxide into oxygen and nitrogen is accompanied by the evolution of this amount of heat; and therefore with nitric oxide, as with all explosive substances and mixtures, the reaction once started is able to proceed by itself. In fact, Berthelot remarked the decomposition of nitric oxide in the explosion of fulminate of mercury. This decomposition does not take place spontaneously; substances even burn with difficulty in nitric oxide, probably because a certain portion of the nitric oxide in decomposing gives oxygen, which combines with another portion of nitric oxide, and forms nitric peroxide, a somewhat more stable compound of nitrogen and oxygen. The further combinations of nitric oxide with

oxidation and the converse reaction is employed in practice as a means for **transferring the oxygen of the air** to substances capable of being oxidised. Starting with nitric oxide, it may easily be converted, with the aid of the oxygen of the atmosphere and water, into nitric acid, N_2O_3 , and NO_2 , and by their means employed to oxidise other substances. In this oxidising action nitric oxide is again formed, and it may again be converted into nitric acid, and so on continuously, if only oxygen and water be present. Hence the fact, which at first appears to be a paradox, that by means of a small quantity of nitric oxide in the presence of oxygen and water it is possible to oxidise an indefinitely large quantity of substances which cannot be directly oxidised, either by the action of the atmospheric oxygen or by the action of nitric oxide itself. The sulphurous anhydride, SO_2 , which is obtained in the combustion of sulphur and in roasting many metallic sulphides in the air, is an example of this kind. In practice this gas is obtained by burning sulphur or iron pyrites, FeS_2 , the latter being thereby converted into oxide of iron and sulphurous anhydride, SO_2 . In contact with the oxygen of the atmosphere this gas does not pass into the higher degree of oxidation, sulphuric anhydride, SO_3 ,^{63a} and if it does form sulphuric acid with water and the oxygen of the atmosphere, $\text{SO}_2 + \text{H}_2\text{O} + \text{O} = \text{H}_2\text{SO}_4$, it does so very slowly. With nitric acid (and especially with nitrous acid, but not with nitrogen tetroxide) and water, sulphurous anhydride, on the contrary, very easily forms sulphuric acid, and especially so when slightly heated (about 40°), the nitric acid (or, better still, nitrous acid) being converted into nitric oxide—

The presence of water is absolutely indispensable here, otherwise sulphuric anhydride is formed, which combines with the oxides of nitrogen (nitrous anhydride), forming a crystalline substance containing oxides of nitrogen (*chamber crystals*, which will be described in Chapter XX). Water destroys this compound, forming sulphuric acid and separating the oxides of nitrogen. The water must be taken in a greater quantity than that required for the formation of the hydrate H_2SO_4 , because the latter absorbs oxides of nitrogen. With an excess of water, however, solution does not take place. If, in the above reaction, only water, sulphurous anhydride, and nitric or nitrous

oxygen all proceed with the evolution of heat, and take place spontaneously by contact with air alone. It is evident from these examples that the application of thermochemical data is limited.

^{63a} But in the presence of spongy platinum (and other contact agents), and when heated, SO_2 does form SO_3 with the oxygen of air. This is now taken advantage of for the manufacture of sulphuric acid. See Chap. XX. (the contact process).

acid be taken in a definite quantity, then a definite quantity of sulphuric acid and nitric oxide will be formed, according to the preceding equation; but there the reaction ends, and the excess of sulphurous anhydride, if there be any, will remain unchanged. But if we add air and water, then the nitric oxide will unite with the oxygen to form nitrogen peroxide, and the latter with water to form nitric and nitrous acids, which again give sulphuric acid from a fresh quantity of sulphurous anhydride. Nitric oxide is again formed, which is able to start the oxidation afresh if there be sufficient air. Thus it is possible with a definite quantity of nitric oxide to convert an indefinitely large quantity of sulphurous anhydride into sulphuric acid, water and oxygen only being required.⁶⁴ This may be easily demonstrated by an experiment on a smaller scale, if a certain quantity of nitric oxide be first introduced into a flask, and sulphurous anhydride, steam, and oxygen be then continually passed in. Thus the above-described reaction may be expressed in the following manner:

if we consider only the original substances and those finally formed. In this way a definite quantity of nitric oxide may serve for the conversion of an indefinite quantity of sulphurous anhydride, oxygen, and water into sulphuric acid. In reality, however, there is a limit to this, because air, and not pure oxygen, is employed for the oxidation, so that it is necessary to remove the nitrogen of the air and to introduce a fresh quantity of air. A certain quantity of nitric oxide will pass away with this nitrogen, and will in this way be lost.⁶⁵

⁶⁴ The instance of the action of a small quantity of NO in inducing a definite chemical reaction between large masses ($\text{SO}_2 + \text{O} + \text{H}_2\text{O} = \text{H}_2\text{SO}_4$) is very instructive, because the details relating to it have been studied, and show that intermediate forms of reaction may be discovered in the so-called contact or catalytic phenomena. The essence of the matter here is that A ($=\text{SO}_2$) reacts upon B ($=\text{O}$ and H_2O) in the presence of C, because it gives BC, a substance which forms AB with A, and again liberates C. Consequently C is a medium, a transferring substance, without which the reaction does not proceed. Many similar phenomena may be found in other departments of life. Thus the merchant is an indispensable medium between the producer and the consumer; experiment is a medium between the phenomena of nature and the cognisant faculties, and language, customs, and laws are media which are as necessary for the exchanges of social intercourse as nitric oxide for those between sulphurous anhydride and oxygen and water.

⁶⁵ If the sulphurous anhydride be prepared by roasting iron pyrites, FeS_2 , then each equivalent of pyrites (equivalent of iron, 56, of sulphur 32, of pyrites 120) requires six equivalents of oxygen (that is, 96 parts) for the conversion of its sulphur into sulphuric acid (for forming $2\text{H}_2\text{SO}_4$ with water), besides $1\frac{1}{2}$ equivalent (24 parts) for converting the iron into oxide, Fe_2O_3 ; hence the combustion of the pyrites for the formation of sulphuric acid and ferric oxide requires the introduction of an equal weight of oxygen (120 parts of oxygen to 120 parts of pyrites), or five times its weight of air, of which four

The preceding series of changes serves as the basis of the **manufacture of sulphuric acid** or so-called **chamber acid**. This acid is prepared on a very large scale in chemical works, because it is the cheapest

FIG. 58.—Section of sulphuric acid chambers, the first and last chambers only being represented. The tower to the left is called the Glover's tower, and that on the right the Gay-Lussac's tower. Less than $\frac{1}{100}$ th of the natural size.

acid whose action can be applied in a great number of cases. It is therefore used in immense quantities.

The process is carried on in a series of chambers (or in one divided by partitions as in fig. 58, which shows the beginning and end of a

(the four-fifths of nitrogen) will remain inactive, and in the removal of the exhausted air will carry off the remaining nitric oxide. If not all, at least a large portion of the nitric oxide may be collected by passing the escaping air, still containing some oxygen, through substances which absorb oxides of nitrogen. Sulphuric acid itself may be employed for this purpose if it be used in the form of the hydrate H_2SO_4 , or containing only a small amount of water, because such sulphuric acid dissolves the oxides of nitrogen. They may be easily expelled from this solution by heating or by dilution with water, as they are only slightly soluble in aqueous sulphuric acid. Besides which, sulphurous anhydride acts on such sulphuric acid, being oxidised at the expense of the nitrous anhydride, and forming nitric oxide from it, which again enters into the cycle of action. For this reason, the sulphuric acid which has absorbed the oxides of nitrogen escaping from the chambers in the tower κ (see fig. 58) is led back into the first chamber, where it comes into contact with sulphurous anhydride, by which means the oxides of nitrogen are re-introduced into the reaction which proceeds in the chambers. This is the use of the towers (Gay-Lussac's and Glover's) which are erected at either end of the chambers.

chamber) constructed of sheet lead. These chambers are placed one against the other, and communicate by tubes or special orifices so placed that the inlet tubes are in the upper portion of the chamber, and the outlet in the lower and opposite end. The current of steam and gases necessary for the preparation of the sulphuric acid passes through these chambers and tubes. The acid as it is formed falls to the bottom of the chambers or runs down their walls, and flows from chamber to chamber (from the last towards the first), to permit of which the partitions do not reach to the bottom. The floor and walls of the chambers should therefore be made of a material on which the sulphuric acid will not act. Among the ordinary metals lead is the only one suitable.^{65a}

For the formation of the sulphuric acid it is necessary to introduce sulphurous anhydride, steam, air, and nitric acid, or some oxide of nitrogen, into the chambers. The sulphurous anhydride is produced by burning sulphur or iron pyrites. This is carried on in the furnace with four hearths to the left of the drawing. Air is led into the chambers and furnace through orifices in the furnace doors. The current of air and oxygen is regulated by opening or closing these orifices to a greater or less extent. The ingoing draught in the chambers is brought about owing to heated gases and vapours passing into the chambers, whose temperature is further raised by the reaction itself, and also by the remaining nitrogen being continually withdrawn from the outlet (above the tower κ) by a tall chimney situated near the chambers. Nitric acid is prepared from a mixture of sulphuric acid and Chili saltpetre, in the furnaces in which the sulphurous anhydride is evolved (or in special furnaces). Not more than eight parts of nitre are taken to every 100 parts of sulphur burnt. On leaving the furnace the vapours of nitric acid and oxides of nitrogen mixed with air and sulphurous anhydride first pass along the horizontal tubes τ into the receiver $B B$, which is partially cooled by water flowing in on the right-hand side and running out on the left by o , in order to reduce the temperature of the gases entering the chamber. The gases then pass up a tower filled with coke, shown to the left of the drawing. In this tower are placed lumps of coke (the residue from the dry distillation of coal), over which sulphuric acid trickles from the reservoir m . This acid has absorbed in the end tower κ the oxides of nitrogen escaping from the chamber. This end tower is also filled with coke, over which a stream of strong sulphuric acid trickles from

^{65a} Other metals, such as iron, copper, zinc, are corroded by it; glass and china are not acted upon, but they crack from the variations of temperature taking place in the chambers, besides which they are more difficult to join properly than lead; wood, &c., becomes charred.

the reservoir M' . The acid spreads over the coke, and, owing to the large surface offered by the latter, absorbs the greater part of the oxides of nitrogen escaping from the chambers. The sulphuric acid in passing down the tower becomes saturated with the oxides of nitrogen, and flows out at h into a special receiver (in the drawing situated by the side of the furnaces), from which it is forced by steam pressure up the tubes $h' h'$ into the reservoir M , situated above the first tower. The gases passing through this tower (hot) from the furnace, on coming into contact with the sulphuric acid, take up the oxides of nitrogen contained in it, and these are thus returned to the chamber and again participate in the reaction. The sulphuric acid left after the extraction of these oxides flows into the chambers. Thus, on leaving the first coke tower the sulphurous anhydride, air, and vapours of nitric acid and of the oxides of nitrogen pass through the upper tube m into the chamber. Here they come into contact with steam introduced by lead tubes into various parts of the chamber. The reaction takes place in the presence of water, the sulphuric acid falls to the bottom of the chamber, and the same process takes place in the following chambers until the whole of the sulphurous anhydride is consumed. A somewhat greater proportion of air than is strictly necessary is passed in, in order that no sulphurous anhydride should be left unaltered for want of sufficient oxygen. The presence of an excess of oxygen is shown by the colour of the gases escaping from the last chamber. If they be of a pale colour it indicates an insufficiency of air (and the presence of sulphurous anhydride), as otherwise peroxide of nitrogen would be formed. A very dark colour shows a large excess of air, which is also disadvantageous, because it increases the inevitable loss of nitric oxide by increasing the mass of the escaping gases.⁶⁶

⁶⁶ By this means as much as 2,500,000 kilograms of chamber acid, containing about 60 per cent. of the hydrate H_2SO_4 and about 40 per cent. of water, may be manufactured per year in one plant of 5,000 cubic metres capacity (without stoppages). This process has been brought to such a degree of perfection that as much as 300 parts of the hydrate H_2SO_4 are obtained from 100 parts of sulphur, the theoretical amount being not greater than 306 parts. The acid parts with its excess of water on heating. For this purpose it is heated in lead vessels. However, the acid containing about 75 per cent. of the hydrate (60° Baumé) already begins to act on the lead when heated, and therefore the further removal of water is conducted by evaporating in glass or platinum vessels, as will be described in Chap. XX. The aqueous acid (50° Baumé) obtained in the chambers is termed chamber acid. The acid concentrated to 60° Baumé is more generally employed, and sometimes the hydrate (66° Baumé) termed vitriol acid is also used. In England alone more than 1,000 million kilograms of chamber acid are produced by this method. The formation of sulphuric acid by the action of nitric acid was discovered by Drebbel, and the first lead chamber was erected by Roebuck, in Scotland, in the middle of the eighteenth century. The essence of the process was only brought to light at the beginning of the last century, when many improvements were introduced into practice.

Nitrous oxide, N_2O ,⁶⁷ is similar to water in its volumetric composition. Two volumes of nitrous oxide are formed from two volumes of nitrogen and one volume of oxygen, as may be shown by the ordinary method for the analysis of the oxides of nitrogen (by passing them over red-hot copper or sodium). In contradistinction to the other oxides of nitrogen, it is not directly oxidised by oxygen, but it may be obtained from the higher oxides of nitrogen by the action of certain deoxidising substances; thus, for example, a mixture of two volumes of nitric oxide and one volume of sulphurous anhydride, if left in contact with water and spongy platinum, is converted into sulphuric acid and nitrous oxide, $2\text{NO} + \text{SO}_2 + \text{H}_2\text{O} = \text{H}_2\text{SO}_4 + \text{N}_2\text{O}$. Nitric acid, also, under the action

⁶⁷ If the hydrate HNO_3 corresponds to N_2O_5 , the hydrate HNO , **hyponitrous acid**, corresponds to N_2O , and in this sense N_2O is **hyponitrous anhydride**. Hyponitrous acid, NHO , was obtained in the form of its corresponding salts RNO , or $\text{R}_2\text{N}_2\text{O}_2$, by Divers. They are prepared by the reduction of nitrous (and consequently of nitric) salts by sodium amalgam. If this amalgam be added to a cold solution of an alkaline nitrite until the evolution of gas ceases, and the excess of alkali be saturated with acetic acid, an insoluble yellow precipitate of silver hyponitrite, NAgO , will be obtained on adding a solution of silver nitrate. This hyponitrite is insoluble in cold acetic acid, and decomposes when heated, with evolution of nitrous oxide. If rapidly heated it decomposes with an explosion. It is dissolved unchanged by weak mineral acids, whilst the stronger acids (for example, sulphuric and hydrochloric acids) decompose it with the evolution of nitrogen, nitric and nitrous acids remaining in solution. Among the other salts of hyponitrous acid, HNO , those of lead, copper, and mercury are insoluble in water. Judging by the bond existing between hyponitrous acid and the other compounds of nitrogen, there is reason for thinking that its formula should be doubled, $\text{N}_2\text{H}_2\text{O}_2$. For instance, Thum (1893) on gradually oxidising hydroxylamine, $\text{NH}_2(\text{OH})$, into nitrous acid, $\text{NO}(\text{OH})$ (note 25), by means of an alkaline solution of KMnO_4 , first obtained hyponitrous acid, $\text{N}_2\text{H}_2\text{O}_2$, and then a peculiar intermediate acid, $\text{N}_2\text{H}_2\text{O}_3$, which, by further oxidation, gave nitrous acid. On the other hand, Wislicenus (1893) showed that in the action of the sulphuric acid salt of hydroxylamine upon nitrite of sodium, there is formed, besides nitrous oxide (according to V. Meyer, NH_3O , $\text{H}_2\text{SO}_4 + \text{NaNO}_2 = \text{NaHSO}_4 + 2\text{H}_2\text{O} + \text{N}_2\text{O}$), a small amount of hyponitrous acid which may be precipitated in the form of the silver salt; and this reaction is most simply expressed by taking the doubled formula of hyponitrous acid, $\text{NH}_2(\text{OH}) + \text{NO}(\text{OH}) = \text{H}_2\text{O} + \text{N}_2\text{H}_2\text{O}_2$. The best argument in favour of the doubled formula is the property possessed by hyponitrous acid of forming acid salts, HNaN_2O_2 (Zorn), and also the determination of its molecular weight in solution by the method described in the following chapter.

According to Thum, the following are the properties of hyponitrous acid. When liberated from the dry silver salt by the action of dry sulphuretted hydrogen, hyponitrous acid is unstable, and easily explodes even at low temperatures. But when dissolved in water (having been formed by the action of hydrochloric acid upon the silver salt), it is stable even when boiled with dilute acids or alkalis. The solution is colourless and has a strongly acid reaction. In the course of time, however, the aqueous solution also decomposes into nitrous oxide and water. The complete oxidation by permanganate of potash proceeds according to the following equation: $5\text{H}_2\text{N}_2\text{O}_2 + 8\text{KMnO}_4 + 12\text{H}_2\text{SO}_4 = 10\text{HNO}_3 + 4\text{K}_2\text{SO}_4 + 8\text{MnSO}_4 + 12\text{H}_2\text{O}$. In alkaline solution, KMnO_4 only oxidises hyponitrous acid into nitrous and not into nitric acid. Nitrous acid has a decomposing action upon hyponitrous acid, and if the aqueous solutions of the two acids be mixed together they immediately give off oxides of nitrogen. Hyponitrous acid does not liberate CO_2 from its salts, but, on the other hand, it is not displaced by CO_2 .

of certain metals—for instance, of zinc ⁶⁸—gives nitrous oxide, although in this case mixed with nitric oxide. The usual method of preparing nitrous oxide consists in the decomposition of ammonium nitrate by the aid of heat, because in this case only water and nitrous oxide are formed, $\text{NH}_4\text{NO}_3 = 2\text{H}_2\text{O} + \text{N}_2\text{O}$ (a mixture of NH_4Cl and KNO_3 is sometimes taken). The decomposition ⁶⁹ proceeds very easily in an apparatus like that used for the preparation of ammonia or oxygen—that is, in a retort or flask with a gas-conducting tube. The decomposition must, however, be carried on carefully, as otherwise nitrogen is formed from the decomposition of the nitrous oxide.⁷⁰

Nitrous oxide is a colourless gas with a faint but characteristic smell. It is somewhat soluble in cold water, but only slightly soluble in warm water (and is therefore collected over warm water). It is not a permanent gas (absolute boiling-point $+39^\circ$), that is, it is easily liquefied by the action of cold under a high pressure; at 15° it may be liquefied by a pressure of about 40 atmospheres. The gas is usually liquefied by means of the force pump ⁷¹ shown in fig. 59. As it is liquefied with comparative ease, and as the cold produced by its vaporisation is very considerable,⁷² it is often employed (as also is liquid carbonic anhydride) in investigations requiring a low temperature.

⁶⁸ It is remarkable that electro-deposited copper powder gives nitrous oxide with a 10 per cent. solution of nitric acid, whilst ordinary copper gives nitric oxide. It is here evident that the physical and mechanical structure of the substance affects the course of the reaction—that is to say, it is a case of contact or surface action.

⁶⁹ This decomposition is accompanied by the evolution of about 25,000 calories per gram-molecule, NH_4NO_3 , and therefore takes place with ease, and sometimes with an explosion.

⁷⁰ In order to remove any nitric oxide that might be present, the gas obtained is passed through a solution of ferrous sulphate. As nitrous oxide is very soluble in cold water (at 0° , 100 volumes of water dissolve 130 volumes of N_2O ; at 20° , 67 volumes), it must be collected over warm water. The nitrous oxide is much more soluble than nitric oxide, which is in agreement with the fact that nitrous oxide is much more easily liquefied than nitric oxide. Villard obtained a crystallohydrate, $\text{N}_2\text{O} \cdot 6\text{H}_2\text{O}$, which was tolerably stable at 0° .

⁷¹ Faraday obtained liquid nitrous oxide by the same method as he employed for liquid ammonia, by heating dry ammonium nitrate in a closed bent tube, one arm of which was immersed in a freezing mixture. In this case two layers of liquid are obtained at the cooled end, a lower layer of water and an upper layer of nitrous oxide. This experiment should be conducted with great care, as the pressure of the nitrous oxide in a liquid state is considerable, namely (according to Regnault), at $+10^\circ$, 45 atmospheres, at 0° , 36 atmospheres, at -10° , 29 atmospheres, and at -20° , 23 atmospheres. It boils at about -90° , and the pressure is then of course 1 atmosphere.

⁷² Liquid nitrous oxide, in vapourising at the same pressures as liquid carbonic anhydride, gives rises to almost equal or even slightly lower temperatures. Thus at a pressure of 25 mm. carbonic anhydride gives a temperature as low as -115° , and nitrous oxide -125° (Dewar). The similarity of these properties and even of the absolute boiling-point ($\text{CO}_2 + 32^\circ$, $\text{N}_2\text{O} + 36^\circ$) is all the more remarkable because these gases have the same molecular weight, namely, 44.

Liquid nitrous oxide is a very mobile, colourless liquid, which boils at -89.8° , acts on the skin, and is incapable of oxidising potassium, phosphorus, or carbon; its specific gravity is slightly less than that of water (0.910 at 0° , 0.856 at 10° , 0.60 at 35° , and 0.45 at

FIG. 59.—Natterer's apparatus for the preparation of liquid nitrous oxide and carbonic anhydride. The gas first passes through the vessel V, for drying, and then into the pump (a section of the upper part of the apparatus is given on the left). The piston *t* of the force pump is moved by the crank E and fly-wheel turned by hand. The gas is pumped into the iron chamber A, where it is liquefied. The valve S allows the gas to enter A, but not to escape from it. The chamber and pump are cooled by the jacket B, filled with ice. When the gas is liquefied the vessel A is unscrewed from the pump, and the liquid may be poured from it by inverting it and unscrewing the valve *r*, when the liquid runs out of the tube *x*.

39° ; Villard, 1894). When it is evaporated under the receiver of an air-pump, its temperature falls to -100° , and the liquid solidifies into a snowlike mass, and partially forms transparent crystals. Both these substances are solid nitrous oxide. It melts at about -102° .⁷³

⁷³ A very characteristic experiment of simultaneous combustion and intense cold may be performed by means of liquid nitrous oxide; if liquid nitrous oxide be poured

When introduced into the respiratory organs (and consequently, owing also to its solubility, in the blood) nitrous oxide produces a peculiar kind of intoxication accompanied by spasmodic movements, and hence this gas, discovered by Priestley in 1776, received the name of *laughing gas*. On prolonged respiration it produces a state of insensibility (it is an anæsthetic like chloroform), and is therefore employed in dental and surgical operations, but too prolonged respiration causes death.

Nitrous oxide is easily decomposed into nitrogen and oxygen by the action either of heat, or of a series of electric sparks; and this explains why a number of substances which cannot burn in nitric oxide do so with great ease in nitrous oxide. In fact, when nitric oxide yields oxygen on decomposition, it immediately absorbs it, forming NO_2 ; whilst nitrous oxide does not possess this capacity for further combination with oxygen.⁷⁴ A mixture of nitrous oxide with hydrogen explodes like detonating gas, gaseous nitrogen being formed, $\text{N}_2\text{O} + \text{H}_2 = \text{H}_2\text{O} + \text{N}_2$. The volume of the remaining nitrogen is equal to that of the original nitrous oxide, and also to that of the hydrogen entering into combination with the oxygen; hence in this reaction equal volumes of nitrogen and hydrogen replace each other. Nitrous oxide is also very easily decomposed by red-hot metals; also sulphur, phosphorus, and charcoal burn in it, although not so brilliantly as in oxygen. A substance in burning in nitrous oxide evolves more heat than an equal quantity burning in oxygen; which clearly shows that in the formation of nitrous oxide by the combination of nitrogen with oxygen there is not an evolution but an absorption of heat, there being no other source for the excess of heat in the combustion of substances in nitrous oxide (see note 28). If a given volume of nitrous oxide be decomposed by a metal—for instance sodium—there remains, after cooling, a volume of nitrogen exactly equal to that of the nitrous oxide taken; consequently the oxygen is, as it were, distributed between the atoms of nitrogen without producing an increase in the volume of the nitrogen.

into a test tube containing mercury the latter will solidify, and if a piece of red-hot charcoal be thrown upon the surface of the nitrous oxide it will continue to burn very brilliantly, giving rise to a high temperature.

⁷⁴ In the following chapter we shall consider the volumetric composition of the oxides of nitrogen, which will explain the difference between nitric and nitrous oxides. Nitrous oxide is formed with a diminution of volume (contraction), but nitric oxide without contraction, its volume being equal to the sum of the volumes of the nitrogen and oxygen of which it is composed. By oxidation, if this could be directly accomplished, two volumes of nitrous oxide and one volume of oxygen would not give three but four volumes of nitric oxide. These facts must be taken into consideration in comparing the heats of formation, the capacities for supporting combustion, and other properties of nitrous and nitric oxides, N_2O and NO .

Although nitrous oxide, N_2O , is not absorbed by caustic alkalies, for instance, NaHO , nor by basic oxides, for instance, PbH_2O_2 , yet saline compounds such as N_2NaHO_2 or PbN_2O_2 and their corresponding **hyponitrous acid**, $\text{N}_2\text{H}_2\text{O}_2$, forming as it were the hydrate of nitrous oxide, are known and are formed in the decomposition of nitrous oxide (see note 67). The salts of hyponitrous acid are best formed by the reduction (by sodium amalgam, hydrated ferrous oxide, &c.) of the salts of nitrous acid, or by their double decomposition with the salts of hydroxylamine.

⁷⁵ It is said that a peculiar isomeride of hyponitrous acid— $\text{N}_2\text{H}_2\text{O}_2$ —is obtained from nitrourethane, $\text{C}_3\text{H}_6\text{N}_2\text{O}_4$, but this question is not sufficiently certain to be treated of in an elementary text-book.

CHAPTER VII

MOLECULES AND ATOMS. THE LAWS OF GAY-LUSSAC AND AVOGADRO-GERHARDT.

HYDROGEN combines with oxygen in the proportion of two volumes to one. The composition by volume of nitrous oxide is exactly similar—this gas being composed of two volumes of nitrogen and one volume of oxygen. By decomposing ammonia by the action of an electric spark it is easy to prove that it contains one volume of nitrogen to three volumes of hydrogen. So, similarly, whenever a compound is decomposed and the **volumes of the gases** proceeding from it are measured, it is found that the volumes of the gases or vapours entering into combination stand in very simple relations to one another. With water, nitrous oxide, &c., this may be proved by direct observation; but in the majority of cases, and especially with substances which, although volatile—that is, capable of passing into a gaseous (or vaporous) state—are liquid at the ordinary temperature, such a direct method of observation presents many difficulties. But, then, if the densities of the vapours and gases be known, the same simplicity in their ratio is shown by calculation. The volume of a substance is proportional to its weight, and inversely proportional to its density, and therefore by dividing the amount by weight of each substance entering into the composition of a compound by its density in the gaseous or vaporous state we shall obtain factors which will be in the same proportion as the volumes of the substances entering into the composition of the compound.¹ Thus, for example, water contains eight parts by weight of oxygen to one part by weight of hydrogen, and their densities are 16

¹ If the weight be indicated by P, the density by D, and the volume by V, then

$$\frac{P}{D} = KV$$

where K is a coefficient depending on the method of expressing P, D, and V. But, whatever it be, K is cancelled in dealing with the comparison of volumes, because comparative and not absolute measures of volumes are taken. In this chapter, as throughout the book, the weight P is given in grams in dealing with absolute weights; and if comparative, as in the expression of chemical composition, then the weight of an atom of oxygen is taken as 16, and that of an atom of hydrogen as 1.008.

and 1; consequently their volumes (or the above-mentioned factors) are 1 and $\frac{1}{2}$, and therefore it is seen without direct experiment that water contains two volumes of hydrogen for every one volume of oxygen. So also, knowing that nitric oxide contains fourteen parts of nitrogen and sixteen parts of oxygen, and knowing that the specific gravities of these last two gases are fourteen and sixteen, we see that the volumes in which nitrogen and oxygen combine for the formation of nitric oxide are in the proportion of 1 : 1. We will cite another example. In the last chapter we saw that the density of NO_2 only becomes constant and equal to twenty-three (referred to hydrogen) above 135° , and as a matter of fact a method of direct observation of the volumetric composition of this substance would be very difficult at so high a temperature. But it may be easily calculated. NO_2 , as is seen from its formula and analysis, contains thirty-two parts by weight of oxygen and fourteen parts by weight of nitrogen, forming forty-six parts by weight of NO_2 , and knowing the densities of these gases we find that one volume of nitrogen with two volumes of oxygen gives two volumes of nitrogen peroxide. Therefore, knowing the amounts by weight of the substances participating in a reaction or forming a given substance, and knowing the densities of the gases or vapours,² the

² As the volumetric relations of vapours and gases, next to the relations of substances by weight, form the most important province of chemistry, and a very important means for the attainment of chemical conclusions, and as, further, these volumetric relations are determined by the densities of gases and vapours, the **methods of determining the densities** of vapours (and also of gases) are necessarily important factors in chemical research. These methods are described in detail in works on physics and physical and analytical chemistry, and therefore we here only touch on the general principles involved.

If we know the weight p of the vapour of a given substance and the volume v , occupied by it at a temperature t and pressure h , its density may be directly obtained by dividing p by the weight of a volume v of hydrogen (if the density be expressed relatively to that of hydrogen, see Chapter II., note 23) at t and h . Hence the methods of determining the densities of vapours and gases are based on the determination of p , v , t , and h . The last two data (the temperature t and pressure h) are given by the thermometer and barometer and the heights of mercury or other liquid confining the gas, and therefore do not require further explanation. It need only be remarked that: (1) In the case of readily volatile liquids there is no difficulty in procuring a bath with a constant temperature, but that it is nevertheless best (especially considering the inaccuracy of thermometers) to have a medium of absolutely constant temperature, and therefore to take either a bath in which some substance is melting—such as one of melting ice at 0° or one of crystals of sodium acetate, melting at $+56^\circ$ —or, as is more generally practised, to place the vessel containing the substance to be experimented with in the vapour of a liquid boiling at a definite temperature, and knowing the pressure under which it is boiling, to determine the temperature of the vapour. For this purpose the boiling-points of water at different pressures are given in Chapter I., note 11, and the boiling-points of certain easily procurable liquids at various pressures are given in Chapter II., note 27. (2) With respect to temperatures above 300° these are most simply obtained constant (to give time for the volume of a substance being observed, and to allow it to attain the calculated temperature t) by means of substances boiling at a high temperature. Thus, for instance, at the

volumetric relations of the substances taking part in a reaction or entering into the composition of a compound, may also be determined.

ordinary atmospheric pressure the temperature t of the vapour of *sulphur* is about 445° , of phosphorus pentasulphide 518° , of tin chloride 606° , of cadmium 770° , of zinc 930° (according to Violle and others), or 1040° (according to Deville), &c. (3) The indications of the thermometer must be corrected in the manner described in text-books of physics. (4) The temperature of the vapour used as the bath should in every case be several degrees higher than the boiling-point of the liquid whose density is to be determined, in order that no portion may remain in a liquid state. But even in this case, as is seen from the example of nitric peroxide (Chapter VI.), the vapour density does not always remain constant with a change of t , as it should do were the law of the expansion of gases and vapours absolutely exact (Chapter II., note 25). If variations of a chemical and physical nature, similar to that which we saw in nitric peroxide, take place in the vapours,

FIG. 60.—Apparatus for determining the vapour density by Dumas' method. A small quantity of the liquid whose vapour density is to be determined is placed in the glass globe, and heated in a water or oil bath to a temperature above the boiling-point of the liquid. When all the liquid has been converted into vapour and has displaced all the air from the globe, the latter is sealed up and weighed. The capacity of the globe is then measured, and in this manner the volume occupied by a known weight of vapour at a known temperature is determined.

FIG. 61.—Deville and Troost's apparatus for determining the vapour densities by Dumas' method, of substances which boil at high temperatures. A porcelain globe containing the substance whose vapour density is to be determined is heated in the vapour of mercury (350°), sulphur (410°), cadmium (850°), or zinc (1040°). The globe is sealed up in an oxyhydrogen flame.

the main interest is centred in *constant* densities, which do not vary with t , and therefore the possible effect of t on the density must always be kept in mind in having recourse to this means of investigation. (5) Usually, for the sake of convenience of observation, the vapour density is determined at the atmospheric pressure, which is read on the barometer; but in the case of substances which are volatilised with difficulty, and also of substances which decompose, or, in general, vary at temperatures near their boiling-points, it is best or even indispensable to conduct the determination at low pressures; whilst for substances which decompose at low pressures the observations have to be conducted under a more or less considerably increased pressure. (6) In many cases it is convenient to determine the vapour density of a substance in admixture with other gases, and consequently under a partial pressure, which may be calculated from the volume of the mixture and that of the intermixed gas (see Chap. I., note 1). This method is especially important for substances which are easily decomposable, because, as shown by the phenomena of

Such an investigation (either direct or by calculation from the densities and composition) of every chemical reaction resulting in the formation of a substance is able to remain unchanged in the atmosphere of one of its products of decomposition. Thus, Wurtz determined the density of phosphoric

FIG. 62.—Hofmann's apparatus for determining vapour densities. The internal tube, which is about one metre long, and is calibrated and graduated, is filled with mercury and inverted in a mercury bath. A small bottle (depicted in its natural size on the left) containing a weighed quantity of the liquid whose vapour density is to be determined, is introduced into the Torricellian vacuum. Steam, or the vapour of amyl alcohol, &c., is passed through the outer tube, and heats the internal tube to the temperature t , at which the volume of vapour is measured.

FIG. 63.—Victor Meyer's apparatus for determining vapour densities. The tube b is heated in the vapour of a liquid of constant boiling-point. A glass tube, containing the liquid to be experimented upon, is caused to fall from d . The air displaced is collected in the cylinder e , in the trough f .

chloride, PCl_5 , in admixture with the vapour of phosphorous chloride, PCl_3 . If the relative density does not vary with the pressure and temperature (at least, to an extent appreciably exceeding the limits of experimental error), then this *constant* density indicates the *gaseous* and *invariable* state of a substance. The laws hereafter laid down refer only to such vapour densities. But the majority of volatile substances show such a constant density at a certain degree above their boiling-points up to the

tion of definite chemical compounds, shows that the volumes of the reacting substances in a gaseous or vaporous state are either equal or are in simple multiple proportion.³ This forms the **first law** of those discovered

starting-point of decomposition. Thus, the density of aqueous vapour hardly varies from the ordinary temperature up to 1000° (there are no trustworthy determinations beyond this) and for pressures varying from fractions of an atmosphere up to several atmospheres. If, however, the density does vary considerably with a variation of p and t , it may serve as a guide for the investigation of the chemical changes which are undergone by the substance in a state of vapour, or at least as an indication of a deviation from the laws of Boyle-Mariotte and Gay-Lussac (for the expansion of gases with t). In certain cases the separation of one form of deviation from the other may be explained by special hypotheses.

With respect to the means of determining p and v , with a view to finding the vapour density, we may distinguish three chief methods: (*a*) by weight, that is, by ascertaining the weight of a definite volume of vapour; (*b*) by volume, that is, by measuring the volume occupied by the vapour of a definite weight of a substance; and (*c*) by displacement. The last mentioned is essentially volumetric, because a known weight of a substance is taken, and the volume of the air displaced by the vapour at a given t and p is determined.

The method by weight (*a*) is the most trustworthy and historically important. **Dumas' method** is typical. An ordinary spherical glass or porcelain vessel, like those shown respectively in figs. 60 and 61, is taken, and an excess of the substance to be experimented upon is introduced into it. The vessel is heated to a temperature t° , higher than the boiling-point of the liquid; this gives a vapour which displaces the air, and fills the spherical space. When the air and vapour cease escaping from the sphere, the latter is fused up or closed by some means; and when cool, the weight of the vapour remaining in the sphere is determined (either by direct weighing of the vessel with the vapour and introducing the necessary corrections for the weight of the air and of the vapour itself, or by determining the weight of the volatilised substance by chemical methods), and the volume of the vapour at t and the barometric pressure h are then calculated.

The volumetric method (*b*) originally employed by Gay-Lussac and then modified by Hofmann and others is based on the principle that a weighed quantity of the liquid to be experimented with (placed in a small closed vessel, which is sometimes fused up before weighing, and, if quite full of the liquid, breaks when heated in a vacuum) is introduced into a graduated cylinder heated to t , or simply into a Torricellian vacuum, as shown in fig. 62, and the number of volumes occupied by the vapour noted when the space holding it is heated to the desired temperature t .

The method of displacement (*c*) proposed by Victor Meyer is based on the fact that a space b is heated to a constant temperature t (by the surrounding vapours of a liquid of constant boiling-point), and the air (or other gas enclosed in this space) is allowed to attain this temperature, and when it has done so a glass bulb containing a weighed quantity of the substance to be experimented with is dropped into the space. The substance is immediately converted into vapour, and displaces the air into the graduated cylinder c . The amount of this air is calculated from its volume, and hence the volume at t° , and therefore also the volume occupied by the vapour, is found. The general arrangement of the apparatus is given in fig. 63.

³ Vapours and gases, as already explained in the second chapter, are subject to the same laws, which are, however, only approximate. It is evident that for the deduction of the laws which will presently be enunciated it is only possible to take into consideration a perfect gaseous state (far removed from the liquid state) and chemical invariability in which the *vapour density is constant*—that is, the volume of a given gas or vapour varies, like a volume of hydrogen, air, or other gas, with the pressure and temperature.

It is necessary to make this statement in order that it may be clearly seen that the laws of gaseous volumes, which we shall describe presently, are in the most intimate connection with the laws of the variation of volume with pressure and temperature. And as these latter laws (Chap. II.) are not infallible but only approximately exact, the

by **Gay-Lussac**. It may be formulated as follows: *The amounts of substances entering into chemical reaction occupy under similar physical conditions, in a gaseous or vaporous state, equal or simple multiple volumes.* This law refers, not only to elements, but also to compounds entering into chemical combination. Thus, for example, one volume of ammonia gas combines with one volume of hydrogen chloride; for in the formation of sal-ammoniac, NH_4Cl , there enter into reaction 17 parts by weight of ammonia, NH_3 , which is 8.5 times denser than hydrogen, and 36.5 parts by weight of hydrogen chloride, whose vapour density is 18.25 times that of hydrogen, as has been proved by direct experiment. By dividing the weights by the respective densities we find that the volume of ammonia, NH_3 , is equal to two, and so also is the volume of hydrogen chloride. Hence the volumes of the compounds which here combine are equal. Taking into consideration that the law of Gay-Lussac holds good, not only for elements, but also for compounds, it should be expressed as follows: **Substances interact with one another in commensurable volumes of their vapours.**⁴

The law of combining volumes and the law of multiple proportion were discovered independently of each other—the one in France by Gay-Lussac, the other in England by Dalton—almost simultaneously. In the language of the atomic hypothesis it may be said that atomic quantities of elements occupy in the gaseous state equal or multiple volumes.

The first law of Gay-Lussac expresses the relation between the volumes of the component parts of a compound. Let us now consider the relation existing between the volumes of the component parts and those of the compounds which proceed from them. This may sometimes be determined by direct observation. Thus the volume occupied by water, formed by two volumes of hydrogen and one volume of oxygen, may be determined by the aid of the apparatus shown in fig. 64. The long same is the case with the laws about to be described. And as it is possible to find more exact laws (a second approximation) for the variation of v with p and t (for example, van der Waals' formula, Chap. II., note 33), so also a more exact expression of the relation between the composition and the density of vapours and gases is possible. But to prevent any doubt arising at the very beginning as to the extent and general application of the laws of volumes, it will be sufficient to mention that the densities of such gases as oxygen, nitrogen, and carbonic anhydride are already known to *remain constant* (within the limits of experimental error) between the ordinary temperature and a white heat; whilst, judging from what is said in my work on the 'Pressure of Gases' (vol. i., p. 9), it may be said that, as regards pressure, the relative density remains very constant, even when the deviations from Mariotte's law are very considerable. However, in this respect the number of data is as yet too small to allow of an exact conclusion.

⁴ We must recollect that this law is only approximate, like Boyle and Mariotte's law, and that, therefore, like the latter, a more exact expression may be found for the exceptions.

FIG. 64.—Apparatus for determining the volume occupied by the steam formed by the explosion of detonating gas.

glass tube is closed at the top and open at the bottom, which is immersed in a cylinder containing mercury. The closed end is furnished with wires like a eudiometer. The tube is filled with mercury, and then a certain volume of detonating gas is introduced. This gas is obtained from the decomposition of water, and therefore, in every three volumes, contains two volumes of hydrogen and one volume of oxygen. The tube is surrounded by a second and wider glass tube, and the vapour of a substance boiling above 100° —that is, whose boiling-point is higher than that of water—is passed through the annular space between them. Amyl alcohol, whose boiling-point is 132° , may be taken for this purpose. The amyl alcohol is boiled in the vessel to the right hand and its vapour passed between the walls of the two tubes. In the case of amyl alcohol the outer glass tube should be connected with a condenser to prevent the escape into the air of the unpleasant-smelling vapour. The detonating gas is thus heated up to a temperature of 132° . When its volume becomes constant it is measured, the height of the column of mercury in the tube above the level of the mercury in the cylinder being noted. Let this volume equal v ; it will therefore contain $\frac{1}{3}v$ of oxygen and $\frac{2}{3}v$ of hydrogen. The current of vapour is then stopped and the gas exploded; water is formed, which condenses into a liquid. The volume occupied by the vapour of the water formed has now to be determined. For this purpose the vapour of the amyl alcohol is again passed between the tubes, and thus the whole of the water formed is converted into vapour at the same temperature as that at which the detonating gas was measured; and the cylinder of mercury being raised until the column of mercury in the tube stands at the same height above the surface of the mercury in the cylinder as it did before the explosion, it is found that the volume of the water formed is equal to $\frac{2}{3}v$, that is, it is equal to the volume of the hydrogen contained in it. Consequently the volumetric composition of water is expressed in the following terms: Two volumes of hydrogen combine with one volume of oxygen to form two volumes of aqueous vapour. For substances which are gaseous at the ordinary temperature this direct method of observation is sometimes very easily carried out; for instance, with ammonia and with nitric and nitrous oxides. Thus to determine the composition by volume of nitrous oxide, the above-described apparatus may be employed. Nitrous oxide is introduced into the tube, and, after measuring its volume, electric sparks are passed through the gas; it is then found that two volumes of nitrous oxide have given three volumes of gases—namely, two volumes of nitrogen and one volume of oxygen. Consequently the composition of nitrous oxide is similar to that of water; two volumes of nitrogen and one

volume of oxygen give two volumes of nitrous oxide. By decomposing ammonia it is found to be composed in such a manner that two volumes of it give one volume of nitrogen and three volumes of hydrogen; also two volumes of nitric oxide are formed by the union of one volume of oxygen with one volume of nitrogen. The same relations may be proved by calculation from the vapour densities, as was described above.

Comparisons of various results made by the aid of direct observations or calculation, an example of which has just been cited, led Gay-Lussac to the conclusion that *the volume of a compound in a gaseous or vaporous state is always in simple multiple proportion to the volume of each of the component parts of which it is formed* (and consequently to the sum of the volumes of the elements of which it is formed). This is the **second law of Gay-Lussac**; it extends the simplicity of the volumetric relations to compounds, and is of the same nature as that presented by the elements entering into mutual combination. Hence not only the substances forming a given compound, but also the substances formed, exhibit a simple relation of volume when measured as vapour or gas.⁵

When a compound is formed from two or more components, there may or may not be a contraction; the volume of the reacting substances is in this case either equal to or greater than the volume of the resultant compound. The reverse is naturally observed in the case of decompositions, when from one substance there are produced several of simpler nature. Therefore in the future we shall term **combination** a reaction in which a contraction is observed—that is, a diminution in the volume of the component bodies in a state of vapour or gas; and we shall term **decomposition** a reaction in which an expansion is produced; while those reactions in which the volumes in a gaseous or vaporous state remain constant (the volumes being naturally compared at the same temperature and pressure) we shall term reactions of **substitution** or of double decomposition. Thus the transition of oxygen into ozone is a reaction of combination, the formation of nitrous oxide from oxygen and nitrogen will also be a combination, the formation of nitric oxide from the same will be a reaction of

⁵ This second law of volumes may be considered as a consequence of the first law. The first law requires simple ratios between the volumes of the combining substances *A* and *B*. A substance *AB* is produced by their combination. It may, according to the law of multiple proportion, combine, not only with substances *C*, *D*, &c., but also with *A* and with *B*. In this new combination the volume of *AB*, combining with the volume of *A*, should be in simple multiple proportion with the volume of *A*; hence the volume of the compound *AB* is in simple proportion to the volume of its component parts. Therefore only one law of volumes need be accepted. We shall afterwards see that the third law of volumes (Avogadro-Gerhardt) also embraces the first two laws.

substitution, the action of oxygen on nitric oxide a combination, and so on.

The amount of contraction produced in the formation of chemical compounds not infrequently leads to the possibility of distinguishing the degree of change which takes place in the chemical character of the components when combined. In those cases in which a contraction occurs, the properties of the resultant compounds are very different from the properties of the substances of which it is composed. Thus ammonia bears no resemblance in its physical or chemical properties to the elements from which it is derived; a contraction takes place in a state of vapour (two volumes of ammonia being formed from three volumes of hydrogen and one volume of nitrogen), indicating a proximation of the elements—the distance between the atoms is diminished, and from gaseous substances there is formed a liquid substance, or at any rate one which is easily liquefied. For this reason nitrous oxide, formed by the condensation of two permanent gases, is a substance which is somewhat easily converted into a liquid; again, nitric acid, which is formed from elements which are permanent gases, is a liquid, whilst, on the contrary, nitric oxide, which is formed without contraction and is decomposed without expansion, remains a gas which is as difficult to liquefy as nitrogen and oxygen. In order to obtain a still more complete idea of the dependence of the properties of a compound on the properties of the component substances, it is further necessary to know the quantity of heat which is developed in the formation of the compound. If this quantity be large—as, for example, in the formation of water—then the amount of energy in the resultant compound will be considerably less than the energy of the elements entering into its composition; whilst, on the contrary, if the amount of heat evolved in the formation of a compound be small, or if there be an absorption of heat, as in the formation of nitrous oxide, the energy of the elements is not destroyed, or is only altered to a slight extent; hence, notwithstanding the contraction (compression) involved in its formation, nitrous oxide supports combustion.

The preceding laws were deduced from purely experimental and empirical data, and as such evoke further consequences, as the law of multiple proportions gave rise to the atomic theory and to the law of equivalents (Chapter IV.). In view of the atomic conception of the constitution of substances, the question naturally arises as to what, then, are the relative volumes proper to those physically indivisible molecules which chemically react on each other and consist of the atoms of elements. The simplest possible hypothesis in this respect would be that the volumes of the molecules of substances are equal; or,

what is the same thing, to suppose that equal volumes of vapours and gases contain an equal number of molecules. This proposition was first enunciated by the Italian savant **Avogadro** in 1810. It was also admitted by the French physico-mathematician **Ampère** (1815) for the sake of simplifying all kinds of physico-mathematical conceptions respecting gases. But Avogadro and Ampère's propositions were not generally received in science until after **Gerhardt** in the forties had applied them to the generalisation of chemical reactions, and had demonstrated, by aid of a series of phenomena, that the reactions of substances actually take place with the greatest simplicity, and more especially that such reactions take place between those quantities of substances which occupy equal volumes, and until he had stated the hypothesis in an exact manner and deduced the consequences that necessarily follow from it. Following Gerhardt, Clausius, in the fifties, placed this hypothesis of the equality of the numbers of molecules in equal volumes of gases and vapours on the basis of the kinetic theory of gases. At the present day the hypothesis of Avogadro and Gerhardt lies at the basis of contemporary physical, mechanical, and chemical conceptions; the consequences arising from it have often been subject to doubt, but in the end have been verified by the most diverse methods; and now, when all efforts to refute those consequences have proved fruitless, the hypothesis must be considered as verified,⁶ and the **law of Avogadro-Gerhardt** must be spoken of as fundamental, and as of great importance for the comprehension of the phenomena of nature. The law may now be formulated from two points of view. In the first place, from a physical aspect, **equal volumes of gases** (or vapours) at the same temperature and pressure **contain the same number of molecules**—or of particles of matter which are neither mechanically nor physically divisible—previous to chemical change. In the second place, from a chemical aspect, the same law may be expressed thus: **the quantities of substances entering into chemical reactions occupy, in a state of vapour or gas, equal volumes**. For our purpose, the chemical aspect is the more important, and therefore, before developing the law and its consequences, we will consider the chemical phenomena from which the law is deduced or which it serves to explain.

⁶ It must not be forgotten that Newton's law of gravity was first an hypothesis, but it became a trustworthy, perfect theory, and acquired the qualities of a fundamental law owing to the concord between its deductions and actual facts. All laws, all theories, of natural phenomena are at first hypotheses. Some are rapidly established by their consequences exactly agreeing with facts, others only take root by slow degrees; and there are many which are refuted owing to their consequences being found to be at variance with facts; while others are retained only because of their possibility and of some convenience or other in their application, but not permanently unless their consequences can be verified in their different aspects and completely.

When two isolated substances interact with each other directly and easily, it is found that the reaction is accomplished between quantities which in a gaseous state occupy equal volumes. Thus ammonia, NH_3 , reacts directly with hydrochloric acid, HCl , forming sal-ammoniac, NH_4Cl , and in this case the 17 parts by weight of ammonia occupy the same volume as the 36.5 parts by weight of hydrochloric acid.⁷ Ethylene, C_2H_4 , combines with chlorine, Cl_2 , in only one proportion, forming ethylene dichloride, $\text{C}_2\text{H}_4\text{Cl}_2$, and this combination proceeds directly and with great facility, the reacting quantities occupying equal volumes. Chlorine reacts with hydrogen in only one proportion, forming hydrochloric acid, HCl , and in this case equal volumes interact with each other. An equality of volumes is also observed in cases of decomposition, taking place in substances which split up into two others. Indeed, acetic acid breaks up into marsh gas, CH_4 , and carbonic anhydride, CO_2 , and in the proportions in which they are formed from acetic acid they occupy equal volumes. From phthalic acid, $\text{C}_8\text{H}_6\text{O}_4$, there may be obtained benzoic acid, $\text{C}_7\text{H}_6\text{O}_2$, and carbonic anhydride, CO_2 , and as all the elements of phthalic acid enter into the composition of these substances, it follows that, although they cannot re-form it by their direct action on each other (the reaction is not reversible), still they form the direct products of its decomposition, and they occupy equal volumes. But benzoic acid, $\text{C}_7\text{H}_6\text{O}_2$, is itself composed of benzene, C_6H_6 , and carbonic anhydride, CO_2 , which also occupy equal volumes.⁸ There is an immense number of similar examples among those organic substances to whose study Gerhardt consecrated his whole life and work, and he did not allow such facts as these to escape his attention. Still more frequently in the phenomena of substitution, when two substances react on each other, and two are produced without a change of volume, it is found that the two sub-

⁷ This is not only seen from the above calculations, but may be proved by experiment. A glass tube, divided in the middle by a stopcock, is taken and one portion filled with dry hydrogen chloride (the dryness of the gases is very necessary, because ammonia and hydrogen chloride are both very soluble in water, so that a small trace of water may contain a large amount of these gases in solution) and the other with dry ammonia, under the atmospheric pressure. One orifice (for instance, of that portion which contains the ammonia) is firmly closed, and the other is immersed under mercury, and the cock is then opened. Solid sal-ammoniac is formed, but if the volume of one gas be greater than that of the other, some of the first gas will remain. By immersing the tube in the mercury in order that the internal pressure shall equal the atmospheric pressure, it may easily be shown that the volume of the remaining gas is equal to the difference between the volumes of the two portions of the tube, and that this remaining gas is part of that whose volume was the greater.

⁸ Let us demonstrate this by figures. From 122 grams of benzoic acid there are obtained (a) 78 grams of benzene, whose density referred to hydrogen is 39, hence its relative volume is 2; and (b) 44 grams of carbonic anhydride, whose density is 22, and hence the volume is 2. It is the same in other cases.

stances acting on each other, as well as each of the two resulting substances, occupy equal volumes. Thus, in general, reactions of substitution take place between volatile acids, HX , and volatile alcohols, $R(OH)$, with the formation of ethereal salts, RX , and water, $H(OH)$, and the volume of the vapour of the reacting quantities, HX , $R(OH)$, and RX , is the same as that of water $H(OH)$, whose weight, corresponding with the formula, 18, occupies 2 volumes, if 1 part by weight of hydrogen occupy 1 volume and the density of aqueous vapour referred to hydrogen is 9. Such general examples, of which there are many,⁹ show that the reaction of equal volumes forms a chemical phenomenon of frequent occurrence, indicating the necessity for acknowledging the law of Avogadro-Gerhardt.

But the question arises, What is the relation of volumes if reaction between two substances takes place in more than one proportion, according to the law of multiple proportions? A definite answer can only be given in cases which have been very thoroughly studied. Thus chlorine, in acting on marsh gas, CH_4 , forms four compounds, CH_3Cl , CH_2Cl_2 , $CHCl_3$, and CCl_4 , and it may be established by direct experiment that the substance CH_3Cl (methyl chloride) precedes the remainder, and that the latter proceed from it by the further action of chlorine. And this substance, CH_3Cl , is formed by the reaction of equal volumes of marsh gas, CH_4 , and chlorine, Cl_2 , according to the equation $CH_4 + Cl_2 = CH_3Cl + HCl$. A great number of similar cases are met with amongst organic—that is, carbon—compounds. Gerhardt was led to the discovery of his law by investigating many such reactions, and by observing that in them the reaction of equal volumes precedes all others.

But if nitrogen or hydrogen gives several compounds with oxygen, the question proposed above cannot be answered with complete clearness, because the successive formation of the different combinations cannot be so strictly defined. It may be supposed, but neither definitely affirmed nor experimentally confirmed, that nitrogen and oxygen first give nitric oxide, NO , and only subsequently the brown vapours N_2O_3 and NO_2 . Such a sequence in the combination of

⁹ A large number of such generalised reactions, showing reaction by equal volumes, occur in the case of the hydrocarbon derivatives, because many of these compounds are volatile. The reactions of alkalies on acids, or anhydrides on water, &c., which are so frequent between mineral substances, present but few such examples, because many of these substances are not volatile and their vapour densities are unknown. But essentially the same is seen in these cases also; for instance, sulphuric acid, H_2SO_4 , breaks up into the anhydride, SO_3 , and water, H_2O , which exhibit an equality of volumes. Let us take another example where three substances combine in equal volumes: carbonic anhydride, CO_2 , ammonia, NH_3 , and water, H_2O (the volumes of all are equal to 2), form acid ammonium carbonate, $(NH_4)HCO_3$.

nitrogen with oxygen can only be assumed on the basis of the fact that NO forms N_2O_3 and NO_2 directly with oxygen. If it be admitted that NO (and not N_2O or NO_2) be first formed, then this instance would also confirm the law of Avogadro-Gerhardt, because nitric oxide contains equal volumes of nitrogen and oxygen. So, also, it may be admitted that, in the combination of hydrogen with oxygen, hydrogen peroxide is first formed (equal volumes of hydrogen and oxygen), which is decomposed by the heat evolved into water and oxygen. This explains the presence of traces of hydrogen peroxide (Chapter IV.) in almost all cases of the combustion or oxidation of hydrogenous substances; for it cannot be supposed that water is first formed and then the peroxide of hydrogen, because up to now such a reaction has not been observed, whilst the formation of H_2O from H_2O_2 is very easily reproduced.¹⁰

Thus a whole series of phenomena show that the chemical reaction of substances actually takes place, as a rule, between equal volumes, but this does not preclude the possibility of the frequent reaction of unequal volumes, although, in this case, it is often possible to discover a preceding reaction between equal volumes.¹¹

The law of Avogadro-Gerhardt may also be easily expressed in an algebraical form. If the weight of a molecule, or of that quantity of a substance which enters into chemical reaction and occupies in a state of vapour, according to the law, a volume equal to that occupied by the

¹⁰ This opinion, which I have always held (since the appearance of the first editions of this work), as to the primary origin of hydrogen peroxide and of the formation of water by means of its decomposition, has in latter days become more generally accepted, thanks more especially to the work of Traube. Probably it explains most simply the necessity for the presence of traces of water in many reactions, as, for instance, in the explosion of carbonic oxide with oxygen, and perhaps the theory of the explosion of detonating gas itself and of the combustion of hydrogen will gain in clearness and truth if we take into consideration the preliminary formation of hydrogen peroxide and its subsequent decomposition.

¹¹ The possibility of reactions between unequal volumes, notwithstanding the general applicability of the law of Avogadro-Gerhardt, may, in addition to what has been said above, depend on the fact that the participating substances, at the moment of reaction, undergo a preliminary modification, decomposition, isomeric (polymeric) transformation, &c. Thus, if NO_2 seems to proceed from N_2O_4 , if O_2 is formed from O_3 , and the converse, then it cannot be denied that the production of molecules containing only one atom—for instance, of oxygen—is also possible, as also is that of higher polymeric types, e.g., the molecule N from N_2 , or H_3 from H_2 . In this manner it is obviously possible, by means of a series of hypotheses, to explain the case of the formation of ammonia, NH_3 , from 3 vols. of hydrogen and 1 vol. of nitrogen. But it must be observed that perhaps our information in similar instances is, as yet, far from being complete. If hydrazine or diamide, N_2H_4 , is formed and the imide N_2H_2 in which 2 vols. of hydrogen are combined with 2 vols. of nitrogen, then the reaction here perhaps first takes place between equal volumes. If it appears that the less stable imide, N_2H_2 , is formed before NH_3 , and splits up with the formation of ammonia, then the first reaction will proceed between equal volumes of nitrogen and hydrogen.

molecules of other bodies, be indicated by the letters M_1, M_2, \dots or, in general, M , and if the letters D_1, D_2, \dots or, in general, D , stand for the density or weight of a given volume of the gases or vapours of the corresponding substances under certain definite conditions of temperature and pressure, then the law requires that

$$\frac{M_1}{D_1} = \frac{M_2}{D_2} \dots = \frac{M}{D} = C,$$

where C is a certain constant. This expression shows directly that the volumes corresponding with the weights M_1, M_2, \dots, M , are equal to a certain constant, because the volume is proportional to the weight and inversely proportional to the density. The magnitude of C is naturally conditioned by and dependent on the units taken for the expression of the weights of the molecules and the densities. The weight of a molecule (equal to the sum of the atomic weights of the elements forming it) is usually expressed by taking the weight of an atom of oxygen as 16; then the weight of an atom of hydrogen is 1.008 (i.e., approximately 1), and hydrogen is now generally chosen as the unit for the expression of the densities of gases and vapours; it is therefore only necessary to find the magnitude of the constant for any one compound, as it will be the same for all others. Let us take water. Its reacting mass is expressed (conditionally and relatively) by the formula or molecule H_2O , for which $M = 18.016$ (or nearly 18) if $O = 16$ and $H = 1.008$, as we already know from the composition of water. Its vapour density, or D , compared with hydrogen is approximately 9, and consequently for water $C = 2$, and therefore, in general, for the molecules of all substances $\frac{M}{D} = 2$.

Consequently the weight of a molecule is equal (or rather nearly equal) to twice its vapour density expressed relatively to that of hydrogen, and conversely **the density of a gas is (nearly) equal to half the molecular weight referred to hydrogen.**

The truth of this may be seen by comparing a very large number of observed vapour densities with the results obtained by calculation. As an illustration, we may point out that for ammonia, NH_3 , the weight of the molecule or quantity of the reacting substance, as well as the composition and weight corresponding with the formula, are very nearly expressed by the figures $14 + 3 = 17$ (more exactly $14.04 + 3 \times 1.008 = 17.064$). Consequently $M = 17$. Hence, according to the law, $D = 8.5$. And this result is also obtained by experiment. The density, according to both formula and experiment, of nitrous oxide, N_2O , is 22; of nitric acid, 15; and of nitric peroxide, 23. In the case of nitrous anhydride, N_2O_3 , a substance which dissociates into $NO + NO_2$, the density should

vary between 38 (so long as the N_2O_3 remains unchanged) and 19 (when $\text{NO} + \text{NO}_2$ are obtained). There are no figures of constant density for H_2O_2 , NHO_3 , N_2O_4 , and many similar compounds which are either wholly or partially decomposed on passing into vapour. Salts and similar substances either have no vapour density because they do not pass into vapour (for instance, potassium nitrate, KNO_3) without decomposition, or, if they do pass into vapour without decomposing, their vapour density is observed only with difficulty at very high temperatures. The practical determination of the vapour density at these high temperatures (for example, for sodium chloride, ferrous chloride, stannous chloride, &c.) requires special methods which have been worked out by Sainte-Claire Deville, Crafts, Nilson and Pettersson, Meyer, Scott, and others. The difficulties of experiment having been overcome, it is found that the law of Avogadro-Gerhardt holds good for such salts as potassium iodide, beryllium chloride, aluminium chloride, ferrous chloride, &c.—that is, the density obtained by experiment proves to be equal to half the molecular weight—naturally within the limits of experimental error or of possible deviation from the law.

When the consequences of a law are verified by a great number of observations, it should be considered as confirmed by experiment. But this does not exclude the possibility of *apparent* deviations. These may evidently be of two kinds: the fraction $\frac{M}{D}$ may be found to be either greater or less than 2—that is, the calculated density may be either greater or less than the observed density. When the difference between the results of experiment and calculation falls within the possible errors of experiment (for example, when it equals only hundredths of the density), or within a possible error owing to the laws of gases having only an approximate application (as is seen from the deviations, for instance, from the law of Boyle and Mariotte), then the fraction $\frac{M}{D}$ proves to be but slightly different from 2 (between 1.9 and 2.2), and such cases as these may be classed among those which ought to be expected from the nature of the subject. It is a different matter if the quotient of $\frac{M}{D}$ be several times, and in general a multiple, *greater* or less than 2. The application of the law must then be explained or it must be laid aside, because the laws of nature admit of no exceptions. We will therefore take two such cases, and first one in which the *quotient* $\frac{M}{D}$ *is greater than 2, or the density obtained by experiment less than is in accordance with the law.*

It must be admitted, as a consequence of the law of Avogadro-Gerhardt, that there is a decomposition in those cases where the volume of the vapour corresponding with the weight of the amount of a substance entering into reaction is greater than the volume of two parts by weight of hydrogen. Suppose the density of the vapour of water to be determined at a temperature above that at which it is decomposed, then, if not all, at any rate a large proportion of the water will be decomposed into hydrogen and oxygen. The density of such a mixture of gases—detonating gas—will be less than that of aqueous vapour; it will be equal to 6 (compared with that of hydrogen), because 1 volume of oxygen weighs 16, and 2 volumes of hydrogen 2; and, consequently, 3 volumes of detonating gas weigh 18 and 1 volume 6, while the density of aqueous vapour is 9. Hence, if the density of aqueous vapour were determined after its decomposition, the quotient $\frac{M}{D}$

would be found to be 3 and not 2. This phenomenon might be considered as a deviation from Gerhardt's law, but this would not be correct, because it may be shown by means of diffusion through porous substances, as described in Chapter II., that water is decomposed at such high temperatures. In the case of water itself there can naturally be no doubt, because its vapour density agrees with the law at all temperatures at which it has been determined.¹² But there are many substances which decompose with great ease directly they are volatilised, and therefore only exist as solids or liquids, and not in a state of vapour. There are, for example, many salts of this kind, besides all definite solutions having a constant boiling-point, all the compounds of ammonia—for example, all ammonium salts—&c. Their vapour densities, determined by Bineau, Deville, and others, show that they do not agree with Gerhardt's law. Thus the vapour density of sal-ammoniac, NH_4Cl , is nearly 14 (compared with hydrogen), whilst its molecular weight is not less than 53.5, whence the vapour density should be nearly 27, according to the law. The molecule of sal-ammoniac cannot be less than NH_4Cl , because it is formed from the molecules NH_3 and HCl , and contains single atoms of nitrogen and chlorine, and therefore cannot be divided; further, it never enters into reactions with the molecules of other substances (for instance, potassium hydroxide, or nitric acid) in

¹² As the density of aqueous vapour remains constant within the limits of experimental accuracy, even at 1000° , when dissociation has certainly commenced, it would appear that only a very small amount of water is decomposed at these temperatures. If even 10 per cent. of water were decomposed, the density would be 8.57 and the quotient $M/D = 2.1$, but at the high temperatures here concerned the error of experiment is hardly less than the difference between this quantity and 2. And probably at 1000° the dissociation is far from being equal to 10 per cent. Hence the variation in the vapour density of water does not give us the means of ascertaining the starting-point of its dissociation.

quantities of less than 53·5 parts by weight, &c. The calculated density (about 27) is here double the observed density (about 13·4); hence $\frac{M}{D} = 4$ and not 2. For this reason the vapour density of sal-ammoniac for a long time served as an argument for doubting the truth of the law. But it proved otherwise, after the matter had been fully investigated. The low density depends on the decomposition of sal-ammoniac, on volatilising, into ammonia and hydrogen chloride. The observed density is not that of sal-ammoniac, but of a mixture of NH_3 and HCl , which should be nearly 14, because the density of NH_3 is 8·5, and that of HCl , 18·2, so that the density of their mixture (in equal volumes) should be about 13·4.¹³ The actual decomposition of the vapours of sal-ammoniac was demonstrated by Pebal and Than by the same method as the decomposition of water, namely, by passing the vapour through a porous substance. The experiment demonstrating the decomposition of sal-ammoniac during volatilisation may be made very easily, and is a very instructive point in the history of the Avogadro-Gerhardt law, because without its aid it would never have been imagined that sal-ammoniac decomposed in volatilising, as this decomposition shows all the signs of simple sublimation; consequently the decomposition was not proved by experiment but foretold by the law. The whole aim and practical use of the discovery of the laws of nature consists in, and is shown by, the fact that they enable the unknown to be foretold, the unobserved to be foreseen. The arrangement of the experiment is based on the following reasoning.¹⁴ According to the law and to experiment, the density of ammonia, NH_3 , is $8\frac{1}{2}$, and that of hydrochloric acid, HCl , $18\frac{1}{4}$, if the density of hydrogen is 1. Consequently, in a mixture of NH_3 and HCl , the ammonia will penetrate much more rapidly through a porous mass, or a fine orifice, than the heavier hydrochloric acid, just as in a former experiment the hydrogen penetrated more rapidly than the oxygen. Therefore, if the vapour of sal-ammoniac comes into contact with a porous mass, the ammonia will pass through it in greater quantities than the hydrochloric acid, and this excess of ammonia may be detected by means of moist red litmus paper, which should be turned

¹³ This explanation of the vapour densities of sal-ammoniac, sulphuric acid, and similar substances which decompose on being distilled was the most natural to resort to as soon as the application of the law of Avogadro-Gerhardt to chemical relations was instituted; it was, for instance, given in my work on *Specific Volumes*, 1856, p. 99. The formula, $M/D = 2$, which was applied later by many other investigators, had already been made use of in that work.

¹⁴ The beginner must remember that an experiment and the mode in which it is carried out must be determined by the principle or fact which it is intended to illustrate, and not *vice versa*, as some suppose. The idea which determines the necessity of an experiment is the chief consideration.

blue. If the vapour of sal-ammoniac were not decomposed, it would pass through the porous mass as a whole, and the colour of the litmus paper would not be altered, because sal-ammoniac is a neutral salt. Thus, by testing with litmus the substances passing through the porous mass, it may be decided whether the sal-ammoniac is decomposed or not when passing into vapour. Sal-ammoniac volatilises at so moderate a temperature that the experiment may be conducted in a glass tube heated by means of a lamp, an asbestos plug being placed near the centre of the tube.¹⁵ The asbestos forms a porous mass, which is unaltered at a high temperature. A piece of dry sal-ammoniac is placed at one side of the asbestos plug, and is heated by a Bunsen burner. The vapours formed are driven by a current of air forced from a gasometer or bag through two tubes containing pieces of moist litmus paper, one blue and one red paper in each. If the sal-ammoniac be heated, then the ammonia appears on the opposite side of the asbestos plug, and the litmus there turns blue, and as an excess of hydrochloric acid remains on the side where the sal-ammoniac is heated, it turns the litmus at that end red. This proves that sal-ammoniac, when converted into vapour, splits up into ammonia and hydrochloric acid, and at the same time gives an instance of the possibility of correctly conjecturing a fact on the basis of the Avogadro-Gerhardt law.^{15a}

So also the fact of a decomposition occurring may be proved in the other instances where $\frac{M}{D}$ proves to be greater than 2, and hence the apparent deviations are, in reality, an excellent proof of the general application and significance of the law of Avogadro-Gerhardt.

In those cases where the *quotient* $\frac{M}{D}$ proves to be *less* than 2, or the observed density *greater* than that calculated, by an integral number of times, the matter is evidently more simple, and the fact observed only indicates that the weight of the molecule is as many times greater than that taken, as the quotient obtained is less than 2. So, for instance,

¹⁵ It is important that the tubes, asbestos, and sal-ammoniac should be dry, as otherwise the moisture retains the ammonia and hydrogen chloride.

^{15a} Baker (1894) showed that the complete decomposition of NH_4Cl in the act of volatilising only takes place in the presence of water, traces of which are quite sufficient, but that in the total absence of moisture (by carefully drying with P_2O_5) there is either no decomposition, and the vapour density of the sal-ammoniac is found to be normal, i.e., nearly 27, or else only a portion of the salt is decomposed (Hartmann). It is not yet quite clear what part the trace of moisture plays here, and it must be presumed that the phenomenon belongs to the category of contact phenomena, which have not yet been fully explained (see Chap. IX., note 29). V. Kurbatoff showed that hydrochloride of aniline (which is essentially an analogue of sal-ammoniac) gives a vapour density 32.6, corresponding very nearly with its decomposition into $\text{NC}_6\text{H}_7 + \text{HCl}$, if the temperature be sufficiently high, but at lower temperatures the decomposition is not complete.

in the case of ethylene, whose composition is expressed by CH_2 , the density was found by experiment to be 14, and in the case of amylene, whose composition is also CH_2 , the density proved to be 35, and consequently the quotient for ethylene = 1, and for amylene = $\frac{2}{5}$. If the molecular weight of ethylene be taken, not as 14, as might be imagined from its composition, but as twice as great—namely, as 28—and that of amylene as five times greater—that is, as 70—then the molecular composition of the first will be C_2H_4 , and that of the second C_5H_{10} , and for both of them $\frac{M}{D}$ will be equal to 2. This application of the

law, which at first sight may appear perfectly arbitrary, is nevertheless strictly correct, because the amount of ethylene which reacts—for example, with sulphuric and other acids—is not equal to 14, but to 28 parts by weight. Thus with H_2SO_4 , Br_2 , or HI , &c., ethylene combines in a quantity C_2H_4 , and amylene in a quantity C_5H_{10} , and not CH_2 . On the other hand, ethylene is a gas which liquefies with difficulty (absolute boiling-point, $+10^\circ$), whilst amylene is a liquid boiling at 35° (absolute boiling-point, $+192^\circ$), and by admitting the greater density of the molecules of amylene ($M = 70$) its difference from the lighter molecules of ethylene ($M = 28$) becomes clear. Thus, the smaller quotient $\frac{M}{D}$ is *an indication of polymerisation*, just as the larger quotient shows decomposition. The difference between the densities of oxygen and ozone is a case in point.

On turning to the elements, it is found that, in certain cases, especially with metals—for instance, mercury, zinc, and cadmium—those weights of the atoms which must be acknowledged in their compounds (of which mention will be afterwards made) appear to be also the molecular weights. Thus the atomic weight of mercury must be taken as = 200, but the vapour density = 100, and the quotient = 2. Consequently the *molecule of mercury contains one atom*, Hg. It is the same with sodium, cadmium, and zinc. This is the simplest molecule, which necessarily is only possible **in the case of elements**, as the molecule of a compound must contain at least two atoms. However, the molecules of many of the elements prove to be complex—for instance, the weight of an atom of oxygen is 16, and its density is also 16, so that its molecule must contain two atoms, O_2 , which might already be concluded by comparing its density with that of ozone, whose molecule contains O_3 (Chapter IV.). So also the molecules of hydrogen, H_2 , of chlorine, Cl_2 , of nitrogen, N_2 , &c., all contain 2 atoms. If chlorine reacts with hydrogen, the volume remains unaltered after the formation of hydrochloric acid, $\text{H}_2 + \text{Cl}_2 = 2\text{HCl}$. It is a case of substitution

between the one and the other, and therefore the volumes remain constant. There are elements whose molecules are much more complex—for instance, sulphur, S_6 —although, by heating, the density is reduced to a third, and S_2 is formed. Judging from the vapour density of phosphorus ($D = 62$), the molecule contains four atoms, P_4 . Hence many elements when polymerised appear in molecules which are more complex than the simplest possible. In carbon, as we shall afterwards find, a very complex molecule must be admitted, as otherwise its non-volatility and other properties cannot be understood. And if compounds are decomposed by a more or less powerful heat, and if polymeric substances are *de-polymerised* (that is, the weight of the molecule diminishes) by a rise of temperature, as N_2O_4 passes into NO_2 , or ozone, O_3 , into ordinary oxygen, O_2 , then we *might expect to find the splitting-up of the complex molecules of elements* into the simplest molecule containing a single atom only—that is to say, if O_2 be obtained from O_3 , then the formation of O might also be looked for. The possibility, but not the proof, of such a proposition is indicated by the *vapour of iodine*. Its normal density is 127 (Dumas, Deville, and others), which corresponds with the molecule I_2 . At temperatures above 800° (up to which the density remains almost constant), this density distinctly decreases, as is seen from the verified results obtained by Victor Meyer, Crafts, and Troost. At the ordinary pressure and a temperature of 1000° it is about 100, at 1250° about 80, at 1400° about 75, and it apparently strives to reduce itself to one-half—that is, to 63. Under a reduced pressure this splitting-up, or de-polymerisation, of iodine vapour actually goes on until a density¹⁶ of 66 is reached, as Crafts demonstrated by reducing the pressure to 100 mm. and raising the temperature to 1500° . From this it may be concluded that at high temperatures and low pressures the molecule I_2 gradually passes into the molecule I containing one atom like that of mercury, and that something similar occurs with other elements with a considerable rise of temperature, which tends to bring about the disunion of compounds and the decomposition of complex molecules.¹⁷

¹⁶ Just as we saw (Chap. VI., note 46) an increase in the dissociation of N_2O_4 and the formation of a large proportion of NO_2 , with a decrease of pressure. The decomposition of I_2 into $I + I$ is a similar dissociation.

¹⁷ Although at first a similar phenomenon was recognised in the case of chlorine, it was afterwards proved that if there is a decrease of density it is only a small one. In the case of bromine it is not much greater, and is far from being equal to that for iodine.

As in general we very often involuntarily confuse chemical with physical processes, it may be that a physical process of change in the coefficient of expansion with a change of temperature acts together with a change in molecular weight, and partially, if not wholly, accounts for the decrease of the densities of chlorine, bromine, and iodine. Thus I have remarked (*Comptes Rendus*, 1876) that the coefficient of expansion of gases increases with

Besides these two cases of **apparent** discrepancy from the law of Avogadro-Gerhardt there is yet a third, which is the last, and is very instructive. In the investigation of separate substances they have to be isolated in the purest possible form, and their chemical and physical properties, and among them the vapour density, then determined. If the latter be normal—that is, if $D = M/2$ —it often serves as a proof of the purity of the substance, i.e., of its freedom from all foreign matter. If it be abnormal—that is, if D be not equal to $M/2$ —then for those who do not believe in the law it appears as a new argument against it; but to those who have already grasped the important significance of the law it becomes clear that there is some error in the observation, or that the density was determined under conditions in which the vapour does not follow the laws of Boyle and Gay-Lussac, or else that the substance has not been sufficiently purified, and contains other substances. In that case the law of Avogadro-Gerhardt furnishes convincing evidence of the necessity of a fresh and more exact research. And as yet the causes of error have always been found. There are not a few examples in point in the recent history of chemistry. We will cite one instance. In the case of pyrosulphuryl chloride, $S_2O_5Cl_2$, $M = 215$,^{17a} and consequently D should be 107.5, instead of which Ogier and others obtained 53.8—that is, a density half as great—and, further, Ogier (1882) demonstrated clearly that the substance is not dissociated by distillation into SO_3 and SO_2Cl_2 , or any other two products, and thus the abnormal density of $S_2O_5Cl_2$ remained unexplained until D. P. Konovaloff (1885) showed that the previous investigators were working with a mixture (containing SO_3HCl), and that pyrosulphuryl chloride has a normal density of approximately 107. Had not the law of Avogadro-Gerhardt served as a guide, the impure liquid would have still passed as pure; the more so since the determination of the amount of chlorine could not aid in the discovery of the impurity. Thus, by following a true law of nature we are led to true deductions.

All cases which have been studied confirm the law of Avogadro-

their molecular weight, and (Chap. II., note 26) the results of direct experiment show the coefficient of expansion of hydrobromic acid ($M = 81$) to be 0.00386 instead of 0.00367, which is that of hydrogen ($M = 2$). Hence, in the case of the vapour of iodine ($M = 254$) a very large coefficient of expansion is to be expected, and from this cause alone the relative density would fall. Taking the coefficient of expansion of iodine vapour as 0.004, at 1000° its density would be 116. So that the dissociation of iodine may be only an apparent phenomenon. However, on the other hand, the heavy vapour of mercury ($M = 200$, $D = 100$) scarcely decreases in density at a temperature of 1500° ($D = 98$, according to Victor Meyer); but it must not be forgotten that the molecule of mercury contains only one atom, whilst that of iodine contains two, and this is very important.

^{17a} For the sake of simplicity and clearness the atomic weights are given here in round numbers; for instance, $H = 1$, $O = 16$, $C = 12$, $S = 32$, $N = 14$, $Cl = 35.5$, &c.

Gerhardt, and as by it a deduction is obtained, from the determination of the vapour density (a purely physical property), as to the weight of the molecule or quantity of a substance entering into chemical reaction, this law links together the two branches of knowledge—physics and chemistry—in the most intimate manner. Besides which the law of Avogadro-Gerhardt places the conceptions of **molecules** and **atoms** on a firm foundation, which was previously wanting. Although since the days of Dalton it had become evident that it was necessary to admit the existence of the elementary atom (the chemical individual indivisible by chemical or other forces), and of the groups of atoms (or molecules) of compounds, indivisible by mechanical and physical forces, still the relative magnitude of the molecule and atom was not defined with sufficient clearness. Thus, for instance, the atomic weight of oxygen might be taken as 8 or 16, or any multiple of these numbers, and nothing indicated a reason for the acceptance of one rather than another of these magnitudes;¹⁸ while as regards the weights of the molecules of elements and compounds there was no trustworthy knowledge whatever. With the establishment of Gerhardt's law the idea of the molecule was fully defined, as well as the relative magnitude of the elementary atom.

The chemical particle or **molecule must be considered as the quantity of a substance which enters into chemical reaction with other molecules, and occupies in a state of vapour the same volume as two parts by weight of hydrogen.**

The molecular weight (which has been indicated by *M*) of a substance is determined by its composition, transformations, and vapour density.

The molecule is not divisible by the mechanical and physical changes of substances, but in chemical reactions it is altered either in

¹⁸ And so it was in the fifties. Some took $O=8$, others $O=16$, H being 1. Water in the first case would be HO and hydrogen peroxide HO_2 , and in the second case, as is now generally accepted, water H_2O , and hydrogen peroxide H_2O_2 or HO . Disagreement and confusion reigned. In 1860 the chemists of the whole world met at Carlsruhe for the purpose of arriving at some agreement and uniformity of opinion. I was present at this Congress, and well remember how great was the difference of opinion, and how a compromise was advocated with great acumen by many scientific men, and with what warmth the followers of Gerhardt, at whose head stood the Italian professor Canizzaro, followed up the consequences of the law of Avogadro. In the spirit of scientific freedom, without which science would make no progress, and would remain petrified as in the middle ages, and with the simultaneous necessity of scientific conservatism, without which the roots of past study could give no fruit, a compromise was not arrived at, nor ought it to have been, but instead of it truth, in the form of the law of Avogadro-Gerhardt, received by means of the Congress a wider development, and soon afterwards convinced all minds. Then the new so-called *Gerhardt* atomic weights established themselves, and in the seventies they were already in general use.

its properties, or quantity, or structure, or in the nature of the motion of its parts.

An agglomeration of molecules, which are alike in all chemical respects, makes up the masses of homogeneous substances in all states.¹⁹

Molecules consist of atoms in a certain state of distribution and motion, just as the solar system²⁰ is made up of inseparable parts (the sun, planets, satellites, comets, &c.). The greater the number of atoms in a molecule, the more complex is the resultant substance. The equilibrium between the dissimilar atoms may be more or less stable, and may for this reason give more or less stable substances. Physical and mechanical transformations alter the velocity of the motion of, and the distances between, either the individual molecules, or the atoms in the molecules, or of their sum total, but they do not alter the original equilibrium of the system; whilst chemical changes, on the other hand, alter the molecules themselves, that is, the velocity of motion, the relative distribution, and the quality and quantity of the atoms in the molecules.

Atoms are the smallest quantities or chemically indivisible masses **of the elements forming the molecules** of elements and compounds.

Atoms have weight, the sum of their weights forms the weight of the molecule, and the sum of the weights of the molecules forms the weight of masses, and is the cause of gravity, and of all the phenomena which depend on the mass of a substance.

The elements are characterised, not only by their independent exist-

¹⁹ If the aggregation of all kinds of heterogeneous molecules be possible in a gaseous state, where the molecules are considerably removed from each other, then in a liquid state, where they are already close together, such an aggregation becomes possible only in the sense of the mutual reaction which results from their chemical attraction for each other, and especially the aptitude of heterogeneous molecules for combining together. Solutions and other so-called indefinite chemical compounds should be regarded in this light. According to the principles developed in this work we should regard them as containing both the compounds of the heterogeneous molecules themselves and the products of their decomposition, as in peroxide of nitrogen, N_2O_4 and NO_2 .

²⁰ This strengthens the fundamental idea of the unity and harmony of type of all creation, and is one of those ideas which impress themselves on man in all ages, and give rise to a hope of arriving in time, by means of a laborious series of discoveries, observations, experiments, laws, hypotheses, and theories, at a comprehension of the internal and invisible structure of concrete substances with that same degree of clearness and exactitude which has been attained in the visible structure of the heavenly bodies. It is not many years ago since the law of Avogadro-Gerhardt took root in science. It is within the memory of many living scientific men, and of mine amongst others. It is not surprising, therefore, that as yet little progress has been made in the province of molecular mechanics; but the theory of gases alone, which is intimately connected with the conception of molecules, shows by its success that the time is approaching when our knowledge of the internal structure of matter will be defined and established.

ence, their incapacity of being converted into each other, &c., but also by the weights of their atoms.

The chemical and physical properties of a substance depend on the weight, composition, and properties of the molecules forming it, and on the weight, properties, and distribution (structure, motion) of the atoms forming the molecules.

This is the substance of those principles of **molecular mechanics** which lie at the basis of all contemporary physical and chemical constructions since the establishment of the law of Avogadro-Gerhardt. The fecundity of the principles enunciated is seen at every step in all the particular cases forming the present store of chemical data. We will here cite a few examples of the application of the law.

As the weight of an atom must be understood as the minimum quantity of an element entering into the composition of all the molecules formed by it, we may, in order to find the weight of an atom of oxygen, take the molecules of those of its compounds which have already been described, together with the molecules of certain of those carbon compounds which will be described in the following chapter:—

	Molecular Weight	Amount of Oxygen		Molecular Weight	Amount of Oxygen
H ₂ O	18	16	HNO ₃	63	48
N ₂ O	44	16	CO	28	16
NO	30	16	CO ₂	44	32
NO ₂	46	32			

The number of substances taken might be considerably increased, but the result would be the same—that is, the molecules of the compounds of oxygen would never be found to contain less than 16 parts by weight of this element, but always $n16$, where n is a whole number. The molecular weights of the above compounds are found either directly from the densities of their vapours or gases, or from their reactions. Thus the vapour density of nitric acid (as a substance which easily decomposes above its boiling-point) cannot be accurately determined, but the fact of its containing one part by weight of hydrogen, as also all its properties and reactions, indicate the above molecular composition and no other. In this manner it is very easy to find the atomic weight of all the elements, knowing the molecular weights and compositions of their compounds. It may, for instance, be easily proved that less than $n12$ parts of carbon never enters into the molecules of carbon compounds, and therefore C must be taken as 12, and not as 6, which was the number in use before Gerhardt. In a similar manner the atomic weights now

accepted for the elements oxygen, nitrogen, carbon, chlorine, sulphur, &c., were found and indubitably established, and they are even now termed the Gerhardt atomic weights. As regards the metals, many of which do not give a single volatile compound, we shall afterwards see that there are also methods by which their atomic weights may be established, but nevertheless the law of Avogadro-Gerhardt is here also ultimately resorted to in order to remove any doubt which may be encountered. Thus, for instance, although much that was known concerning the compounds of beryllium necessitated its atomic weight being taken as $\text{Be}=9$ —that is, the oxide as BeO and the chloride as BeCl_2 —still certain analogies gave reason for considering its atomic weight to be $\text{Be}=13\cdot5$, in which case its oxide would be expressed by the composition Be_2O_3 , and the chloride by BeCl_3 .²¹ It was then found that the vapour density of beryllium chloride was approximately 40, when it became quite clear that its molecular weight was 80; and as this satisfies the formula BeCl_2 , but does not suit the formula BeCl_3 , it became necessary to regard the atomic weight of Be as 9 and not as $13\frac{1}{2}$.

With the establishment of a true conception of molecules and atoms, chemical formulæ became direct expressions, not only of composition,²² but also of molecular weight or **vapour density**, and conse-

²¹ If $\text{Be}=9$, and beryllium chloride be BeCl_2 , then for every 9 parts of beryllium there are 71 parts of chlorine, and the molecular weight of $\text{BeCl}_2=80$; hence the vapour density should be 40 or $n40$. If $\text{Be}=13\cdot5$, and beryllium chloride be BeCl_3 , then to 13·5 of beryllium there are 106·5 of chlorine; hence the molecular weight would be 120, and the vapour density 60 or $n60$. The composition is evidently the same in both cases, because $9 : 71 :: 13\cdot5 : 106\cdot5$. Thus, if the symbol of an element designate different atomic weights, apparently very different formulæ may equally well express both the percentage composition of compounds and those properties which are required by the laws of multiple proportions and equivalents. The choice of one or the other multiple quantity for the atomic weight is impossible without a firm and concrete conception of the molecule and atom, and this is only obtained as a consequence of the law of Avogadro-Gerhardt, and hence the modern atomic weights are the results of this law.

²² In general, when it is required to transfer a formula into its percentage composition, we must replace the symbols by their corresponding atomic weights and find their sum, and knowing the amount by weight of a given element in it, it is easy by proportion to find the amount of this element in 100 or any other number of parts by weight. If, on the contrary, it be required to find the formula from a given percentage composition, we must proceed as follows: Divide the percentage amount of each element entering into the composition of a substance by its atomic weight and compare the figures thus obtained—they should be in simple multiple proportion to each other. Thus, for instance, from the percentage composition of hydrogen peroxide, 5·88 of hydrogen and 94·12 of oxygen, it is easy to find its formula; it is only necessary to divide the amount of hydrogen by unity and the amount of oxygen by 16. The numbers 5·88 and 5·88, which are thus obtained, are in the ratio 1 : 1, which means that in hydrogen peroxide there is one atom of hydrogen to one atom of oxygen.

It may be further observed that even the very language or nomenclature of chemistry acquires a particular clearness and conciseness by means of the conception of molecules, because then the names of substances may directly indicate their composition. Thus

quently of a series of fundamental chemical and physical data, inasmuch as a number of the properties of substances are dependent on their vapour density, or molecular weight and composition. The vapour density $D = \frac{M}{2}$. For instance, the formula of ethyl ether is $C_4H_{10}O$,

corresponding with the molecular weight 74, and the vapour density 37, which is the number actually found. Therefore the density of vapours and gases has ceased to be an empirical magnitude obtained by experiment only, and has acquired a rational meaning. It is only necessary to remember that 2 grams of hydrogen, or the molecular weight of this primary gas in grams, occupies at 0° and 760 mm. pressure a volume of 22.3 litres (or 22,300 cubic centimetres) in order to directly determine the weights of cubical measures of gases and vapours from their formulæ, because **the molecular weights in grams of all other vapours at 0° and 760 mm. occupy the same volume, 22.3 litres.** Thus, for example, in the case of carbonic anhydride, CO_2 , the molecular weight $M=44$; hence 44 grams of carbonic anhydride at 0° and 760 mm. occupy a volume of 22.3 litres—consequently a litre weighs 1.97 gram. By combining the laws of gases—Gay-Lussac's, Mariotte's, and Avogadro-Gerhardt's—we obtain²³ a general formula for gases:

$$6200s(273+t) = Mp,$$

where s is the weight in grams of a cubic centimetre of a vapour or gas at a temperature t and pressure p (expressed in centimetres of mercury) if the molecular weight of the gas $=M$ (expressed on the basis that the atomic weight of O is 16, and that of H, 1.008). Thus, for instance, at 100° and 760 millimetres pressure (i.e., at the atmospheric pressure)

the term 'carbon dioxide' tells more about and expresses CO_2 better than carbonic acid gas, or even carbonic anhydride. Such nomenclature is already employed by many. But expressing the composition without an indication or even hint as to the properties would be neglecting the advantageous side of the present nomenclature. Sulphur dioxide, SO_2 , expresses the same as barium dioxide, BaO_2 , but sulphurous anhydride indicates the acid properties of SO_2 . Probably in time one harmonious chemical language will succeed in embracing both advantages.

²³ This formula (which is given in my work on *The Pressure of Gases* and in a somewhat modified form in the *Comptes Rendus*, February 1876) is deduced in the following manner. According to the law of Avogadro-Gerhardt, $M=2D$ for all gases, where M is the molecular weight and D the density referred to that of hydrogen. But it is equal to the weight s_0 of a cubic centimetre of a gas in grams (at 0° and 76 cm. pressure) divided by 0.00008994, for this is the weight in grams of a cubic centimetre of hydrogen. But the weight s of a cubic centimetre of a gas at a temperature t and under a pressure p (in centimetres) is equal to $s_0p/76(1+at)$. Therefore $s_0=s.76(1+at)p$; hence $D = 76.s(1+at)/0.0000898p$, so that $M=152s(1+at)/0.00008994p$, which gives the above expression, for $1/a=273$, and 152 multiplied by 273 and divided by 0.00008994 is nearly 6200. In place of s , m/v may be taken, where m is the weight and v the volume of a vapour.

molecules. Q.E.D.²⁶ The specific heats of gases (Chapter XIV.), and many of their other properties are determined by their density, and consequently by their molecular weight. Gases and vapours in passing into a liquid state evolve the so-called **latent heat** (i.e., a portion of the internal energy of the motion of the molecules is converted into heat energy), which also proves to have a connection with the molecular weight. The observed latent heats of evaporation of carbon bisulphide, CS_2 , 86 ; of ether, $\text{C}_4\text{H}_{10}\text{O}$, 84 ; of benzene, C_6H_6 , 94 ; of alcohol, $\text{C}_2\text{H}_6\text{O}$, 201 ; of chloroform, CHCl_3 , 55, &c., show the amounts of heat expended in converting one part by weight of the above substances into vapour. A great uniformity is observed if the measure of this heat be referred to the weight of the molecule. For carbon bisulphide, the formula CS_2 expresses a weight 76 ; hence the latent heat of evaporation referred to the molecular quantity $\text{CS}_2 = 76 \times 86 = 6,536$, for ether = 6,216, for benzene = 7,332, for alcohol = 9,246, for chloroform = 6,902, for water = 9,640, &c. That is, for molecular quantities, the latent heat varies comparatively little, only from 6,000 to 10,000 heat units, whilst for equal parts by weight it is ten times greater for water than for chloroform and many other substances.²⁷

²⁶ The velocity of the transmission of sound through gases and vapours bears closely on this. It has the value $\sqrt{Kpg/D (1 + \alpha t)}$, where K is the ratio between the two specific heats (it is approximately 1.4 for gases containing two atoms in a molecule), p the pressure of the gas expressed by weight (that is, the pressure expressed by the height of a column of mercury multiplied by the density of mercury), g the acceleration of gravity, D the weight of a cubic measure of the gas, $\alpha = 0.00367$, and t the temperature. Hence, if K be known, as well as D , which can be found from the composition of a gas, we can calculate the velocity of the transmission of sound in that gas. Or if this velocity be known, we can find K . The relative velocities of sound in two gases can be easily determined (Kundt).

If a horizontal glass tube (about 1 metre long and closed at both ends) full of any gas, be firmly fixed at its middle point, it is easy to bring the tube and gas into a state of vibration by rubbing it from centre to end with a damp cloth. The vibration of the gas is easily rendered visible if the interior of the tube be dusted with lycopodium (the yellow powder-dust or spores of the lycopodium plant, which is often employed in medicine) before the gas is introduced and the tube fused up. The fine lycopodium powder arranges itself in patches, whose number depends on the velocity of sound in the gas. If there be 10 patches, then the velocity of sound in the gas is ten times slower than in glass. It is evident that this is an easy method of comparing the velocity of sound in gases. It has been demonstrated by experiment that the velocity of sound in oxygen is four times less than in hydrogen, and the square roots of the densities and molecular weights of hydrogen and oxygen stand also in this ratio.

²⁷ If the conception of the molecular weights of substances does not directly give an exact law when applied to the latent heat of evaporation, at all events it brings to light a certain uniformity in figures, which otherwise only represent the simple result of observation. Molecular quantities of liquids appear to require almost equal amounts of heat for their evaporation. The laws of thermodynamics show a more intimate connection between the latent heat of evaporation L and the molecular weight M , in dependence on the absolute boiling-point $T = 273 + t$ (Personne, Ramsay, de Forcrand, Le Chatelier, Konvaloff, &c.), which is also seen in the empirical **law of Trouton**, $\frac{L \cdot M}{T} = \text{a constant}$, which

Generalising from the above, the weight of the molecule determines the properties of a substance *independently of its composition*—i.e., of the number and quality of the atoms entering into the molecule—whenever the substance is in a gaseous state (for instance, the density of gases and vapours, the velocity of sound in them, their specific heat, &c.), or passes into that state, as we see in the latent heat of evaporation. This is intelligible from the point of view of the atomic theory in its present form, for, besides a rapid motion proper to the molecules of gaseous bodies, it is further necessary to postulate that these molecules are dispersed in space (filled throughout with the so-called luminiferous ether) like the heavenly bodies distributed throughout the universe. Here, as there, it is only the degree of removal (the distance) and the masses of substances which take effect, whilst those peculiarities of a substance which are expressed in chemical transformations, and only come into action on near approach or on contact, are in abeyance by reason of the dispersal. Hence it is at once obvious, in the first place, that in the case of solids and liquids, in which the molecules are closer together than in gases and vapours, a greater complexity is to be expected, i.e., a dependence of all the properties not only upon the weight of the molecule but also upon its composition and quality, or upon the properties of the individual chemical atoms forming the molecule; and, in the second place, that, in the case of a small number of molecules of any substance being disseminated through a mass of another substance—for example, in the formation of weak (dilute) solutions (although in this case there is an act of chemical reaction—i.e., a combination, decomposition, or substitution)—the dispersed molecules will alter the properties of the medium in which they are dissolved, almost in proportion to the molecular weight and almost independently of their composition. The greater the number of molecules—i.e., the stronger the solution—the more clearly defined will become those properties which depend upon the

varies, according to the results of experiment (when there is no decomposition), from $C = 19$ to $C = 26$, but is most often nearly 21, as is seen from the following examples:—

	t	L	M	C
Bromine, Br_2 . . .	61·6°	43·7	160	20·9
Mercury, Hg . . .	357°	62	200	19·7
CS_2	46·6°	85·7	76	20·4
C_6H_6	80·2°	93·6	78	20·6
$\text{C}_6\text{H}_7\text{N}$	184·5°	104·7	93	21·2

For water and alcohol C is about 25·9, but, judging by their capillarity, these exhibit, as Ramsay and others observed, a certain discrepancy which is considered more fully in physical chemistry. I would only remark that these discrepancies do not obscure the general application of Trouton's law, and therefore if L and t be known, it is possible to *approximately* determine M , just as in the case of the depression of solutions, as will be presently explained (see note 27a).

composition of the dissolved substance and its relation to the molecules of the solvent, for the distribution of one kind of molecules in the sphere of attraction of others cannot but be influenced by their mutual chemical reaction. These general considerations give a starting-point for explaining why, since the appearance of van't Hoff's memoir (1886), 'The Laws of Chemical Equilibrium in a Diffused Gaseous or Liquid State' (see Chapter I., note 19), it has been found more and more that *dilute* (weak) solutions exhibit such variations of properties as depend wholly upon the weight and number of the molecules and not upon their composition, and even give the means of determining the weight of molecules by studying the variations of the properties of a solvent on the introduction of a small quantity of a substance passing into solution. Although this subject has been already partially considered in the first chapter (in speaking of solutions), we touch upon it here because the meaning and importance of molecular weights are seen in it in a new and peculiar light, and because it gives a method for determining them in the event of a substance being non-volatile but capable of forming solutions. Details upon this new and complicated subject must, however, be sought in works on physical chemistry. Of the numerous properties of dilute solutions which have been investigated (for instance, the osmotic pressure, depressions, vapour pressure, boiling-point, internal friction, capillarity, variation with change of temperature, specific heat, electro-conductivity, index of refraction, &c.), we will cursorily consider the osmotic pressure and the 'depression' or fall of the temperature of freezing (Raoult's cryoscopic method), not only because these methods have been the most studied, but also because the latter is the most easily carried out and most frequently applied for determining the weight of the molecules of substances in solution, although, owing to the novelty of the subject, there are here also many experimental anomalies which cannot as yet be explained by theory.

Osmotic Pressure.—It is found by direct experiment that when a solution, held in a membrane which transmits the solvent but not the substance dissolved (dialysis), is placed in a vessel containing the solvent only, it draws in a certain amount of the solvent, and by so doing raises the pressure within the membrane until it attains a limit called the 'osmotic pressure' of the solution. This happens, for instance, when a porous vessel containing a solution of sugar in water (in whose pores a gelatinous precipitate has been deposited by the action of ferricyanide of potassium on a solution of a copper salt) is immersed in water. The rise of pressure within the membrane may be noted and expressed in terms of the column of mercury supported, and therefore in fractions of the atmospheric pressure by taking one atmosphere as equal to

76 cm. of mercury. With strong solutions the rise of pressure is considerable, and always varies with the strength of the solution. With dilute solutions the pressure is found to be almost proportional to the strength of the solution. This proves that the pressure is produced by the substance dissolved. Thus the osmotic pressure of a solution of 1 part by weight of sugar in 100 parts of water is $\frac{2}{3}$ atmosphere (at the ordinary temperature), while that of a 2 per cent. solution is $1\frac{1}{2}$ atmosphere. Hence there is no difficulty in measuring the value of the osmotic pressure with accuracy, and experiment proves that it varies with the temperature in just the same manner as the vapour pressure of a confined gas. This fact suffices to show that there is a perfect parallelism between the dissolution or dispersion of a substance in passing into a dilute solution and in passing into a state of vapour or gas. A series of observations made by Pfeffer, Traube, Devries, Naccari, Ladenburg, Tammann, and others, and generalised by van't Hoff, showed that the osmotic pressure is also dependent upon the molecular weight and volume of the substance in solution, just as is the case in the gaseous state. Therefore the osmotic pressure p or h may be calculated in dependence upon the molecular weight M , or conversely, by the above formula for the gaseous or vaporous state of matter. As an example we will take a 1 per cent. solution of sugar, $C_{12}H_{22}O_{11}$, for which $M=342\cdot18$. In this case the weight $m=1$ gram, and v , or the volume, is determined by the sp. gr., and is nearly 100·5 c.c. Therefore, according to the last of the above formulæ (II),

$$342\cdot18 = \frac{81\cdot6 \times 1 \times (273 + t)}{100\cdot5h}$$

whence the osmotic pressure h in atmospheres is

$$h = 0\cdot002373 (273 + t).$$

Pfeffer (1877, nine years before van't Hoff made his generalisation) observed the osmotic pressure of such a 1 per cent. solution of sugar at different temperatures, and his results are given in the accompanying table, together with those given by calculation according to the above formula :—

1 per cent. Solution of Sugar.	Osmotic Pressures.	
	According to Pfeffer.	According to Theory.
$t = 7^{\circ}$	0·664 atmosphere	0·664 atmosphere
14°	0·681 „	0·681 „
22°	0·721 „	0·700 „
32°	0·716 „	0·724 „
36°	0·746 „	0·733 „

It is hence evident that the results of calculation entirely (naturally

within the limits of possible error of experiment) agree with those of experiment, and therefore *the molecular weight of a substance* (which is not saline, not an electrolyte) *may be determined from the osmotic pressure of its dilute solutions*. Thus, if M be calculated by the formula from the average of Pfeffer's observations, it is found to be nearly 342, which is very nearly the value of the molecular weight of sugar according to its formula, $C_{12}H_{22}O_{11}$, and its reactions.

Beyond the fact that the solutions of saline substances (electrolytes) give disturbing anomalies (the observed pressure being greater than that obtained by calculation, and the molecular weight obtained less than the actual weight, Chap. I., note 49) in the above rule, which are, however, met with in all other methods of determining the molecular weight of substances in solution, the osmotic method of determining the molecular weight M presents some inconvenience in its practical experimental aspect, as it is difficult to prepare closed vessels whose walls will transmit the various solvents, and not permit the passage of the substance dissolved; and as such walls are incapable of sustaining high pressures (this may be overcome by employing isotonic solutions giving equal osmotic pressures), this method, although of great theoretical importance, is generally replaced in practice by other more convenient ones. These methods are all essentially based on the fact that all those cases where the solvent or substance dissolved separates out from a solution exhibit the same simplicity of relations as the osmotic pressure. And isotonic solutions (i.e., those having equal osmotic pressures) have all the same vapour pressure (i.e., an equal fall of boiling-point) and one and the same depression (i.e., equal fall of the temperature of separation of the solvent in a solid form), &c., which gives the possibility of determining the molecular weight by those properties of solutions just as well as by the osmotic pressure. Among these the **cryoscopic** or **depression** method is the one most usually resorted to, not only because it was worked out more fully and earlier than the others by Rudorff, de Coppet, Raoult (1882), Paterno, Ponsot, Abegg, Eijkman, Pickering, Chrushchoff, and others, but also because the great variety of solvents which are able to pass into the solid and liquid states permits of its being applied to the most diverse substances, starting with metals dissolving in each other (Hg, Sn, &c.) and gases soluble in water and ending with non-volatile and oily substances soluble in corresponding liquid solvents which readily solidify, such as benzene, phenol, acetic acid, &c. The method depends essentially upon the fact that dilute solutions (of non-electrolytes) follow the formula:

$$\frac{\Delta}{q} \cdot M = C = \frac{0.02(273 + t)^2}{w}.$$

where Δ is the depression (difference between the melting-points of the pure solvent and of the solution taken), q the amount by weight of the substance dissolved per 100 parts by weight of the solvent, and M the molecular weight of the substance dissolved. The first portion of the equation is called the 'molecular depression.' For a given dilute solution the molecular depression (of non-electrolytes) tends to reach a constant value, C , as the dilution increases, and this constant is determined, as the equation shows, by two factors of the solvent, namely, t , its melting-point, and w , its latent heat of fusion. In the case of water $t=0$ and $w=79$, and therefore with dilute aqueous solutions :

$$C = \frac{0.02 \times 273^2}{79} = \frac{\Delta}{q} M = 18.9,$$

or

$$\Delta = \frac{18.9q}{M}.$$

Hence with aqueous solutions $M = \frac{18.9q}{\Delta}$, or the greater the molecular

weight the smaller will be the depression Δ for a given number of grams, q , of substance per 100 grms. of water. It follows also that for a given substance (i.e., when M is constant) the fraction q/Δ is also constant and equal to $M/18.9$. With other solvents (besides water) the constant, C , varies according to their properties (i.e., with t and w) ; thus, for benzene, C_6H_6 ($t=55^\circ$, $w=30$) it is about 50, for nitrobenzene about 70, for acetic acid about 39, &c. Extreme accuracy in the determination of the constant C cannot be expected, because the above relations are best seen in very dilute solutions, when the small amount of depression is difficult to determine. But as the cryoscopic method is only used in the laboratory to discover whether the molecular weight of the substance dissolved is M or some multiple of it, $2M$, $3M$, &c., a simple approximation to the true value is most important, especially for substances which are not at all volatile or which decompose when volatilised, more particularly as the value of M given by the cryoscopic method corresponds to low temperatures near the freezing-point of the solvent.

As an example we will again take a solution of ordinary sugar ($C_{12}H_{22}O_{11}$). P. D. Chrustchoff (1902) determined the depression of such solutions with a very sensitive electrical thermometer, and obtained the following results :—

Sugar in 100 grams of solution.	Sugar per 100 grams of Water. q	Observed Depression. Δ
0.998 gram	1.008 gram	0.0576°
2.081 „	2.125 „	0.1182°
4.302 „	4.495 „	0.2462°

According to these data :

$\frac{q}{\Delta}$	$C = \frac{\Delta M}{q}$	$M = 18.9q/\Delta$
17.50	19.55	330.8
17.98	19.03	339.7
18.26	18.74	344.9

Thus the molecular weight of sugar calculated from the depression is nearly the actual value (342.2), and if there be a slight difference (less than $3\frac{1}{2}$ per cent.) it is not sufficient to double or halve it. And this proves that sugar (even at low temperatures, when the molecules of many substances become more complex) has the same molecular weight as is directly deduced from its composition and reactions.

Thus depression gives the possibility of proving that the molecule of peroxide of hydrogen, for instance, is composed of H_2O_2 and not HO , that the molecules of oxygen, O_2 , chlorine, Cl_2 , and bromine, Br_2 , contain two atoms, as is also seen from their densities in a gaseous state ; that the saccharine body, raffinose, has a molecular formula, $C_{18}H_{32}O_{16}$ (according to Loiseau and Scheibler), and not $C_{36}H_{64}O_{32}$, as was formerly thought ; that many metals, judging by the depression of their dilute solutions (alloys) in Na, Sn, Bi, Cu, and Pb, generally (Heycock and Neville), contain one atom in their molecules, as is seen also from the vapour densities of certain of them (Cd, Hg, &c.)—Ramsay came to the same conclusion by determining the vapour pressures of their mercury solutions ; that the molecules of sulphur and phosphorus are complex both in solutions and in a state of vapour (see Chaps. XIX. and XX.), &c. One of the advantages of the cryoscopic method is that it gives an easy means of determining the polymerisation or complexity of molecules of similar composition. As an example may be cited citraconic, itaconic, and mesaconic acids, all having the same composition, $C_6H_6O_4$. It might have been thought that the difference between them lay, at least in part, in the polymerisation of their molecules, but Paterno and Nasini showed that solutions of all three acids of equal concentration exhibit a similar depression, so that the cause of the differences in their properties was necessarily due to true isomerism, i.e., to a difference in the structure or distribution of the atoms in the molecules. This was also confirmed by other chemical relations of these acids.

Raoult (1880–1885) showed that the rise of the boiling-point of solutions (i.e., the difference D between the boiling-points of the solution and of the solvent) and the relative fall of vapour pressure (i.e., the quotient obtained by dividing the difference between the vapour pressure of the solvent and of the solution by that of the solvent) also essentially

follow the same regularity as the depression,^{27a} and therefore give a means for directly determining the molecular weight.

The extreme and very remarkable simplicity in the relations between the variation of the osmotic pressure and depression (and other properties) of solutions with the amount (q grms. per 100 grms. of the solvent) of the substance dissolved and its molecular weight (M) ceases when we pass to saline substances (acids, bases, salts), and especially to their aqueous solutions, which are capable of transmitting an electric current (electrolytes). In the case of depression, for instance, we then obtain, not a constant (for a given solvent) value (C), but magnitudes which

^{27a} From the fact that solutions having similar osmotic pressures and depressions give a similar rise in the boiling-point and one and the same vapour pressure of the solvent, it follows that the dependence on the degree of concentration and molecular weight can be expressed in terms of D as well as of Δ , thus :

$$\frac{D}{q} M = C_2 = \frac{0.02(273 + t_1)^2}{w_1},$$

where C_2 is the constant for a given solvent, t_1 its boiling-point, and w_1 its latent heat of evaporation. Thus, for water $t_1 = 100$, and $w_1 = 538$, and, therefore $C_2 = 5.17$. For instance, for sugar, where (see above) $q = 1.008$, D has the value 0.0153 (hence for water, D is nearly four times less than Δ). For alcohol, C_2 is about 11.5° , for ether, nearly 21° , for acetic acid nearly 25° , for chloroform nearly 36° , and so on. Without going into details (which may be found in works on physical chemistry) we may state that as regards the fall of vapour pressure it follows the expression (Raoult, van't Hoff):

$$\frac{f - f_1}{f} \cdot \frac{M}{q} = C_3 = 0.02d,$$

where f is the vapour pressure (at a given t) of the solvent, f_1 the vapour density of the solution containing q grms. of the substance dissolved per 100 grms., M the molecular weight of the substance dissolved, d the vapour density of the solvent (density of hydrogen = 1) near its boiling-point in a state of saturation. Therefore C_3 is nearly 0.19 for water, 0.8 for CS_2 , 1.3 for CHCl_3 , and 1.5 for CH_3I , &c. In the case of acetic acid, $\text{C}_2\text{H}_4\text{O}_2$, the density of its superheated vapour is about 30, but when saturated at the ordinary temperature it is about 48, and therefore C_3 is about 0.96 for its solutions (Raoult and Recoura, 1890).

I think it not superfluous to mention here that the constant C obtained for the depression of different liquids (when the solvent crystallises out) has values for the majority of solvents equal to nearly 63 per cent. of their molecular weights. For instance, for benzene $C = 50$, and the molecular weight = 78, for acetic acid $C = 39$ and the molecular weight 60; but for water there is a different ratio, for $C = 18.9$ and the molecular weight = 18. This apparently shows that the molecules of water may be one and a half time as complex at low temperatures as in a state of vapour, and that a portion of the molecules become associated or polymerised. Researches on the surface tension of liquids (Eotvos, Ramsay and Shields, Rose Innes) determined by the magnitude of the capillary constant (Chap. I., note 11) and its variation with the temperature lead to the same conclusion (this subject, however, belongs to the province of physical chemistry). These researches show that the molecules of certain liquids have the same weight as in a state of vapour (CS_2 , C_6H_6 , &c.), whilst in others, including water, the molecule is associated or enlarged. In the case of water it is found that at low temperatures the molecule is more complex to the extent of $1\frac{1}{3}$ (Rose Innes), or maybe three times (Ramsay and Shields). Further details must be sought in works on physical chemistry, all the more so since no direct relation has yet been discovered between the association of the molecules of water and its chemical reactions at different temperatures (note 27).

either distinctly rise or fall with the dilution of the solution, and are generally greater than those given by solutions not capable of conducting an electric current, and which moreover vary for different substances dissolved. Therefore the observed results for such solutions do not give the true molecular weights, M , corresponding to the composition, but a certain value (M_1 , *generally* less than M , and the fraction $\frac{M}{M_1}$, designated by i) is found to be greater than unity (see Chapter I., notes 19 and 49).²⁸ The following examples show, on the one hand,

²⁸ Owing to the fact that the molecular weight of electrolytes, M_1 , calculated from the depression osmotic pressure, electro-conductivity, &c., of solutions, is found to be less than M , that is, found to be greater than unity, Arrhenius, Ostwald, Nernst, and many others hypothetically assume: (1) that a portion of the electrolyte in a solution is split up into **ions** (for instance, NaCl into Na and Cl, K_2SO_4 into K, K and SO_4); (2) that these ions produce the same action in solutions as whole molecules; and (3) that the measure of the decomposition into ions is determined by the degree of dilution, so that when the amount of water is considerable the value of i approaches the number of possible ions, but when the amount of water is less a portion of the molecules remains undecomposed, and therefore i is less for strong than for weak solutions. A whole series of remarkable scientific researches (increasing our knowledge of the chemistry of solutions) were devoted to the development of this **hypothesis of electrolytic dissociation** at the close of the nineteenth century, just as in former epochs of chemistry much labour was devoted, with the enrichment of science, to electro-chemistry, to the typical representation of the structure of substances, to the principles of thermo-chemistry and to chemical mechanics, and such-like theories, which gave their most valuable contributions to the treasure-house of our science, but which have yet been forsaken in their essential points and have played the part of 'working hypotheses,' suitable for a given period of the development of science, and although a means for prompting enquiry were yet found to be far from realities and were eventually abandoned. And such in my opinion is the hypothesis of electrical dissociation (see Chap. I., note 49), all the more so as it is at variance with many facts. And as it has so far not contributed anything to the purely chemical aspect of the theory of elements, I consider it superfluous to treat of it fully in this book, the more so as this subject is, owing to its novelty, generally considered in detail by most works on physical chemistry. The chief motive which gave rise to this hypothesis is the deviation from van't Hoff's and Raoult's laws exhibited by solutions of electrolytes, which give values for i greater than unity, that is, a molecular weight M_1 less than M (the chemical molecular weight), which might be taken to indicate a splitting up of the chemical molecules of the dissolved substance in such a solution. But at the same time the same physico-chemical researches gave evidence of discrepancies in a contrary direction, indicating the association of molecules, in the case of water (note 27a), alcohol, acetic acid, and other—more especially hydroxylic—solvents, so that the matter reduces itself to this, that certain classes of chemical compounds (saline, hydroxylic) exhibit deviations from the normal behaviour proper to such indifferent bodies as the hydrocarbons and the majority of organic compounds. I think that the best interpretation of all these (abnormal) phenomena can only be obtained by increasing the number of researches (especially on the depression and fall of vapour pressure) with other solvents than water, like those made by Professor Walden (1901, Riga) on solutions in liquid sulphurous anhydride, SO_2 . By employing the method of the rise of the boiling-point, and using the constant $C_2 = 15.0$ for SO_2 (non-conductors gave i nearly equal to 1, although C_2 was calculated as shown in the preceding note from the boiling-point and latent heat of evaporation of SO_2), Walden showed that, among the electrolytes, many substances give values of i nearly equal to 1 (or tending towards unity) in very dilute solutions; for instance RbI and $N(CH_3)_3HCl$, while other saline compounds of the composition $N(CH_3)_4Cl$,

how far the results of different observers agree in respect to the value of C (if M be taken according to the chemical composition), and, on the other hand, that C not only varies with the amount q , but also with the properties and composition of the substance dissolved. The last column but one gives the value of $i = M/M_1 = M \frac{18.9q}{\Delta}$, in order to show that, with electrolytes in aqueous solution, i is generally greater than unity and varies (like C) with q and the substance taken.^{28a} In each case the concentration of the solution increases as we descend the table. The last column gives n , or the number of molecules of the substance dissolved per 100 molecules of water, that is, $n = 18q/M$, as this expresses the concentration of the solution very clearly.

For common salt NaCl ($M=58.5$), according to Pickering's (1892) observations, we obtain :

Salt per 100 grams of Water. q	Depression. Δ	$\frac{\Delta M}{q}$ C	$\frac{C}{18.9} = \frac{M}{M_1}$ i	Number of molecule per 100 H_2O . n
0.0325 gram	0.0177°	31.8	1.7	0.01
0.0975 „	0.0598°	35.9	1.9	0.03
0.1625 „	0.0992°	35.7	1.9	0.05
0.3250 „	0.1958°	35.3	1.9	0.10
1.6250 „	0.9544°	34.3	1.8	0.50

$\text{N}(\text{C}_2\text{H}_5)_4\text{I}$, and even $\text{S}(\text{CH}_3)_3\text{I}$, in solutions of SO_2 , give values of i either slightly greater than 1 or of such magnitude that they exceed 1 on further dilution. For some of the electrolytes, for instance, KI , KCNS , &c., i is distinctly less than 1, but in all these cases it increases as the solution becomes more dilute, so that i may be assumed to approximate to 1, for the limit of dilution. Walden only obtained $i=2.05$ for the crystalline compound of picric acid with β -naphtol, although the solution does not conduct an electric current, and it is difficult to suppose that decomposition takes place in the act of solution, because picric acid is insoluble in liquid SO_2 . Moreover (as with aqueous solutions) the addition of the solvent to these solutions causes the value of i sometimes to fall and sometimes to rise, and the electro-conductivity of the solutions of some salts in SO_2 is greater than that of their aqueous solutions, while for others it is less. Such facts as these, which are at variance with the hypothesis of electrolytic dissociation, may be explained, although most arbitrarily, in the sense of this hypothesis by the supposition that association takes place simultaneously with the dissociation, but it appears to me far more natural to acknowledge that exceptions to van't Hoff's law of various kinds do undoubtedly exist and are most frequently met with among electrolytes, and that so far we can only partially distinguish a uniformity in a series of phenomena in passing from one property of a solution to another, but that the internal cause of the anomalies is not yet known. If the cause of these anomalies be sought in the chemism of electrolytic solutions, we must first ask what is the effect of the reaction of the solvent on the substance dissolved. Is there not the beginning of an act of combination and of double decomposition like the action of water on a salt: $\text{MX} + \text{H}_2\text{O} = \text{MHO} + \text{MX}$? And are not the exceptions to the law exhibited by saline substances due to the fact that these substances are capable of 'instantaneous' (see Chap. I., note 49 (Kahlenberg's experiment) and in general energetic chemical reaction?

^{28a} The normal value of i for non-conductors is approximately 1; for instance, for the three solutions of sugar, judging from the above, $i=1.035$, 1.008 , and 0.992 .

The more exact observations made by Chrustchoff (1902) with the electrical thermometer agree with the above in their essential features, as the following table shows :

q	Δ	C	i	n
0.0927 gram	0.0544°	34.33	1.82	0.0302
0.1853 „	0.1082°	34.16	1.81	0.0605
0.3751 „	0.2190°	34.15	1.81	0.1225
0.7559 „	0.4420°	34.20	1.81	0.2468
1.4940 „	0.8608°	33.71	1.78	0.4877

It is seen that the value of C for dilute aqueous solutions of NaCl remains almost constant as the dilution increases, and gives $i=1.8$ (nearly) or a molecular weight, M_1 , of about 32.5. With strong solutions of NaCl the value of i increases and even exceeds 2. For instance, the solution containing 20 per cent. of salt ($q=25.0$) forms ice at -17.6° (De Coppet), i.e., $\Delta=17.6$, and therefore $C=41.2$ and $i=2.2$.^{28b} The solutions of KCl (and many other salts) closely resemble those of NaCl in their molecular depression, but many salts, even in dilute solution, exhibit a rapid increase of the molecular depression C as they become more dilute, and therefore with them the value of i increases with the amount of water. Sulphate of potassium, K_2SO_4 ($M=174.3$), is an instance in question. According to Chrustchoff :

q	Δ	C	i	$n = q \times 0.1031$
0.2798	0.0808°	50.69	2.66	0.0288
1.0941	0.2760°	43.97	2.33	0.1128
4.6096	1.0198°	38.56	2.04	0.4752

A similar increase of C and i with the degree of dilution with water is seen in many other solutions, for instance, in Chrustchoff's researches on $Pb(NO_3)_2$.²⁹

^{28b} This suffices to show that although i frequently increases and approaches the value 2, or in general a whole number, as the dilution of a solution of an electrolyte increases, still it is not a universal phenomenon, as is seen, for example, from Walden's (note 28) data. And this, and much more, undermines the hypothesis of electrolytic dissociation which is upheld by many chemists and physicists, only because of its simplicity and the ease with which it serves for constructing many new supplementary hypotheses. It seems to me that this hypothesis (of electrolytic dissociation) will in time occupy a position in the history of our science similar to that long ago accorded to phlogiston. Phlogiston had its numerous partisans who contributed much to science, although they pleaded for a false hypothesis.

²⁹ But in the case of sulphuric acid, the rise of C and i proceeds, starting with the solution containing about $2\frac{1}{2}$ per cent., in both directions, that is, on the addition of

Thus, within the limits of dilute solutions, C and i for a given electrolyte either remain almost constant or increase (this is most frequent), or in some cases decrease as the degree of dilution increases. This proves the evident complexity of the phenomenon and obliges us to look for like cases in other variations exhibited by solutions when diluted with water, and this forms one of the problems of modern physico-chemical research. And it is particularly instructive to note that the value of i in many instances of the solution of chemically similar electrolytes (for instance, KCl and $NaCl$) exhibits an analogy and dependence on the composition, while in other cases this is not observed. Thus, with sulphuric acid i is less than 2, and in the extreme limit of dilution apparently tends to approximate to the value 2; with sulphate of potassium i is greater than 2; with sulphate of magnesium (and in general RSO_4) it only slightly exceeds 1, which is also the case with $HgCl_2$ and certain other electrolytes. These instances illustrate the great complexity of the phenomena going on in the solution of saline substances. Consequently even dilute solutions of the electrolytes (in contradistinction to non-conductors) exhibit in their depression (osmotic pressure, vapour pressure, &c.) evident deviations from the laws of Raoult, van't Hoff, &c., for they evince a dependence not on the molecular weight alone, but also on the individual peculiarities of their composition.

Still it is found that certain of the properties of dilute solutions of the electrolytes are not so much determined by the individual properties of the component elements as by the molecular weight of the substance in solution, as illustrated by the vapour pressure of all substances and the osmotic pressure, depression, &c., of non-conductors. For instance, the specific gravity of corresponding (for example, chlorides) salts in dilute solutions, as is seen from the fact that solutions of the composition $RCl_n + 200H_2O$ (i.e., containing the molecular weight in grams of the salt RCl_n to 3,600 grams of water) exhibit a gradual rise in

either water or acid, as is seen from the very exact determinations of Chrustchhoff ($H_2SO_4, M = 98.08$):

q	Δ	C	i	$n = q \times 0.1835$
0.7065	0.2526°	35.07	1.85	0.1296
1.4354	0.4836°	33.04	1.75	0.2634
2.9444	0.9188°	31.61	1.67	0.5403
4.2494	1.3852°	31.97	1.69	0.7798

A like behaviour (minimum) of i is known for solutions of $BaCl_2$, $CaCl_2$, &c. (Arrhenius Pickering).

specific gravity with a rise in the molecular weight of the salt dissolved :—

	Molecular weight.	Sp. gr. at 15°.
HCl	36·5	1·0041
NaCl	58·5	1·0106
KCl	74·5	1·0121
BeCl ₂	80	1·0138
MgCl ₂	95	1·0203
CaCl ₂	111	1·0236
NiCl ₂	130	1·0328
ZnCl ₂	136	1·0331
BaCl ₂	208	1·0489

Thus not only in vapours and gases, but also in dilute solutions of solid and liquid substances, we see that if not all, still many properties are wholly dependent upon the molecular weight and not upon the quality of a substance, and that this gives the possibility of determining the weights of molecules by studying these properties (for instance, the vapour density, depression of the freezing-point, &c.). It is apparent from the foregoing that even the physical and still more so the chemical properties of homogeneous substances, especially solids and liquids, do not depend exclusively upon the weights of their molecules, but that many are in definite (see Chapter XV.) dependence upon the nature and weights of the atoms of the elements entering into their composition, and are determined by their individual peculiarities. Thus the density of solids and liquids (as will afterwards be shown) is chiefly determined by the weights of the atoms of the elements entering into their composition, inasmuch as dense elements (in a free state) and compounds are only met with among substances containing elements with large atomic weights, such as gold, platinum, and uranium. And these elements themselves, in a free state, are the heaviest of all elements. Substances containing such light elements as hydrogen, carbon, oxygen, and nitrogen (like many organic substances) never have a high specific gravity; in the majority of cases it scarcely exceeds that of water. The density generally decreases with the increase in the amount of hydrogen, which is the lightest element, and a substance is often obtained lighter than water, but all these relations are more complex than those exhibited by the vapour density. The refractive power of substances also depends entirely on the composition and the properties of the component elements.^{29a} The history of chemistry presents a

^{29a} With respect to the optical refractive power of substances, it must first be observed that the coefficient of refraction is determined by two methods: (*a*) either all the data are referred to one definite ray—for instance, to the Fraunhofer (sodium) line D

striking example in point—Newton foresaw from the high refractive index of the diamond that it would contain a combustible substance, since so many combustible oils have a high refractive power. We shall afterwards see (Chapter XV.) that many of those properties of substances which are in direct dependence not upon the weight of the molecules but upon their composition, or, in other words, upon the properties and quantities of the elements entering into them, exhibit a peculiar (periodic) dependence upon the atomic weights of the elements; that is, the mass (of molecules and atoms), proportional to the weight, determines the properties of substances as (with the distance) it also determines the motions of the heavenly bodies. The mass (weight) of

of the solar spectrum—that is, to a ray of definite wave-length, and often to that red ray (of the hydrogen spectrum) whose wave-length is 656 millionths of a millimetre; (*b*) or else Cauchy's formula is used, showing the relation between the coefficient of refraction and dispersion to the wave-length, $n = A + \frac{B}{\lambda^2}$, where A and B are two constants varying

for every substance but constant for all rays of the spectrum, and λ is the wave-length of that ray whose coefficient of refraction is n . In the latter method the investigation usually concerns the magnitudes of A, which are independent of dispersion. We shall afterwards cite the data, investigated by the first method, by which Gladstone, Landolt, and others established the conception of the refraction equivalent.

It has long been known that the **coefficient of refraction** n for a given substance decreases with the density D, so that the magnitude $(n-1) \div D = C$ is almost constant for a given ray (having a definite wave-length) and for a given substance. This constant is called the *refractive energy*, and its product with the atomic or molecular weight of a substance the *refraction equivalent*. The coefficient of refraction of oxygen is 1.00021, that of hydrogen 1.00014, their densities (referred to water) being 0.00143 and 0.00009, and their atomic weights, O = 16, H = 1; hence their refraction equivalents are 2.4 and 1.6 respectively. Water contains H_2O ; consequently the sum of the refraction equivalents is $(2 \times 1.6) + 2.4 = 5.6$. But as the coefficient of refraction of water = 1.331, its refraction equivalent is 5.958, or nearly 6. Comparison shows that the sum of the refraction equivalents of the atoms forming compounds (or mixtures) is approximately equal to the refraction equivalent of the compound. The researches of Gladstone, Landolt, Kannonikoff, Brühl, and others give the refraction equivalents of the elements determined from the composition (and chemical structure) of their compounds. The refraction equivalents of many elements could only be calculated from the solutions of their compounds. The composition of a solution being known, it is possible to calculate the refraction equivalent of one of its component parts, those for all its other components being known, and taking the sum of their equivalents as equal to the equivalent for the compound. The results are founded on the acceptance of a law which cannot be strictly applied. Nevertheless the representation of the refraction equivalents gives an easy means for directly, although only approximately, obtaining the coefficient of refraction from the chemical composition of a substance. For instance, from the composition of carbon bisulphide, CS_2 , and its density, 1.27, we find its coefficient of refraction to be 1.618 (because the refraction equivalent = $5 + 2 \times 16 = 37$, if $C = 5$ and $S = 16$), which is very near the actual figure. It is evident that in the above representation compounds are looked on as simple mixtures of atoms, and the physical properties of a compound as the sum of the properties present in the elementary atoms forming it. If this representation of the presence of simple atoms in compounds had not existed, the idea of combining by a few figures a whole mass of data relating to the coefficient of refraction of different substances could hardly have arisen. For further details on this interesting subject see works on physical chemistry.

the molecules determines, as we saw, many of the physical and chemical properties of substances, starting with their vapour densities and the amount entering into reaction, while the mass (weight of the atom) of the elements composing the molecule determines, as we shall afterwards see, many other chemical and physical properties of substances. The dependence of the visible properties on the masses of invisible molecules and atoms forms one of the greatest acquisitions of our science.³⁰

³⁰ It must be remembered, however, that the conception of mass or quantity of ponderable matter has remained, from the time of Newton and Galileo, in many respects obscure, and most important results for natural science may be expected from researches (and therefore hypotheses) on the attractions evidenced by masses of matter.

CHAPTER VIII

CARBON AND THE HYDROCARBONS

It is necessary to clearly distinguish between the two closely allied terms, charcoal and carbon. Charcoal is well known to everybody, although it is no easy matter to obtain it in a chemically pure state. Pure charcoal is a simple, insoluble, infusible, combustible substance produced by heating organic matter, and has the familiar aspect of a black mass, devoid of any crystalline structure, and completely insoluble. **Charcoal is a substance** possessing a peculiar combination of physical and chemical properties. This substance, while in a state of ignition, combines directly with oxygen; in organic substances it is found in combination with hydrogen, oxygen, nitrogen, and sulphur. But in all these combinations there is no real charcoal, in the same way as there is no ice in steam. What is found in such combinations is termed **carbon**—that is, **an element** common to charcoal, to those substances which can be formed from it, and also to those substances from which it can be obtained. Carbon may take the form of charcoal, but occurs also as diamond and as graphite. Truly no other element has such a wide terminology. Oxygen is always called 'oxygen,' whether it is in a free gaseous state, or in the form of ozone, or as oxygen in water, nitric acid, or carbonic anhydride. But here there is some confusion. It is evident that in water there is no oxygen in a gaseous form, such as can be obtained in a free state, and no oxygen in ozone, but a substance which is capable of producing oxygen, ozone, and water. As an element, oxygen possesses a known chemical individuality, and exerts an influence on the properties of those combinations into which it enters. Hydrogen gas is a substance which reacts with difficulty, but the element hydrogen represents in its combinations an easily displaceable component part. Carbon may be considered as an atom of carbon matter, and charcoal as a collection of such atoms forming a whole substance, or mass of molecules of the substance. The accepted atomic weight of carbon is 12, because that is the least quantity of carbon which enters

into combination in molecules of its compounds ; but the weight of the molecules of charcoal is probably very much greater. The molecular weight is unknown, because charcoal is capable of but few direct reactions, and those only occur at a high temperature (when the weight of its molecules probably changes, as does that of ozone when it changes into oxygen), and it does not turn into vapour and has no solvent.

Carbon exists in nature, both in a free and a combined state, in most varied forms and aspects. Carbon in a free state is found in at least *three* different forms, namely, charcoal, graphite, and the diamond. In a combined state it enters into the composition of what are called **organic substances**—a multitude of substances found in all plants and animals. It exists as carbonic anhydride both in air and in water, and in the soil and crust of the earth as salts of carbonic acid and as organic remains.

The variety of the substances of which the structure of plants and animals is built up is familiar to all. Wax, oil, turpentine, and tar, cotton and albumin, the tissue of plants and the muscular fibre of animals, tartaric acid and starch, all these and many other substances entering into the composition of the tissues and juices of plants and animals are carbon compounds.¹ The class of carbon compounds is so

¹ **Wood** is the non-vital part of ligneous plants, the vital part of ordinary trees being situated between the bark and the lignine. Every year a layer of lignine is deposited on this part by the juices which are absorbed by the roots and drawn up by the leaves, so that the age of trees may be determined by the number of lignine layers deposited. The woody matter consists principally of fibrous tissue on to which the lignine or so-called incrusting matter has been deposited. The tissue has the composition $C_6H_{10}O_5$, the substance deposited on it containing more carbon and hydrogen and less oxygen. This matter is saturated with moisture when the wood is in a fresh state. Fresh birch wood contains about 31 per cent. of water, lime wood 47 per cent., oak 35 per cent., pine and fir about 37 per cent. When dried in the air the wood loses a considerable quantity of water, and not more than 19 per cent. remains. By artificial means this loss of water may be increased. If water be driven into the pores of wood it sinks, as the lignine of which it is composed has a density of about 1.6. One cubic centimetre of birch wood does not weigh more than 0.901 gram, fir 0.894, lime wood 0.817, poplar 0.765, when in a fresh state; when in a dry state birch weighs 0.622, pine 0.550, fir 0.355, lime 0.430, guaiacum 1.342, and ebony 1.226 gram per c.c. On one hectare (2.7 acres) of woodland in the temperate zone the yearly growth attains 3,000 kilograms (or about 3 tons) of wood, but rarely reaches as much as 5,000 kilos. (of stems and roots, not including small branches and leaves). The average chemical composition of wood dried in air may be expressed as follows:—Hygroscopic water 15 per cent., carbon 42 per cent., hydrogen 5 per cent., oxygen and nitrogen 37 per cent., ash 1 per cent. Wood parts with its hygroscopic water and begins to decompose at 150° , and at about 300° it gives a brown, brittle, so-called red charcoal; above 350° black charcoal is produced. As the 5 per cent. of hydrogen contained in wood requires for its combustion about forty parts by weight of oxygen, which is present to the amount of about 37 per cent., all that burns of the wood is the carbon which it contains, 100 parts of wood only giving out as much heat as forty-two parts of charcoal, and therefore it would be far more profitable to use charcoal for heating purposes than wood, if it were possible to obtain it in such quantities as correspond with its percentage ratio—that is, forty parts per 100 parts of wood.

vast that it forms a separate branch of chemistry, known under the name of organic chemistry—that is, the chemistry of carbon compounds, or, more strictly, of the hydrocarbons and their derivatives.

Generally, however, the quantity produced is far less, not more than 30 per cent., because part of the carbon is given off as gas, tar, and other volatile substances. If wood has to be transported great distances, or if it is necessary to obtain a very high temperature by burning it, even as little as 25 per cent. of charcoal from 100 parts of wood may be advantageous. Charcoal (from wood) develops on burning 8,000 heat units, whilst wood dried in air does not develop more than 3,400 units, so that one part of charcoal gives as much heat as $2\frac{1}{2}$ parts of wood. As regards the temperature of combustion, it is far higher with charcoal than with wood, because burning wood gives, besides the carbonic anhydride which is also formed together with charcoal, a large proportion of water, the evaporation of which requires a considerable amount of heat.

The composition of the **growing parts** of plants, the leaves, young branches, shoots, &c., differs from the composition of the wood in that these vital parts contain a considerable quantity of sap which contains much nitrogenous matter (in the wood itself little of this exists), mineral salts, and a large amount of water. Let us take, for example, the compositions of clover and pasture hay in the green and dry states; in green clover there is about 80 per cent. of water and 20 per cent. of dry matter, about 3·5 of which is nitrogenous albuminous matter, about 9·5 soluble, and about 5 insoluble non-nitrogenous matter, and about 2 per cent. of ash. In dry clover or clover-hay there is about 15 per cent. of water, 13 per cent. of nitrogenous matter, about 70 per cent. of cellulose and other non-nitrogenous carbohydrates, and 7 per cent. of ash. This composition shows the difference existing between the nutritive properties of wood and the substances mentioned. These latter serve as food for animals, because they contain those substances which are capable

FIG. 65.—Apparatus for the dry distillation of wood. The retort *a* containing the wood is heated by the flues *c e*. The steam and volatile products of distillation pass along the tube *g* through the condenser *m*, where they are condensed. The form, distribution, and dimensions of the apparatus vary.

of being dissolved (entering into the blood) and of forming the bodies of animals; such substances are proteids, starch, &c. Let us remark here that with a good harvest an acre of land gives in the form of grass as much (and even more) organic substance in a year as it yields in the form of wood.

Dry wood is capable of giving, on **dry distillation**, besides 25 per cent. of charcoal and 10 per cent. or more of tar, 40 per cent. of watery liquid, containing acetic acid and wood spirit, and about 25 per cent. of gases, which may be used for heating or lighting purposes, because they do not differ from ordinary illuminating gas, which can indeed be obtained

If any one of these organic compounds be strongly heated without free access of air—or, better still, in a vacuum—it decomposes with more or less facility. If the supply of air be insufficient, or the temperature too low for combustion (see Chapter III.), and if the first volatile products of transformation of the organic matter are subjected to condensation (for example, if the door of a stove be opened), an *imperfect* combustion takes place, and **smoke**, with charcoal or soot, is formed.² The nature of the phenomenon, and the products arising from

from wood. As wood-charcoal and tar are valuable products, in some cases the dry distillation of wood is carried on principally for producing them. For this purpose those kinds of woods are particularly suitable which contain resinous substances, especially coniferous trees, such as the fir, pine, &c.; birch, oak, and ash give much less tar, but on the other hand they yield more aqueous liquor. The latter is used for the manufacture of wood spirit, CH_4O , and acetic acid, $\text{C}_2\text{H}_4\text{O}_2$. In such cases the dry distillation is carried on in stills. The stills are nothing more than horizontal or vertical cylindrical retorts, made of boiler plate, heated with fuel and having apertures at the top and sometimes also at the bottom for the exit of the light and heavy products of distillation. The dry distillation of wood in stoves is carried on in two ways, either by burning a portion of the wood inside the stove in order to submit the remainder to dry distillation by means of the heat obtained in this manner, or by placing the wood in a stove the thin sides of which are surrounded with a flue leading from the fuel, placed in a space below. The first method does not give such a large amount of the liquid products of dry distillation as the latter. In the latter process there is generally an outlet below for emptying out the charcoal at the close of the operation. For the dry distillation of 100 parts of wood from forty to twenty parts of fuel are used.

In the north of Russia wood is so plentiful and cheap that this locality is admirably fitted to become the centre of a general trade in the products of its dry distillation, especially acetic acid. Coal (note 6), seaweed, turf, animal substances (Chap. VI.), &c., are also submitted to the process of dry distillation.

² The result of imperfect combustion is not only the loss of a part of the fuel and the production of smoke, which in some respects is inconvenient and injurious to health, but also a low flame-temperature, which means that a less amount of heat is transmitted to the object heated. Imperfect combustion is not only always accompanied by the formation of soot or unburnt particles of charcoal, but also by that of carbonic oxide, CO , in the smoke (Chap. IX.) which burns, emitting much heat. In works and factories where large quantities of fuel are consumed, many appliances are adopted to ensure perfect combustion, and to combat against such a ruinous practice as the imperfect combustion of fuel. The most effective and radical means consists in employing combustible gases (producer and water gases), because by their aid perfect combustion can be easily realised without a loss of heat-producing power and the highest temperature can be reached. When solid fuel is used (such as coal, wood, and turf), imperfect combustion is most liable to occur when the furnace doors are opened for the introduction of fresh fuel. The step furnace may often prove a remedy for this defect. In the ordinary furnace fresh fuel is placed on the burning fuel, and the products of the dry distillation of the fresh fuel have to burn at the expense of the oxygen remaining uncombined with the burnt fuel. Imperfect combustion is observed in this case also from the fact that the dry distillation and evaporation of the water of the fresh fuel lying on the top of that burnt lowers the temperature of the flame, because part of the heat becomes latent. On this account a large amount of smoke (imperfect combustion) is observed when a fresh quantity of fuel is introduced into the furnace. This may be obviated by constructing the furnace (or managing the stoking) in such a way that the products of distillation pass through the red-hot charcoal remaining from the burnt fuel. It is only necessary, in order to ensure this, to allow a sufficient quantity of air for perfect combustion. All this may be easily attained by the use of step fire-bars. The fuel is fed into a hopper and

it, are the same as those produced by heating, since that part which is in a state of combustion serves to heat the remainder of the fuel. The decomposition which takes place on heating a compound composed of carbon, hydrogen, and oxygen is as follows:—A part of the hydrogen is separated in a gaseous state, another part in combination with oxygen, and a third part separates in combination with carbon, and sometimes in combination with carbon and oxygen in the form of gaseous or volatile products, or, as they are also called, the products of dry distillation. If the vapours of these products are passed through a strongly heated tube, they are changed again in a similar manner, and finally resolve themselves into hydrogen and charcoal. Altogether these various products of decomposition contain a smaller amount of carbon than the original organic matter; part of the carbon remains in a free state, forming charcoal.³ It remains in that space where falls on to the fire-bars, which are arranged in the form of a staircase. The burning charcoal is below, and hence the flame formed by the fresh fuel is heated by the contact of the red-hot burning charcoal. Coke, charcoal, and anthracite burn without smoke, because they do not contain hydrogenous substances which furnish the products of dry distillation, but imperfect combustion may occur with them also; in that case the smoke contains carbonic oxide. Details on the subject of fuel and furnaces, &c., must be sought in works on chemical technology.

³ Under the action of air, organic substances are capable of oxidising to such an extent that all the carbon and all the hydrogen they contain will be transformed into carbonic anhydride and water. The refuse of plants and that of animals are subjected to such a change whether they slowly decompose and putrefy, or rapidly burn with direct access of air. But if the supply of air be limited, there can be no complete transformation into water and carbonic anhydride, and there will then be other volatile matters (rich in hydrogen), while charcoal must remain as a non-volatile substance. All animal and vegetable substances are unstable, and change at ordinary temperatures, particularly if water is present. It is therefore easy to understand that charcoal may in many cases be obtained through the transformation of substances entering into the composition of organisms, but that it is never found in a pure state.

However, water and carbonic anhydride are not the only products separated from organic substances. Carbon, hydrogen, and oxygen are capable of giving a multitude of compounds; some of these are volatile compounds, gaseous, soluble in water—they are carried off from organic matter, undergoing change without access of air. Others, on the contrary, are non-volatile, rich in carbon, unaffected by the action of natural agents. The latter remain in admixture with charcoal in the place where the decomposition takes place; such, for example, are tarry substances. The quantity of those bodies found mixed with the charcoal is very varied, and depends on the energy and duration of the decomposing agent. The annexed table shows, according to the data of Violette, those changes which wood undergoes at various temperatures when submitted to dry distillation by means of superheated steam.—

Temperature	Residue from 100 parts of alder wood	In 100 parts of the residual charcoal			
		C	H	O and N	Ash
150°	100·0	47·5	6·1	46·3	0·1
350°	29·7	76·6	4·1	18·4	0·6
1032°	18·7	81·9	2·3	14·1	1·6
1500°	17·3	95·0	0·7	3·8	1·7

the decomposition took place, in the shape of the black, infusible and non-volatile charcoal familiar to all. The earthy matter, ash and all non-volatile substances forming a part of the organic matter remain behind with the charcoal. The tar-like substances, which require a high temperature in order to decompose them, also remain mixed with the charcoal. If a volatile organic substance, such as a gaseous compound containing oxygen and hydrogen, be taken, the carbon separates when the vapour is passed through a tube heated to a high temperature. Organic substances when burning with an insufficient supply of air give off soot—that is, charcoal—proceeding from carbon compounds in a state of vapour, the hydrogen of which has, by combustion, been converted into water; thus, for instance, turpentine, naphthalene, and other hydrocarbons which are with difficulty decomposed by heat, readily yield carbon in the form of soot during combustion.

Wood charcoal is prepared in large quantities in a similar manner—that is, by the partial combustion of wood.⁴ In nature a similar process of carbonisation of vegetable refuse takes place in its transformation under water, as shown by the marshy vegetation which forms peat.⁵

⁴ The object of producing charcoal from wood has been explained in note 1. **Wood charcoal** is obtained in so-called stacks by partially burning the wood, or by means of dry distillation (note 1) without the access of air. It is principally manufactured for metallurgical processes, especially for smelting and forging iron. The preparation of charcoal in stacks has one advantage, and that is, that it may be done on any spot in the forest. But in this way all the volatile products of the dry distillation are lost. For charcoal burning, a pile or stack is generally built, in which the logs are placed close together, either horizontally, vertically, or inclined, forming a stack of from six to fifty feet in diameter, and even larger. Under the stack are several horizontal air passages, and in the middle an opening to let out the smoke. The surface of the stack is covered with earth and sods, in order to hinder the free passage of air and to concentrate the heat inside. When the stack is kindled, the pile begins to settle down by degrees, and it is then necessary to look after the turf casing and keep it in repair. As the combustion spreads throughout the whole pile, the temperature rises and real dry distillation commences. It is then necessary to stop the air holes, in order to prevent as far as possible unnecessary combustion. The essence of the process is, that part of the fuel burns and develops the heat required for subjecting the remainder to dry distillation. The charring is stopped when the products of dry distillation, which are emitted, no longer burn with a brilliant flame, but with the pale blue flame of carbonic oxide. Dry wood in stacks yields about one-fourth of its weight of charcoal.

⁵ When dead vegetable matter undergoes transformation in the air, in the presence of moisture and lower organisms, there remains a substance richer in carbon—namely, **humus**, black earth, or mould. In a dry state humus contains about 70 per cent. of carbon. The non-vital vegetable substance (ligneous tissue) first forms brown matter (ulmic compounds), and then black matter (humic substances), which are both insoluble in water; after this a brown acid is produced, which is soluble in water (apocrenic acid), and lastly a colourless acid also soluble in water (crenic acid). Alkali dissolves a part of the original brown and black substances, forming solutions of a brown tint (ulmic and humic acids) which sometimes communicate their colour to springs and rivers. The proportion of humus in soil generally has a direct influence on its fertility; first, because putrefying plants develop carbonic anhydride and ammonia, and yield the

In this manner were doubtless formed ⁶ the enormous masses of coal which, following the example set by England, are now utilised

substances forming the ashes of plants, which are necessary to vegetation; secondly, because humus is capable of attracting the moisture of the air and of absorbing water (twice its weight) and in this way keeps the soil in a damp condition, which is indispensable for nourishment; thirdly, humus renders the soil porous; and, fourthly, it renders it more capable of absorbing the heat of the sun's rays. On this account black earth is often possessed of most remarkable fertility. One object of manuring is to increase the quantity of humus in the soil, and any easily changeable vegetable or any animal matter (composts) may be used. The boundless tracts of black earth soil in Russia are capable of bestowing countless wealth on the country.

The origin and extent of black earth soil are treated in detail in Professor Dokouchaëff's works.

If those substances which produce humus undergo decomposition under water, less carbonic anhydride is formed, a quantity of marsh gas, CH_4 , is evolved, and the solid residue forms an acid humus found in large quantities in marshy places and called **peat**. Peat is especially abundant in the lowlands of Holland, North Germany, Ireland, and Bavaria. In Russia it is likewise found in large quantities, especially in the central districts. The old hard forms of peat resemble, in composition and properties, brown coal; the newest formations, as yet unhardened by pressure, form very porous masses which retain traces of the vegetable matter from which they have been formed. Dried (and sometimes pressed) peat is used as fuel. The composition of peat varies considerably with the locality in which it is found. When dried in air it does not contain less than 15 per cent. of water and 8 per cent. of ash; the remainder consists of 45 per cent. of carbon, 4 per cent. of hydrogen, 1 per cent. of nitrogen, and 28 per cent. of oxygen. Its heating power is about equivalent to that of wood. The **brown** earthy varieties of **coal** were probably formed like peat. In other cases they have a marked woody structure, and are then known as lignites. Brown coals present an intermediate stage between peat and coals.

⁶ Grass and wood, the vegetation of primeval seas and similar refuse of all geological periods, must have been in many cases subjected to the same changes as they now undergo—that is, under water they formed peat and lignites. Such substances, preserved for a long time underground, subjected to the action of water, compressed by the more recent strata formed above them, transformed by the separation of their more volatile component parts (peat and lignites, even in their last condition, still continue to evolve nitrogen, carbonic anhydride, and marsh gas), form **coal**. Coal is a dense homogeneous mass, black, with an oily or glassy lustre, or more rarely dull without any evident vegetable structure; this distinguishes it in appearance from the majority of lignites. The density of coal (not counting the admixture of pyrites, &c.) varies from 1.25 (dry bituminous coal) to 1.6 (anthracite, flameless), and even reaches 1.9 in the very dense variety of coal found in the Olonetzky Government (termed shungite), which according to the investigations of Professor Inostrantzeff may be regarded as the extreme member of the various forms of coal.

In order to explain the formation of coal from vegetable matter, Cagniard de la Tour enclosed pieces of dried wood in a tube and heated them to the boiling-point of mercury, when the wood was changed into a semi-liquid black mass, from which a substance exceedingly like coal separated. In nature the decomposition was in rare cases probably effected by heat alone; more generally it was effected by means of water and heat, but in either case the result should be almost the same.

The average composition of coal compiled from many analyses, disregarding the ash, is as follows: 84 parts of carbon, 5 parts of hydrogen, 1 part of nitrogen, 8 parts of oxygen, 2 of sulphur. The quantity of ash is on an average 5 per cent., but there are coals which contain a larger quantity, and naturally they are not so suitable for use as fuel. The **anthracites** form a remarkable variety of coals, giving no volatile products, or but a very small amount, as they contain but little hydrogen compared with oxygen. In

everywhere as the principal material for heating steam boilers, and in general for all purposes of heating and burning.⁷ Russia possesses many very rich coalfields, amongst which the Donetz district is most worthy of remark at the present day.⁸

the average composition of coal we saw that for 5 parts of hydrogen there were 8 parts of oxygen; therefore 4 parts by weight of the hydrogen are capable of forming hydrocarbons, because 1 part of hydrogen is necessary in order to form water with the 8 parts of oxygen. These 4 parts by weight of hydrogen can convert 48 parts of carbon into volatile products, because 1 part of hydrogen by weight is combined in these substances with 12 parts of carbon. The anthracites differ essentially from this: neglecting the ash, their average composition is as follows: 94 parts of carbon, 3 of hydrogen, and 3 of oxygen and nitrogen. According to the analyses of A. A. Voskresensky, the Grousheffsky anthracite (Don district) contains: C = 93.8, H = 1.7, ash = 1.5. So that the anthracites contain but little hydrogen capable of combining with the carbon to form hydrocarbons which burn with a flame. Anthracites are the oldest forms of coal. The newest and least transformed coals, which resemble some of the brown varieties, are the *dry* coals. They burn with a flame like wood, and leave a coke having the appearance of lumps of coal, half their component parts being absorbed by the flame (they contain much hydrogen and oxygen). According to Grüner, the remaining varieties of coal (gas coal, smithy coal, coking, and anthracite) form in all respects connecting links between the dry coals and the anthracites. These coals burn with a very smoky flame, and on being heated leave **coke**, which bears the same relation to coal as charcoal does to wood. The quantity and quality of the coke vary considerably with the different sorts of coal from which it is formed. In practice coals are most often distinguished by the properties and quantity of the coke which they give. In this particular the so-called bituminous coals are especially valuable, as even slack of this variety gives on dry distillation large spongy masses of coke. The best coking coals give 65 per cent. of dense caking coke. Such coal is very valuable for metallurgical purposes (see note 8). Besides coke, the dry distillation of coal produces gas (see further, illuminating gas), coal-tar (which gives benzene, carbolic acid, naphthalene, tar for artificial asphalt, &c.) and also an aqueous alkaline liquor (with wood and lignites the liquid is acid from acetic acid) which contains ammonium carbonate (see note 6).

⁷ In England the output of coal in 1850 was as much as 48 million tons, and in latter years it has risen to about 220 millions. The United States of America already exceed England in output, and the whole world produces yearly about 650 million tons of coal, of which about 25 million tons fall to the share of Russia. Thus the world consumes over half a milliard tons of coal a year, representing a value of not less than half a milliard pounds sterling. Coal thus forms, after corn, the most important article of commerce. Its chief demand is for the generation of mechanical power in steamers, railways, and manufactories, and also for the production of iron and other metals, and for heating purposes. As every horse-power (= 75 kilogrammetres per second) of a steam-engine uses up on the average more than 25 kilograms in 24 hours, or in a year (counting stoppages) as much as 5 tons, not less than 65 million horse-power must be at work in the world. For this reason coal serves as a criterion of the industrial development of a country. About 15 per cent. of the coal is used for the manufacture of cast iron, wrought iron, steel, and articles made of them.

⁸ The principal coal beds of Russia under exploitation are: The Don basin (1901, about 930 million poods; 62 poods = 1 ton), the Polish basin (Dombrovo and others), the Toula and Riazan beds of the Moscow basin, the Ural basin, the Caucasian (Kviboul, near Kutais), the Khirjhis steppes, the smithy coal basin (Government of Tomsk), the Sahaline, &c. The Polish and Moscow basins do not give any coking coals. The presence of every variety of coal (from the dry coal near Lisichansk on the Donetz to the anthracites of the entire south-east basin), the great abundance of excellent metallurgical coal (coking, see note 6) in the western part of the basin, its vast extent (as much as 25,000 sq. versts),

Judging from what has been already said, **soot** is finely divided charcoal separated during the imperfect combustion of the vapours and gases of carbonaceous substances rich in carbon. Specially prepared soot (lampblack) is very largely used as a black paint and a large quantity goes for the manufacture of printer's ink. It is prepared by burning tar, oil, natural gas, naphtha, &c. The quantity of organic and tarry matter remaining undecomposed in the charcoal depends on the temperature to which it has been submitted. Charcoal prepared at the lowest temperature still contains a considerable quantity of hydrogen and oxygen—even as much as 4 per cent. of hydrogen and 20 per cent. of oxygen. Such charcoal still preserves the structure of the substance from which it was obtained. Ordinary charcoal, for instance, in which the structure of the tree is still visible, is of this kind. On submitting it to further heating, a fresh quantity of hydrogen with carbon and oxygen (in the form of gases or volatile matter) may be separated, and the purest charcoal will be obtained on submitting it to the greatest heat.⁹ If it be required to prepare pure charcoal from soot, it is necessary to first wash it with alcohol and ether in order to remove the soluble tarry products, and then submit it to a powerful heat to drive off the impurities containing hydrogen and oxygen. Its porosity,¹⁰ bad conducting power for heat, capacity for

the proximity of the seams to the surface (the shafts are now from 20 to 150 fathoms deep, and in England and Belgium as deep as 500 fathoms), the fertility of the soil (black earth), the proximity of the sea (about 100 versts from the Sea of Azov) and of the rivers Donetz, Don, and Dneiper, the abundant seams of excellent iron ore (Korsan Mogila, Krivoy Rog, Soulin, &c.), copper ore, mercury ore (near Nikitovka, in the Bakhmouth district of the Ekaterinoslav Government), and other ores, the richest probably in the whole world, the beds of rock-salt (near the stations of the Stoupka and Brianzovka), the excellent clay of all kinds (china, fire-clay), gypsum, slate, sandstone, and other **wealth of the Don coal basin**, give complete assurance of the fact that, with the growth of industrial activity in Russia, this bountiful land of the Cossacks and New Russia will become the centre of the most extensive productive enterprise, not for the requirements of Russia alone, but for those of the whole world, because in no other place can be found such a concentration of favourable conditions.

⁹ As it is difficult to separate from the charcoal the admixture of ash—that is, the earthy matter contained in the vegetable substance used for producing charcoal—in order to obtain it in its purest condition it is necessary to use such organic substances as do not contain any ash, for example, completely refined or purified crystallised sugar, crystallised tartaric acid, &c.

¹⁰ The cavities in charcoal are the passages through which those volatile products formed at the same time as the charcoal have passed. The degree of porosity of charcoal varies considerably in different kinds of charcoal, and has a technical significance. The most porous charcoal is very light; a cubic metre of wood charcoal weighs about 200 kilograms. Many of the properties of charcoal which depend exclusively on its porosity and surface conditions are shared by certain other porous (contact) substances, and vary with the way it is prepared. The property which charcoal has of absorbing gases, liquids, and many substances in solution is a case in point. The densest kind of charcoal is formed by the action of great heat on sugar and other fusible substances.

absorbing the luminous rays (hence its blackness and opacity), and many other qualities, are familiar from everyday experience.¹¹ The specific gravity of charcoal varies from 1·4 to 1·9, and that it floats on water is due to the air contained in its pores. If charcoal is reduced to a powder and moistened with spirit, it immediately sinks in water.

The lustrous grey dense coke formed in gas retorts is also of this character. This dense coke collects on the internal walls of the retorts subjected to great heat, and is produced by the vapours and gases separated from the heated coal in the retorts. In virtue of its density such coke becomes a good conductor of the galvanic current and approximates to graphite. It is principally used in galvanic batteries. Coke, or the charcoal remaining from the imperfect combustion of coal and tarry substances, is also but slightly porous, brilliant; does not soil or mark paper, is dense, almost devoid of the faculty of retaining liquids and solids, and does not absorb gases. The light sorts of charcoal produced from charred wood, on the other hand, show this absorptive power in a most marked degree. This property is particularly developed in that very fine, friable charcoal prepared by heating animal substances such as hides and bones. **The absorptive power of charcoal** for gases is similar to the condensation of gases in spongy platinum. There is here evidently a case of the adherence of gases to a solid, precisely as liquids adhere to various solids. One volume of charcoal will absorb the following volumes of gases (charcoal is capable of absorbing an immense amount of chlorine, almost equal to its own weight):—

Saussure. Boxwood Charcoal		Favre. Cocoanut Charcoal		Heat emitted per gram of gas absorbed	
NH ₃	90	172	vols.	494	units
CO ₂	35	97	„	158	„
N ₂ O	40	99	„	169	„
HCl	85	165	„	274	„

The quantity of gas absorbed by the charcoal increases with the pressure, and is approximately proportional to it. The quantity of heat given out by the absorption nearly approaches that set free by the gas on dissolving, or on passing into a liquid condition.

Charcoal absorbs not only gases, but a number of other substances. For instance, alcohol which contains disagreeably smelling fusel oil, on being mixed with charcoal or filtered through it, loses most of the fusel oil. The practice of filtering substances through charcoal in order to get rid of foreign matters is often applied in chemical and manufacturing processes. Oils, spirits, various extracts, and vegetable and other solutions are filtered through charcoal in order to purify them. The bleaching power of charcoal may be tested by using various coloured solutions—such as aniline dyes, litmus, &c. Charcoal which has absorbed one substance to saturation is still capable of absorbing certain other substances. Animal charcoal, produced in a very finely divided state (and containing a certain amount of nitrogenous matter), especially by heating bones, is the best form for the purposes of absorption. Bone charcoal is used in large quantities in sugar works for filtering syrups and all saccharine solutions, in order to purify them, not only from colouring and odorous matter, but also from the lime which is mixed with the syrups in order to render them less unstable during boiling. The absorption of lime by animal charcoal very probably depends in a great degree on the presence of mineral constituents.

¹¹ Charcoal is a very bad conductor of heat, and therefore forms an excellent insulator or packing to prevent the transmission of heat. A charcoal lining is often made use of in crucibles for heating substances, as it does not melt, and resists a far greater heat than many other substances.

It is **infusible** in the furnace and even at the temperature of the oxyhydrogen flame. In the heat generated by means of a powerful galvanic current charcoal only softens but does not completely melt, and on cooling it is found to have undergone a complete change both in properties and appearance, and to present more or less of a transition towards graphite. The physical stability of charcoal is without doubt allied to its chemical stability. It is evidently a substance devoid of energy, for it is insoluble in all known liquids, and **at ordinary temperatures does not combine with anything**; it is an inactive substance, like nitrogen.¹² But these properties of charcoal change with a rise of temperature; thus, unlike nitrogen, charcoal, at a high temperature, combines directly with oxygen. This is well known, as charcoal burns in air. Indeed, not only does oxygen **combine with charcoal at a red heat**, but sulphur, hydrogen, silicon, and also iron and many other metals ^{12a} do so at a very high temperature—that is, when the molecules of the charcoal have reached a state of great instability—whilst at ordinary temperatures neither oxygen, sulphur, nor metals act on charcoal in any way. When burning in oxygen, charcoal forms carbonic anhydride, CO_2 , or in the presence of an excess of charcoal gaseous carbon monoxide, CO , whilst in the vapours of sulphur, carbon bisulphide, CS_2 , is formed; further iron and other metals, when acted on by carbon, form solid non-soluble carbides. At the great heat obtained by passing the galvanic current through carbon electrodes, charcoal combines with hydrogen, forming acetylene, C_2H_2 . Charcoal does not combine directly with nitrogen, but in the presence of metals and alkaline oxides, nitrogen is absorbed, forming a metallic cyanide, such, for instance, as potassium cyanide, KCN . In all respects the faculty of carbon for combining with oxygen is its most important property.

¹² The unalterability of charcoal under the action of atmospheric agencies, which produce changes in the majority of stony and metallic substances, is often made use of in practice. For example, charcoal is frequently strewn in boundary ditches. The surface of wood is often charred to render it durable in those places where the soil is damp and wood itself would soon rot. The chambers (or in some works towers) through which acids pass (for example, sulphuric and hydrochloric) in order to bring them into contact with gases or liquids, are filled with charcoal or coke, because at ordinary temperatures it resists the action of even the strongest acids.

^{12a} The carbides of Ca, Se, Ba are mentioned at the end of Chap. XIV., Al_4C_3 in Chap. XVII., note 3, &c. As regards the different carbides, Moissan, who obtained them by the action of charcoal on oxides under the influence of the heat of the voltaic arc, observed that water does not act on some of them (Fe_3C , Cr_3C_2 , Cr_4C_4 , Mo_2C , WC , VC , ZrC , TiC), whilst others—for instance, C_2Li_2 , C_2Ca (also Sr , Ba), Be_2C , CMn_3 , C_3Ur_2 —are decomposed with the evolution of hydrocarbons. Some of the carbides (of Au, Bi, Sn) do not dissolve carbon in the heat of the electric furnace, while others (of Cu, Ag, Pt) dissolve it to a greater or less extent under these conditions, but in the majority of cases deposit it as graphite on cooling. It must be mentioned that K_2C_2 and Na_2C_2 are easily decomposed by heat, and can only be obtained indirectly (see Chapter XII.).

Certain substances containing oxygen give up a part of it to charcoal at a relatively low temperature. For instance, nitric acid when boiled with charcoal gives carbonic anhydride and nitrogen peroxide. Sulphuric acid is reduced to sulphurous anhydride when heated with carbon. When heated to redness charcoal absorbs oxygen from water and a large number of the oxides. Even such oxides as those of sodium and potassium, when heated to redness, yield their oxygen to charcoal, although they do not part with it to hydrogen. Only a few of the oxides, like silica (oxide of silicon) and lime (calcium oxide), resist the reducing action of charcoal at the temperature produced by the combustion of charcoal itself, but they frequently react with it at the temperature obtained in the electric arc (3000° – 3500°). Thus lime, CaO , gives up its oxygen and forms carbon monoxide, and the metallic calcium set free combines with the excess of carbon at the temperature of the voltaic arc, and forms carbide of calcium, CaC_2 . Charcoal is capable of changing its structure and physical condition without undergoing any alteration in its essential chemical properties—that is, it passes into **isomeric** or **allotropic forms**. The two other particular forms in which carbon appears are the **diamond** and **graphite**. The identity of composition of these with charcoal is proved by burning equal quantities of all three separately in oxygen (at a very high temperature), when each gives the same quantity of carbonic anhydride—namely, 12 parts of charcoal, diamond, or graphite in a pure state, yield on burning 44 parts by weight of carbonic anhydride. The physical properties present a marked contrast; the densest sorts of charcoal only have a density of 1.8, whilst the density of graphite is about 2.3, and that of the diamond 3.5. A great many other properties depend on the density, for instance, combustibility. The lighter charcoal is, the more easily it burns; graphite burns with considerable difficulty even in oxygen, and the diamond burns only in oxygen and at a very high temperature. On burning, charcoal, the diamond, and graphite develop different quantities of heat. One part by weight of wood charcoal converted by burning into carbonic anhydride develops 8,080 heat units; dense charcoal separated in gas retorts develops 8,050 heat units; natural graphite, 7,800 heat units; and the diamond 7,770. The greater the density the less the heat evolved by the combustion of the carbon.¹³ Graphite is comparatively soft, and leaves a streak when

¹³ When subjected to pressure, charcoal loses a portion of its internal energy (heat); hence the densest form stands to the less dense in the same relation as a solid to a liquid, or as a compound to an element. From this the conclusion may be drawn that the molecules of graphite are more complex than those of charcoal, and those of the diamond still more so. The specific heat shows the same variation, and, as we shall see further on, the increased complexity of a molecule leads to a diminution of the specific

drawn over paper, &c. (whence its name from the Greek *γράφω*, I write), and is therefore employed for the manufacture of pencils.

By means of intense heat charcoal may be transformed into **graphite**. If a charcoal rod 4 mm. in diameter and 5 mm. long be enclosed in an exhausted receiver and the current from 600 Bunsen's elements, placed in parallel series of 100, be passed through it, the charcoal becomes strongly incandescent, partially volatilises, and is deposited in the form of graphite. If sugar be placed in a charcoal crucible and a powerful galvanic current passed through it, it is baked into a mass similar to graphite. If charcoal be mixed with wrought iron and heated, cast iron is formed, which contains as much as five per cent. of carbon. If molten cast iron be suddenly chilled, the carbon remains in combination with the iron, forming so-called white cast iron; but if the cooling proceeds slowly, the greater part of the carbon separates out in the form of graphite, and if such cast iron (so-called grey cast iron) be dissolved in acid, graphite is left as a residue. Graphite is met with in nature, sometimes in the form of large compact masses, sometimes permeating rocky formations like the schists or slates, and in fact is met with in those places which, in all probability, have been subjected to the action of subterranean heat.¹⁴ The graphite in cast iron, and sometimes also natural graphite, occasionally appears in a crystalline form in the shape of six-sided plates, but more often it occurs as a compact amorphous mass having the characteristic properties of the familiar black-lead pencil.¹⁵

heat. At ordinary temperatures the specific heat of charcoal is 0.24, that of graphite 0.20, and that of the diamond 0.147. For retort carbon Le Chatelier (1893) found that the product of the sp. heat and atomic weight varies, between 0° and 250°, according to the formula: $1.92 + 0.0077t$; and between 250° and 1,000°, it is $3.54 + 0.00246t$ (see Chapter XIV., note 4).

¹⁴ There are places where anthracite gradually changes into graphite as the strata sink. I myself had the opportunity of observing this gradual transformation in the valley of Aosta.

¹⁵ Pencils are made of graphite worked up into a homogeneous mass by disintegrating, powdering, and cleansing it from earthy impurities; the best kinds are made of completely homogeneous graphite sawn up into the requisite sticks. Graphite is found in many places. In Russia the so-called Siberian or Aliberoffsky graphite is particularly renowned; it is found in the Altai mountains near the Chinese frontier; in many places in Finland and likewise on the banks of the Little Tungouska, Sidoroff also found a considerable quantity of graphite. A large amount of graphite comes from Ceylon. Natural graphite always contains mineral impurities. When mixed with clay, graphite is used for making crucibles and pots for melting metals.

Like most forms of charcoal, graphite still contains a certain quantity of hydrogen, oxygen, and ash, so that in its natural state it does not contain more than 98 per cent. of carbon.

In practice, graphite is purified simply by washing it when in a finely ground state, by which means the bulk of the earthy matter may be separated. The process, proposed by Brodie, consists in mixing the powdered graphite with $\frac{1}{14}$ part of its weight of potas-

The **diamond** is a crystalline and transparent form of carbon. It is of rare occurrence in nature, and is found in the alluvial deposits of the diamond mines of Brazil, India, South Africa, &c.^{15a} It has also been found in meteorites. It crystallises in octahedra, dodecahedra, cubes, and other forms of the regular system.¹⁶ The efforts which have been made to produce diamonds artificially, although they have not been fruitless, have not as yet led to the production of large-sized crystals, because those means by which crystals are generally formed are inapplicable to carbon. Indeed, carbon in all its forms is insoluble at low temperatures, and deposits graphite from its solutions at higher temperatures under the ordinary pressure. Diamonds may, however, be obtained in the shape of minute crystals having the appearance of a black powder, but when viewed under the microscope appearing transparent, and possessing that hardness which is the peculiar characteristic of the diamond. This diamond powder is deposited on the negative

sium chlorate and heating the mixture with twice its weight of strong sulphuric acid until no more odoriferous gases are emitted; on cooling, the mixture is thrown into water and washed, the graphite being then dried and heated to a red heat, when it shrinks considerably in volume and forms a very fine powder, which is then washed. By acting on graphite several times with a mixture of potassium chlorate and nitric acid heated up to 60°, Brodie transformed it into a yellow insoluble acid substance which he called graphitic acid, having very nearly the composition $C_{11}H_4O_5$. The diamond remains unchanged when subjected to this treatment, whilst amorphous charcoal is completely oxidised. Availing himself of this possibility of distinguishing graphite from the diamond or amorphous charcoal, Berthelot showed that when compounds of carbon and hydrogen are decomposed by heat, amorphous charcoal is mainly formed, whilst when compounds of carbon with chlorine, sulphur, and boron are decomposed, graphite is principally deposited.

^{15a} Diamonds are found in a particular dense rock, known by the name of itacolumnite, and are dug out of the *débris* produced by the destruction of the itacolumnite by water; when the *débris* is washed the diamonds remain behind. They are found principally in Brazil, in the provinces of Rio and Bahia, and at the Cape of Good Hope. The *débris* gives the black or amorphous diamond, carbonado, and the ordinary colourless or yellow translucent diamond. As the diamond possesses a very marked cleavage, the first operation consists in splitting it, and then roughly and finely polishing it with diamond powder. It is very remarkable that Professors P. A. Latchinoff and Eroféeff found (1887) diamond powder in a meteoric stone which fell in the Government of Penza, in the district of Krasnoslobodsk, near the settlement of Novo Urei (Sept. 10, 1886). Up to that time charcoal and graphite (a special variety, cliftonite) had been found in meteorites and the diamond only conjectured to occur therein. The Novo Urei meteorite was composed, like many others, of siliceous matter and metallic iron (with nickel). Rossel (1896) found minute particles of diamond in hardened steel.

¹⁶ Diamonds are sometimes found in the shape of small balls, and in that case it is impossible to cut them because directly the surface is ground or broken they fall into minute pieces. Sometimes minute diamond crystals form a dense mass like sugar, and this is generally reduced to diamond powder and used for grinding. Some known varieties of the diamond are almost opaque and of a black colour. Such diamonds are as hard as the ordinary ones, and are used for polishing diamonds and other precious stones, and also for rock boring and tunnelling. They evolve gas, and become almost or quite colourless when heated to 200°.

electrode, when a weak galvanic current is passed through liquid chloride of carbon.^{16a}

Moissan (Paris, 1893) produced artificial diamonds at the high temperature attained in the electric furnace¹⁷ by dissolving carbon in molten cast iron, and allowing the solution or alloy containing CFe_3 to cool under the powerful pressure exerted by rapidly cooling the metal.^{17a}

^{16a} Hannay, in 1880, obtained diamonds by heating a mixture of heavy liquid hydrocarbons (paraffin oils) with magnesium in a thick iron tube. This investigation, however, was not repeated.

¹⁷ The **electric furnace** is an invention of recent times, and gives the possibility of obtaining a temperature of 3500° , which is unattainable not only in ordinary furnaces, but even in the oxyhydrogen flame, the temperature of which does not exceed 2000° . The electric furnace consists of two pieces of lime, laid one on the other. A cavity is made in the lower piece for the reception of the substance to be melted between two thick electrodes of dense carbon. On passing a current of 70 volts and 450 ampères a temperature of 3000° is easily obtained. At a temperature of 2500° (100 ampères and 40 volts) not only do all metals melt, but even lime and magnesia (when placed in the space between the carbon electrodes, i.e. in the voltaic arc) become soft and crystallise on cooling. At 3000° lime becomes very fluid, and volatilises and yields metallic calcium, which partially separates out, and a carbon compound, which remains liquid for a long time. At this temperature oxide of uranium is reduced to the suboxide and metal, zirconia and rock crystal fuse and partially volatilise, as also does alumina; platinum, gold, and even carbon appreciably volatilise; the majority of the metals form carbides. Moissan gives the following interesting example to show the effect of the different temperatures obtained in the electric furnace. A current of 100 ampères and 50 volts reduces titanous anhydride to the lower oxide. With 300 ampères and 70 volts a molten yellow nitride of titanium is formed; whilst with 1200 ampères and 70 volts carbide of titanium is formed—that is, the carbon replaces the nitrogen which is evolved owing to the rise of temperature. Most of Moissan's experiments with the electric furnace were made in the years 1892–1899.

^{17a} Moissan first investigated the solution of carbon in molten metals (and the formation of the carbides) such as magnesium, aluminium, iron, manganese, chromium, uranium, silver, platinum, and silicon. At the same time Friedel, owing to the discovery of the diamond in meteoric iron, admitted that the formation of the diamond is dependent upon the influence of iron and sulphur. With this object, that is, in order to obtain the diamond, Friedel caused sulphur to react upon samples of cast iron rich in carbon, in a closed vessel at a maximum temperature of 500° , and after dissolving the sulphide of iron formed, he obtained a small quantity of a black powder which scratched corundum, i.e., diamond. Moissan's experiments (1893) were more successful, probably owing to his employment of the electric furnace. If iron is saturated with carbon at a temperature between 1100° and 3000° , then at 1100° – 1200° a mixture of amorphous carbon and graphite is formed, while at 3000° graphite alone is obtained in very beautiful crystals. Thus, under these conditions the diamond is not formed, and it can only be obtained if the high temperature be aided by powerful pressures. For this purpose Moissan took advantage of the pressure produced in the passage of a mass of molten carbide of iron, Fe_3C , in passing from the liquid to the solid state, as it increases in volume on solidifying, and when thrown into water forms a crust, which compresses the internal mass in which a portion of the carbon separates out in the form of the diamond. He first melted 150–200 grams of iron in the electric furnace, and quickly introduced a cylinder of carbon into the molten iron. He then removed the crucible with the molten iron from the furnace and plunged it into a reservoir containing water. After treatment with boiling hydrochloric acid, three varieties of carbon were obtained (if the crust remained

Judging from the fact that carbon forms a number of gaseous bodies (carbonic oxide, carbonic anhydride, methane, ethylene, acetylene, &c.) and volatile substances (for example, many hydrocarbons and their most simple derivatives), and considering that the atomic weight of carbon, 12, approaches that of nitrogen, 14, and that of oxygen, 16, and that the compounds CO (carbonic oxide) and N₂C₂ (cyanogen) are gases, it may be argued that if carbon formed the molecule C₂, like N₂ and O₂, it would be a gas. And as by polymerisation or the combination of like molecules (the passage of O₂ into O₃ or of NO₂ into N₂O₄), the temperatures of ebullition and fusion rise (which is particularly clearly proved with the hydrocarbons of the C_nH_{2n} series), we must assume that **the molecules of charcoal, graphite, and the diamond are very complex**, seeing that they are substances far removed from a gaseous state. The aptitude which the atoms of carbon show for combining together and forming complex molecules appears in all carbon compounds. Among the volatile compounds of carbon many are well known, the molecules of which contain C₅ . . . C₁₀ . . . C₂₀ . . . C₃₀, &c., in general C_n, where *n* may be very large, and in none of the other elements is this faculty of complexity so greatly developed as in carbon.¹⁸ Up to the present time there is no basis for determining the degree of polymerisation of the charcoal, graphite, or diamond molecules, and it can only be supposed that they contain C_n, where *n* is a large quantity. Charcoal and those complex non-volatile organic substances which represent the gradual transitions

intact; otherwise it would only contain Fe₂C and graphite): (1) a small amount of graphite (if the cooling be rapid); (2) carbon of a chestnut colour in very fine twisted threads, showing that it had been subjected to a very high pressure (a similar variety was met with in various specimens of the Canon Diablo meteorites); and lastly (3) an inconsiderable quantity of an exceeding dense mass which was freed from the admixture of the lighter modifications by treatment with *aqua regia*, sulphuric and hydrofluoric acids, and from which Moissan, by means of liquid bromoform (sp. gr. 2.900), succeeded in separating some small pieces, having a greater density than bromoform, which scratched the ruby and had the properties of the diamond. Some of these pieces were black, others were transparent and refracted light strongly. The dark grey tint of the former resembled that of the black diamonds (carbonado). Their density was between 3 and 3.5. K. Chrustchoff showed that at its boiling-point silver dissolves 6 per cent. of carbon. This silver was rapidly cooled, so that a crust formed on the surface and prevented the metal expanding, and thus produced a powerful pressure. A portion of the carbon which separates out under these conditions exhibits the properties of the diamond. Rousseau, for the same purpose, heated carbide of calcium in the electric furnace. There is no doubt that all these investigators obtained the diamond as a transparent body, which burnt into CO₂, and possessed an exceptional hardness, but only in the form of a fine powder.

¹⁸ The existence (up to 600°) of molecules S₈ and S₆ is known, and it must be held that this accounts for the formation of hydrogen persulphide, H₂S₂. Phosphorus appears in the molecule P₄ and gives P₄H₂. When expounding the data on specific heat we shall have occasion to return to the question of the complexity of the carbon molecule.

to charcoal¹⁹ and form the principal solid substances of organisms, contain a store or accumulation of internal power in the form of the energy binding the atoms into complex molecules. When charcoal or complex compounds of carbon burn, the energy of the carbon and oxygen is turned into heat, and this fact is taken advantage of at every turn for the generation of heat from fuel.²⁰

No other two elements are capable of combining together in such variety as carbon and hydrogen. The **hydrocarbons** of the C_nH_{2m} series in many cases differ widely from each other, although they have some properties in common. All hydrocarbons, whether gaseous, liquid, or solid, are combustible substances sparingly soluble or insoluble in water. The liquefied gaseous hydrocarbons, as well as those which are liquid at ordinary temperatures, and those solid hydrocarbons which have been liquefied by fusion, have the appearance and property of oily liquids, more or less viscous or fluid.²¹ The solid

¹⁹ The hydrocarbons poor in hydrogen and containing many atoms of carbon, like chrysene and carbopetrocene, &c., $C_nH_{2(n-m)}$, are solids, and become less fusible as n and m increase. They present a certain approach to the properties of the diamond. And in proportion to the diminution of the water in the carbohydrates $C_nH_{2m}O_m$ —for example in the humic compounds (note 5)—the transition of complex organic substances to charcoal is very evident. That residue resembling charcoal and graphite which is obtained by the separation (by means of copper sulphate and sodium chloride) of iron from white cast iron containing carbon chemically combined with the iron, also seems, especially after the researches of G. A. Zaboudsky, to be a complex substance containing $C_{12}H_6O_3$. The endeavours which have been directed towards determining the measure of complexity of the molecules of charcoal, graphite, and the diamond, will probably at some period lead to the solution of this problem and will most likely prove that the various forms of charcoal, graphite, and the diamond contain molecules of different and very considerable complexity. The constancy of the grouping of benzene, C_6H_6 , and the wide diffusion and facility of formation of the carbohydrates containing C_6 (for example, cellulose, $C_6H_{10}O_5$, glucose, $C_6H_{12}O_6$) give reason for thinking that the group C_6 is the first and simplest of those possible to free carbon, and it may be hoped that some time or other it may be possible to get carbon in this form. Perhaps in the diamond there may be found such a relation between the atoms as exists in the benzene group, and in charcoal such as is found in carbohydrates.

²⁰ When charcoal burns, the complex molecule C_n is resolved into the simple molecules nCO_2 , and therefore part of the heat—probably no small amount—is expended in the destruction of the complex molecule C_n . Perhaps by burning the most complex substances, which are the poorest as regards hydrogen, it may be possible to form an idea of the work required to split up C_n into separate atoms.

²¹ The **viscosity**, or degree of mobility, of **liquids** is determined by their *internal friction*. It is estimated by passing the liquids through narrow (capillary) tubes, the mobile liquids passing through with greater facility and speed than the viscous ones. The viscosity varies with the temperature and nature of the liquids, and in the case of solutions changes with the amount of the substance dissolved, but is not proportional to it. So that, for example, with alcohol at 20° the viscosity will be 69, and for a 50 per cent. solution 160, the viscosity of water being taken as 100. The volume of the liquid which passes through is, both by experiment (Poiseuille) and by theory (Stokes), proportional to the time, the pressure, and the fourth power of the diameter of the (capillary) tube, and inversely proportional to the length of the tube; this renders it

hydrocarbons more or less resemble wax in their properties, although ordinary oils generally contain oxygen and wax in addition to carbon and hydrogen, but in relatively small proportion. There are also many hydrocarbons which have the appearance of tar—as, for instance, metacinnamene and gutta-percha. Those liquid hydrocarbons which boil at a high temperature are like oils, and those which have a low boiling-point resemble ether, whilst the gaseous hydrocarbons in many of their properties are akin to hydrogen. All this tends to show that in hydrocarbons physically considered the properties of solid non-volatile charcoal are strongly modified and hidden, whilst those of the hydrogen predominate. All hydrocarbons are neutral substances (neither basic nor acid), but under certain conditions they enter into peculiar reactions. It has been seen in those hydrogen compounds which have been already considered (water, nitric acid, ammonia) that in almost all cases the hydrogen enters into reaction, being displaced by metals. The hydrogen of the hydrocarbons, it may be said, has no metallic character—that is to say, it is not directly²² displaced by metals, even such as sodium and potassium. On the application of more or less heat all hydrocarbons decompose,²³ forming charcoal and hydrogen. The majority of the hydrocarbons do not combine with

possible to form comparative estimates of the coefficients of internal friction and viscosity.

As the complexity of the molecules of hydrocarbons and their derivatives increases by the addition of carbon (or CH_2), so also does the degree of viscosity. The extensive series of investigations referring to this subject belong to the province of physical chemistry. That connection which (already partly observed) ought to exist between the viscosity and the other physical and chemical properties obliges us to conclude that the magnitude of the internal friction plays an important part in molecular mechanics. It has already been seen from existing data that at the absolute boiling-point the viscosity becomes as small as it is in gases.

²² In a number of hydrocarbons and their derivatives such a substitution of metals for the hydrogen may be attained by indirect means. The property shown by acetylene, C_2H_2 , and its analogues, of forming metallic derivatives is in this respect particularly characteristic. Judging from the fact that carbon is an acid element (that is, gives an acid anhydride with oxygen), though only comparatively slightly so (for carbonic acid is not at all a strong acid and compounds of chlorine and carbon, even CCl_4 , are not decomposed by water, as is the case with phosphorus chloride and even silicic chloride and boric chloride, although these correspond with acids of but little energy), one might expect to find in the hydrogen of hydrocarbons this faculty for being substituted by metals. The metallic compounds which correspond with hydrocarbons are known under the name of *organo-metallic compounds* if they contain both a metal and hydrogen. Such, for instance, is zinc ethyl, $\text{Zn}(\text{C}_2\text{H}_5)_2$, which corresponds with ethyl hydride or ethane, C_2H_6 , two atoms of hydrogen in the latter having been exchanged for one of zinc. The compounds of carbon with a metal only are called *carbides*, for instance, carbide of calcium, C_2Ca (Chap. XIV.).

²³ Gaseous and volatile hydrocarbons decompose when passed through a heated tube or introduced into the voltaic arc. When hydrocarbons are decomposed by heating, the primary products are generally other more stable hydrocarbons, among which are acetylene, C_2H_2 , benzene, C_6H_6 , naphthalene, C_{10}H_8 , &c.

the oxygen of the air or oxidise at ordinary temperatures, but under the action of nitric acid and many other oxidising substances most of them undergo oxidation, in which either a portion of the hydrogen and carbon is separated, or the oxygen enters into combination.²⁴ When heated in air, hydrocarbons burn, and, according to the amount of carbon they contain, their combustion is attended with a separation of more or less soot—that is, finely divided charcoal—which imparts great brilliancy to the flame, and on this account many of them are used for the purposes of illumination—as, for instance, kerosene, coal gas, oil of turpentine, and acetylene. As hydrocarbons contain reducing elements (that is, those capable of combining with oxygen), they often act as reducing agents—for instance, when heated with oxide of copper, they burn, forming carbonic anhydride and water, and leave metallic copper. Gerhardt proved that all hydrocarbons contain an **even number of hydrogen atoms**. Therefore the general formula for all hydrocarbons is C_nH_{2m} , where n and m are whole numbers. This fact is known as **the law of even numbers** (the cause of which is explained in the following pages as a consequence of the laws of substitution and of limits). Hence, the simplest possible hydrocarbons ought to be: CH_2 , CH_4 , CH_6 . . . C_2H_2 , C_2H_4 , C_2H_6 , C_2H_8 . . . but they do not all exist, since the quantity of H which can combine with a certain amount of carbon is limited, as we shall learn directly.

Some of the hydrocarbons are capable of combination, whilst others do not show that power. Those which contain less hydrogen belong to the former category, and those which, for a given quantity of carbon, contain the maximum amount of hydrogen belong to the latter. The composition of those last mentioned is expressed by the general formula C_nH_{2n+2} . These so-called **saturated hydrocarbons** are incapable of combination.²⁵ The hydrocarbons CH_4 , C_2H_6 , C_3H_8 , &c. . . . do not

²⁴ E. E. Wagner (1888) showed that when certain unsaturated hydrocarbons are shaken with a weak (1 per cent.) solution of potassium permanganate, $KMnO_4$, at ordinary temperatures, they form glycols—for example, C_2H_4 yields $C_2H_6O_2$, i.e., both water and oxygen are taken into combination.

²⁵ My article on this subject appeared in the *Journal of the St. Petersburg Academy of Sciences* in 1861. Up to that time, although many additive combinations with hydrocarbons and their derivatives were known, they had not been generalised, and were even continually being quoted as cases of substitution. Thus the combination of ethylene, C_2H_4 , with chlorine, Cl_2 , was often regarded as a formation of the products of the substitution of C_2H_3Cl and HCl , which it was supposed were held together as is the water of crystallisation in salts. Even earlier than this (1857, *Journal of the Petroffsky Academy*) I considered similar cases as true compounds. In general, according to the law of limits, an unsaturated hydrocarbon, or its derivative, on combining with any compound, gives a substance which is either saturated or else approaching the limit. The investigations of Frankland with many organo-metallic compounds clearly showed the limit in the case of metallic compounds, which we shall constantly refer to later on; but carbon also has its limit, attained in C_nH_{2n+2} .

exist. Those containing the maximum amount of hydrogen will be represented by CH_4 ($n = 1$, $2n + 2 = 4$), C_2H_6 ($n = 2$), C_3H_8 ($n = 3$), C_4H_{10} , &c. This may be termed **the law of limits**. Placing this in juxtaposition with the law of even numbers, it is easy to perceive that the possible hydrocarbons can be ranged in series, the terms of which may be expressed by the general formulæ $\text{C}_n\text{H}_{2n+2}$, C_nH_{2n} , $\text{C}_n\text{H}_{2n-2}$, &c. . . . Those hydrocarbons which contain for n atoms of carbon a number of atoms of hydrogen expressed in terms of n are said to be *homologous* with one another. Thus, the hydrocarbons CH_4 , C_2H_6 , C_3H_8 , C_4H_{10} , &c. . . . are members of the limiting (saturated) homologous series $\text{C}_n\text{H}_{2n+2}$. So that the difference between any two members of an homologous series is $n\text{CH}_2$.²⁶ Not only the composition but also the properties of the members of a series tend to classification in one group. For instance, the members of the series $\text{C}_n\text{H}_{2n+2}$ are not capable of forming additive compounds, whilst those of the series C_nH_{2n} are capable of combining with chlorine, sulphuric anhydride, &c.; and the members of the $\text{C}_n\text{H}_{2n-6}$ group, belonging to the coal tar series, are easily nitrated (give nitro-compounds, Chapter VI.), and have other properties in common. The physical properties of the members of a given homologous series vary in some such manner as this; the boiling-point generally rises and the internal friction increases as n becomes greater²⁷—that is, as the relative amount of carbon and the molecular weight increase; the specific gravity also changes regularly as n becomes greater.²⁸

²⁶ The conception of homology has been applied by Gerhardt to all organic compounds in his classical work, *Traité de Chimie Organique*, finished in 1855 (4 vols.), in which he divided all organic compounds into *fatty* and *aromatic*, a classification which is in principle still adhered to, although the latter are more often called benzene derivatives, on account of the fact that Kekulé, in his beautiful investigations on the structure of aromatic compounds, showed the presence in them all of the 'benzene ring or nucleus,' C_6H_6 .

²⁷ This is always true for hydrocarbons, but for derivatives of the lower homologues the law is sometimes different; for instance, in the series of saturated alcohols, $\text{C}_n\text{H}_{2n+1}(\text{OH})$, when $n=0$, we obtain water, $\text{H}(\text{OH})$, which boils at 100° , and whose specific gravity at 15° is 0.9992; when $n=1$, we have wood spirit, $\text{CH}_3(\text{OH})$, which boils at 66° , and at 15° has a specific gravity, 0.7964; $n=2$ gives ordinary alcohol, $\text{C}_2\text{H}_5(\text{OH})$, boiling at 78° and having the specific gravity 0.7936 at 15° ; with further increase of CH_2 the specific gravity increases. For the glycols, $\text{C}_n\text{H}_{2n}(\text{OH})_2$, the phenomenon of a similar kind is still more striking; at first the temperature of the boiling-point and the density increase, and then for higher (more complex) members of the series diminish. The reason for this, it is evident, must be sought for in the influence and properties of water, and that strong affinity which, acting between hydrogen and oxygen, determines many of the exceptional properties of water (Chapter I.)

²⁸ As, for example, in the saturated series of hydrocarbons, $\text{C}_n\text{H}_{2n+2}$, the lowest member ($n=0$) must be taken as hydrogen H_2 , a gas which (with a critical temperature below -190°) is liquefied with great difficulty, and when in a liquid state has doubtless a very small density. Where $n=1, 2, 3$, we have the hydrocarbons CH_4 , C_2H_6 , C_3H_8 ,

Many of the hydrocarbons met with in nature are the products of organisms, and do not belong to the mineral kingdom. A still greater number are produced artificially. These are formed by what is termed the combination of residues. For instance, if a mixture of the vapours of hydrogen sulphide and carbon bisulphide be passed through a tube in which copper is heated, the latter absorbs the sulphur from both the compounds, and the liberated carbon and hydrogen combine to form a hydrocarbon, methane. If carbon be combined with any metal and this compound MC_n be treated with an acid, HX , then the haloid X will give a salt with the metal and the residual carbon and hydrogen will yield a hydrocarbon. Thus cast iron, which contains a compound of iron and carbon, gives liquid hydrocarbons like naphtha under the action of acids. C_2Ca gives acetylene C_2H_2 . If a mixture of bromo-benzene, C_6H_5Br , and ethyl bromide, C_2H_5Br , be heated with metallic sodium, the sodium combines with the bromine of both compounds, forming sodium bromide, $NaBr$, and the residues combine together, giving the compound $C_6H_5.C_2H_5$ or C_8H_{10} . Hydrocarbons are also produced by the breaking up of more complex organic or hydrocarbon compounds, especially by heating—that is, by dry distillation. For instance, gum-benzoin contains an acid called benzoic acid, $C_7H_6O_2$, the vapours of which, when passed through a heated tube, split up into carbonic anhydride, CO_2 , and benzene, C_6H_6 . Carbon and hydrogen only unite directly in one ratio of combination—namely, to form acetylene, having the composition C_2H_2 , which, as compared with other hydrocarbons, exhibits very great stability at a high temperature.²⁹

which are gases, more and more readily liquefiable. The absolute boiling-point for CH_4 is -100° , and for ethane, C_2H_6 , and the higher members it rises. The hydrocarbon C_4H_{10} liquefies at about 0° . C_5H_{12} in some of its isomeric forms boils at from $+9^\circ$ (Lvoff) to 37° , C_6H_{14} from 58° to 78° , &c. The specific gravities in a liquid state at 15° increase appreciably with n :

C_5H_{12}	C_6H_{14}	C_7H_{16}	$C_{10}H_{22}$	$C_{16}H_{34}$
0.63	0.66	0.70	0.75	0.85

²⁹ If at the ordinary temperature (assuming therefore that the water formed will be in a liquid state) a gram molecule (26 grams) of acetylene, C_2H_2 , be burnt, 310 thousand calories will be emitted (Thomsen), and as 12 grams of charcoal produce 97 thousand calories, and 2 grams of hydrogen 69 thousand calories, it follows that, if the hydrogen and carbon of the acetylene were burnt there would be only $2 \times 97 + 69$, or 263 thousand calories produced. It is evident, then, that acetylene in its formation from carbon and hydrogen *absorbs* 310–263, or 47 thousand calories. The reason of this must first be sought in the fact that the solid carbon has passed into a gas, and, as it were, disseminated throughout the hydrogen. In the formation of CH_4 , C_2H_6 , &c., however, a contraction has taken place with regard to the hydrogen, which should be accompanied by the evolution of heat. In this way the thermo-chemical data represent the result of the sum of the physical and chemical changes accomplished.

As regards the combustion of carbon compounds, we will first enumerate the

There is one substance known among the hydrocarbons composed of 1 atom of carbon and 4 atoms of hydrogen ; this is the compound containing the highest percentage of hydrogen (CH_4 contains 25 per cent. of hydrogen), and at the same time it is the only hydrocarbon whose molecule contains but a single atom of carbon. This saturated hydrocarbon, CH_4 , is called **marsh gas** or **methane**. If vegetable or animal refuse suffers decomposition in a space to which air has not free access, or no access at all, then the decomposition is accompanied with the formation of marsh gas, and this either at the ordinary temperature or at a comparatively much higher one. On this account **plants**, when decomposing under water in **marshes**, give out this gas.^{29a} It is well known that if the mud in bogs be stirred up, the act is accompanied with the evolution of a large quantity of gas bubbles ; these may, although slowly, also separate of their own accord. The gas which is

quantities of heat separated by the combustion of definite chemical carbon compounds, and then give a few figures bearing on the kinds of fuel used in practice.

For molecular quantities the following amounts of **heat** are given out in complete **combustion** (when gaseous carbonic anhydride and liquid water are formed), according to Thomsen's data : (1) for gaseous $\text{C}_n\text{H}_{2n+2}$: $52.8 + 158.8n$ thousand calories ; (2) for C_nH_{2n} : $17.7 + 158.1n$ thousand calories ; (3) according to Stohmann (1888), for liquid saturated alcohols, $\text{C}_n\text{H}_{2n+2}\text{O}$: $11.8 + 156.3n$, and as the latent heat of evaporation is about $8.2 + 0.6n$, in the gaseous state, the value will be $20.0 + 156.9n$; (4) for monobasic saturated liquid acids, $\text{C}_n\text{H}_{2n}\text{O}_2$: $95.3 + 154.3n$, and (as their latent heat of evaporation is about $5.0 + 1.2n$) in a gaseous form, about $90 + 155n$; (5) for solid saturated bibasic acids, $\text{C}_n\text{H}_{2n-2}\text{O}_4$: $253.8 + 152.6n$, or, if they are expressed as $\text{C}_n\text{H}_{2n}\text{C}_2\text{H}_2\text{O}_4$, $51.4 + 152.6n$; (6) for benzene and its liquid homologues (still according to Stohmann) $\text{C}_n\text{H}_{2n-6}$: $158.6 + 156.3n$, and in the gaseous state about $155 + 157n$; (7) for the gaseous homologues of acetylene, $\text{C}_n\text{H}_{2n-2}$ (according to Thomsen), $5 + 157n$. It is evident from the preceding figures that the group CH_2 , or CH_3 substituted for H, on burning, gives out from 152 to 159 thousand calories. This is less than that given out by $\text{C} + \text{H}_2$, which is $97 + 69$ or 166 thousand. According to Stohmann, for dextro-glucose, $\text{C}_6\text{H}_{12}\text{O}_6$, the heat of combustion is 65 ; for common sugar, $\text{C}_{12}\text{H}_{22}\text{O}_{11}$, 1322 ; for cellulose, $\text{C}_6\text{H}_{10}\text{O}_5$, 672 ; starch, 662 ; dextrin, 666.2 ; glycol, $\text{C}_2\text{H}_6\text{O}_2$, 281.7 ; glycerine, 397.2, &c. The heats of combustion of the following solids (determined by Stohmann) are expressed per unit of weight : naphthalene, C_{10}H_8 , 9,621 ; urea, $\text{CN}_2\text{H}_4\text{O}$, 2,465 ; white of egg, 5,579 ; dry rye bread, 4,421 ; wheaten bread, 4,302 ; tallow, 9,365 ; butter, 9,192 ; linseed oil, 9,323. A collection of arithmetical data for the heats of combustion will be found in V. F. Longinin's work, *Description of the various Methods of Determining the Heats of Combustion of Organic Compounds* (Moscow, 1894).

The number of units of heat given out by *unit weight* during the complete combustion and cooling of the ordinary kinds of **fuel** in their usual state of dryness and purity may be taken as $Q = 81c + 300h - 26(o - s)$, where c , h , o , and s express the percentage amounts of carbon, hydrogen, oxygen, and sulphur respectively in the fuel. For instance, for naphtha containing 86 per cent. carbon, 12 of hydrogen, and 2 of oxygen, Q is found by experiment and calculation to be about 10,500 calories. The above formula is given in my work on fuel (see note 1). The same work shows also that 890 to 935 calories are yielded for every cubic metre of air in the combustion of all kinds of solid fuel, if the water remains in the products of combustion in the form of vapour. Gaseous fuels give as much as 1,000 calories per cubic metre of air.

^{29a} Manure, decomposing under the action of bacteria, evolves CO and CH_4 .

evolved consists principally of marsh gas.³⁰ When wood, coal, and many other vegetable and animal substances are decomposed by the **action of heat** without access of air—that is, are subjected to dry distillation—they evolve in addition to many other gaseous products of decomposition (carbonic anhydride, hydrogen, and various other substances), a great deal of methane. Generally the gas which is used for lighting purposes is obtained by this means, and therefore always contains marsh gas, mixed with dry hydrogen and other vapours and gases, although it is subsequently purified from many of them.³¹ As the

³⁰ It is easy to collect the gas which is evolved in marshy places if a glass bottle be inverted in the water and a funnel put into it (both being filled with water); if the mud of the bottom be now agitated, the bubbles which rise may be easily caught by the inverted funnel.

³¹ **Illuminating gas** is generally prepared by heating gas coal rich in bitumen in oval cylindrical horizontal cast-iron or clay retorts. Several such retorts *BB* (fig. 58) are disposed in the furnace *A*, and heated together. When the retorts are heated to a red heat, lumps of coal are thrown into them, and they are then closed with a tightly fitting cover. The illustration shows the furnace, with five retorts. Coke (see note 1, dry distillation) remains in the retorts, and the volatile products in the form of vapours and gases travel along the pipes *d*, rising from each retort. These pipes branch above the stove, and communicate with the receiver *f* (hydraulic main) placed above the furnace. Those products of the dry distillation which most easily pass from the gaseous into the liquid and solid states collect in the hydraulic main. From the latter the vapours and gases travel along the pipe *g* and the series of vertical pipes *j* (which are sometimes cooled by water trickling over the surface), in which the vapours and gases cool owing to contact with the colder surface, and a fresh quantity of vapour condenses. The condensed liquids pass from the pipes *g* and *j* and into the troughs *H*. These troughs always contain liquid at a constant level (the excess flowing away) so that the gas cannot escape, and thus they form, as it is termed, a hydraulic joint. In the state in which it leaves the condensers the gas consists principally of the following vapours and gases: (1) vapour of water, (2) ammonium carbonate, (3) liquid hydrocarbons, (4) hydrogen sulphide, H_2S , (5) carbonic anhydride, CO_2 , (6) carbonic oxide, CO , and (7) sulphurous anhydride, SO_2 ; but a great part of the illuminating gas consists of (8) hydrogen, (9) marsh gas, (10) olefiant gas, C_2H_4 , and other gaseous hydrocarbons. The hydrocarbons (3, 9, and 10), the hydrogen, and carbonic oxide are capable of combustion, and are useful constituents, but the carbonic anhydride, the hydrogen sulphide, and sulphurous anhydride, as well as the vapours of ammonium carbonate, form an injurious admixture, because they do not burn (CO_2 , SO_2) and lower the temperature and brilliancy of the flame, or else, although capable of burning (for example, H_2S , CS_2 , and others), they give out during combustion sulphurous anhydride which has a disagreeable smell, is injurious when inhaled, and spoils many surrounding objects. In order to separate the injurious products, the gas is washed with water, a cylinder (not shown in the illustration) filled with coke continually moistened with water serving for this purpose. The water coming into contact with the gas dissolves the ammonium carbonate; hydrogen sulphide, carbonic anhydride, and sulphurous anhydride, being only partly soluble in water, have to be got rid of by special means. To this end the gas is passed through moist lime or other alkaline liquid, as the above-mentioned gases have acid properties and are therefore retained by the alkali. When lime is used, calcium carbonate, sulphite and sulphide, all solid substances, are formed. It is necessary to renew the purifying material as its absorbing power decreases. A mixture of lime and sulphate of iron, FeSO_4 , acts still better, because the latter, with lime, $\text{Ca}(\text{HO})_2$, forms ferrous hydroxide, $\text{Fe}(\text{HO})_2$ and gypsum, CaSO_4 . The suboxide (partly turning into oxide) of iron absorbs

FIG. 66.—General view of gas works, *B*, retorts; *f*, hydraulic main; *H* and *I*, tar well; *i*, condensers; *L*, purifiers; *P*, gasholder.

decomposition of the organic matter, which forms coal, is still going on underground, the evolution of large quantities of marsh gas frequently

H_2S , forming FeS and H_2O , and the gypsum retains the remainder of the ammonia, the excess of lime absorbing carbonic anhydride and sulphuric anhydride. [In English works a native hydrated ferric hydroxide is used for removing hydrogen sulphide.] This purification of the gas takes place in the apparatus *L*, where the gas passes through perforated trays *m*, covered with sawdust mixed with lime and sulphate of iron. It is necessary to remark that in the manufacture of gas it is indispensable to draw off the vapours from the retorts, so that they should not remain there long (otherwise the hydrocarbons would in a considerable degree be resolved into carbon and hydrogen),

FIG. 67. — Blowpipe. Air is blown in at the trumpet-shaped mouthpiece, and escapes in a fine stream from the platinum jet placed at the extremity of the side tube.

FIG. 68. — Blowpipe table A B with gas blowpipe C, into which the gas passes by the tube *a b* and the air by the tube *c d* connected with the bellows *e f*, which are worked by means of the lever B and the weights *g*.

and also to avoid a great pressure of gas in the apparatus, otherwise a quantity of gas would escape at all cracks such as must inevitably exist in such a complicated arrangement. For this purpose there are special pumps (exhausters) so regulated that they only pump off the quantity of gas formed (the pump is not shown in the illustration). The purified gas passes through the pipe *n* into the *gasometer* (gasholder) *P*, which is a dome made of iron plate. The edges of the dome dip into water poured into a ring-shaped channel, *g*, in which the sides of the dome rise and fall. The gas is collected in this holder, and distributed to its destination by pipes communicating with the pipe *o*, issuing from the dome. The pressure of the holder on the gas enables it, on issuing from a long pipe, to pass through the small aperture of the burner. A hundred kilograms of coal give about 20 to 30 cubic metres of gas, having a density from four to nine times greater than that of hydrogen. A cubic metre (1,000 litres) of hydrogen

occurs in coal mines.³² When mixed with air it gives an explosive mixture, which forms one of the great dangers of coal mining, as subterranean work has always to be carried on by lamp-light. This danger is, however, overcome by the use of *Humphry Davy's safety-lamp*.³³

weighs about 87 grams; therefore 100 kilograms of coal give about 18 kilograms or about one-sixth of its weight of gas. Illuminating gas is generally lighter than marsh gas, as it contains a considerable amount of hydrogen, and is only heavier than marsh gas when it contains much of the heavier hydrocarbons. Thus olefiant gas, C_2H_4 , is fourteen times, and the vapours of benzene thirty-nine times, heavier than hydrogen, and illuminating gas sometimes contains 15 per cent. of its volume of them. The brilliancy of the flame of the gas increases with the quantity of olefiant gas and similar heavy hydrocarbons, as it then contains more carbon for a given volume, and a greater number of carbon particles are separated. Gas usually contains from 35 to 60 per cent. of its volume of marsh gas, from 30 to 50 per cent. of hydrogen, from 3 to 5 per cent. of carbonic oxide, from 2 to 10 per cent. of heavy hydrocarbons, and from 3 to 10 per cent. of nitrogen. Wood gives almost the same sort of gas as coal and in about the same quantity; but the wood gas contains a great deal of carbonic anhydride, although on the other hand there is an almost complete absence of sulphur compounds. Tar, oils, naphtha, and similar materials furnish a large quantity of good illuminating gas. An ordinary burner of 8 to 12 candle-power burns 5 to 6 cubic feet of coal gas per hour, but only a cubic foot of naphtha gas. One pood (36 lb. Eng.) of naphtha gives 500 cubic feet of gas—that is, one kilogram of naphtha produces about one cubic metre of gas. The formation of combustible gas on heating coal was discovered in the beginning of the eighteenth century, but was only put into practice towards the end of it by Le-Bon in France and Murdoch in England. In England, Murdoch, together with the renowned Watt, built the first gas works in 1805.

In practice illuminating gas is used not only for lighting (electricity and kerosene are cheaper in Russia), but also as the motive power for gas engines (see p. 175), which consume about half a cubic metre per horse-power per hour; gas is also used in laboratories for heating purposes. When it is necessary to concentrate the heat, either the ordinary blowpipe (fig. 67) is applied, placing the end in the flame and blowing through the mouthpiece; or, in other forms, gas is passed through the blowpipe; when a large, hot, smokeless flame is required for heating crucibles or glass-blowing, a foot-blower is used. High temperatures, which are often required for laboratory and manufacturing purposes, are most easily attained by the use of gaseous fuel (illuminating gas, producer gas, and water gas, which will be treated of in the following chapter), because complete combustion may be effected without access of air. It is evident that in order to obtain high temperatures means must be taken to diminish the loss of heat by radiation, and to ensure perfect combustion.

³² The gas which is set free in coal mines contains nitrogen, some carbonic anhydride, and a large quantity of marsh gas. The best means of avoiding an explosion consists in efficient ventilation. It is best to light coal mines with electric lamps.

³³ The Davy lamp, of which an improved form is represented in the accompanying figure, is used for lighting coal mines and other places where combustible gas is found. The wick of the lamp is enclosed in a thick glass

FIG. 69.—Davy safety-lamp.
[Modern form.]

Sir Humphry Davy observed that on introducing a piece of wire gauze into a flame, it absorbs so much heat that combustion does not proceed beyond it (the unburnt gases which pass through it may be ignited on the other side). In accordance with this, the flame of the Davy lamp is surrounded with a thick glass (as shown in the drawing), and has no communication whatever with the explosive mixture except through a wire gauze which prevents it igniting the mixture of the marsh gas, issuing from the coal, with air. In some districts, particularly in those where petroleum is found—as, for instance, near Baku, where a temple of the Indian fire-worshippers was built, and in Pennsylvania, and other places—marsh gas in abundance issues from the earth, and is used, like coal gas, for the purposes of lighting and warming.³⁴ Tolerably pure marsh gas may be obtained by heating a mixture of an acetate with an alkali. Acetic acid, $C_2H_4O_2$, on being heated is decomposed into marsh gas and carbonic anhydride, $C_2H_4O_2 = CH_4 + CO_2$.

An alkali—for instance, $NaHO$ —gives with acetic acid a salt, $C_2H_3NaO_2$, which on decomposition retains carbonic anhydride, forming sodium carbonate, Na_2CO_3 , and marsh gas is given off :

Carbide of aluminium, Al_4C_3 , prepared by the direct action of charcoal on aluminium in the heat of the voltaic arc (in the electric furnace), gives methane and alumina in the form of hydrate when acted upon by water :

The purest gas is obtained from methyl iodide, CH_3I (prepared by the action of HI on methyl, or wood, alcohol), by the substitution of the iodine by hydrogen, which is done, for instance, by taking zinc dust and alcohol or ready-made zinc methyl and water :

Marsh gas is difficult to liquefy ; it is almost insoluble in water, and is without taste or smell. The most important point in connection

cylinder which is firmly held in a metallic holder. Over this a metallic cylinder and the wire gauze are placed. The products of combustion pass through the gauze, and the air enters through the space between the cylinder and the wire gauze. To ensure greater safety the lamp cannot be opened without extinguishing the flame.

³⁴ In Pennsylvania (beyond the Alleghany Mountains) many of the shafts sunk for petroleum only emitted gas, but many useful applications for it were found and it was conducted in metallic pipes to works hundreds of miles distant, principally for metallurgical purposes. Natural gas is also beginning to be used at Baku.

³⁵ Details of the methods of preparation and reactions of CH_4 , $Zn(CH_3)_2$, CH_3I , and other carbon compounds must be sought in text-books of organic chemistry.

with its chemical reactions is that it does not combine directly with anything, whilst the other hydrocarbons which contain less hydrogen than is expressed by the formula C_nH_{2n+2} are capable of combining with hydrogen, chlorine, certain acids, &c.

While the law of substitution gives a very simple explanation of the formation of hydrogen peroxide as a compound containing two aqueous residues (OH)(OH), and while the same conceptions explain all the transitions from ammonia to nitric acid with great simplicity, it is possible also, on the basis of this law, to derive all hydrocarbons from methane, CH_4 , as being the simplest hydrocarbon.³⁶ The increase in complexity of a molecule of methane is brought about by the faculty of mutual combination possessed by the atoms of carbon, and, as a consequence of the most detailed study of the subject, much that might have been foreseen and conjectured from the law of substitution has been actually brought about; and although this subject on account of its magnitude really belongs, as has been already stated, to the sphere of organic chemistry, it has been alluded to here in order to show, although only in part, the best investigated example of the application of the law of substitution. According to the law of substitution, a molecule of methane, CH_4 , is capable of undergoing substitution in the four following ways:—(1) *Methyl substitution*, when the radicle, equivalent to hydrogen, called **methyl**, CH_3 , replaces hydrogen. In CH_4 this radicle is combined with H, and therefore can replace it, as (OH) replaces H, because it gives with it water; (2) *methylene substitution*, or the exchange between H_2 and CH_2 (this radicle is called methylene), is founded on a similar division of the molecule CH_4 into two equivalent parts, H_2 and CH_2 ; (3) *acetylene substitution*, or the exchange between CH on the one hand and H_3 on the other; and (4) *carbon substitution*—that is, the substitution of H_4 by an atom of carbon C, which is founded on the law of substitution, just as is the methyl substitution. These four cases of substitution render it possible to understand the principal relations of the hydrocarbons and of their products (derivatives). For instance, the *law of even numbers* is seen from the fact that in all the cases of substitution mentioned the hydrogen atoms increase or decrease by an even number; but as in CH_4 they are likewise even, it follows that no matter how many substitutions are effected there will always be obtained an even number of hydrogen atoms. When H is replaced by CH_3 there is an increase of CH_2 ; when H_2 is replaced by CH_2 there is no increase of hydrogen; in the acetylene

³⁶ Methylene, CH_2 , does not exist. When attempts are made to obtain it (for example, by removing X_2 from CH_2X_2), C_2H_4 or C_3H_6 are produced—that is to say, it undergoes polymerisation.

substitution CH replaces H_3 , so that there is an increase of C and a decrease of H_2 ; in the carbon substitution there is a decrease of H_4 . In a similar way the *law of limits* may be deduced as a corollary of the law of substitution. For the largest possible quantity of hydrogen is introduced by the methyl substitution, since it leads to the addition of CH_2 ; starting from CH_4 we obtain C_2H_6 , C_3H_8 , and in general, C_nH_{2n+2} , and these contain the greatest possible amounts of hydrogen. *Unsaturated hydrocarbons*, containing less hydrogen, are evidently only formed when the increase of the new molecule derived from methane proceeds from one of the other forms of substitution. When the methyl substitution alone takes place in methane, CH_4 , it is evident that the saturated hydrocarbon formed is C_2H_6 or $(CH_3)(CH_3)$.³⁷ This is called **ethane**. By means of the methylene substitution alone, **ethylene**, C_2H_4 , or $(CH_2)(CH_2)$, may be directly obtained from CH_4 , and by the acetylene substitution C_2H_2 or $(CH)(CH)$, or **acetylene**, both the latter being unsaturated hydrocarbons. Thus we have *all the possible* hydrocarbons with two atoms of carbon in the molecule, C_2H_6 , ethane, C_2H_4 , ethylene, and C_2H_2 , acetylene. But in them, according to the law of substitution, the same forms of substitution may be repeated, and further substitutions will hence serve as a source for the production of a fresh series of saturated and unsaturated hydrocarbons, containing more and more carbon in the molecule and, in the case of the acetylene substitution and carbon substitution, containing less and less hydrogen. Thus *by means of the law of substitution we can foresee* not only the limit C_nH_{2n+2} , but an *unlimited number of unsaturated hydrocarbons*, C_nH_{2n} , C_nH_{2n-2} . . . $C_nH_{2(n-m)}$, where m varies from 0 to $n-1$,³⁸ and where n increases indefinitely. From these facts not only does the

³⁷ Although the methods of formation and the reactions connected with hydrocarbons are not described in this work, because they are dealt with in organic chemistry, yet in order to clearly show the mechanism of those transformations by which the carbon atoms are built up into the molecules of the carbon compounds, we here give a general example of reactions of this kind. From marsh gas, CH_4 , on the one hand the substitution of chlorine or iodine, CH_3Cl , CH_3I , for the hydrogen may be effected; and on the other hand such metals as sodium and zinc may be substituted for the hydrogen, giving, e.g., CH_3Na , $Zn(CH_3)_2$. These and similar products of substitution serve as a means of obtaining other more complex substances from given carbon compounds. If we place the two above-named products of substitution of marsh gas (metallic and haloid) in mutual contact, the metal combines with the halogen, forming a very stable compound—namely, common salt, $NaCl$, and the carbon groups which were in combination with them separate in mutual combination, as shown by the equation:

This is the most simple example of the formation of a complex hydrocarbon from these radicles.

³⁸ When $m = n - 1$, we have the series C_nH_{2n-2} . The lowest member is acetylene, C_2H_2 . These are hydrocarbons containing a minimum amount of hydrogen.

existence of a multitude of polymeric hydrocarbons, differing in molecular weight, become intelligible, but it is also seen that there is a possibility of cases of isomerism with the same molecular weight. This **polymerism** so common to hydrocarbon compounds is already apparent in the first unsaturated series C_nH_{2n} , because all the terms of this series C_2H_4 , C_3H_6 , C_4H_8 . . . $C_{30}H_{60}$. . . have one and the same composition, CH_2 , but different molecular weights, as has been already explained in Chapter VII. The differences in the vapour densities, boiling-points, melting-points, the quantities entering into reactions,³⁹ and the methods of preparation⁴⁰ also so clearly tally with the conception of polymerism, that this example will always be the clearest and most conclusive for the illustration of polymerism and molecular weight. Such a case is also met with among other hydrocarbons. Thus benzene, C_6H_6 , and cinnamene, C_8H_8 , correspond with the composition of acetylene or with a compound of the composition, CH .⁴¹ The first boils at 81° , the second at 144° ; the specific gravity of the first at 0° is 0.899, that of the second, 0.925—that is, here also the boiling-point rises with the increase of molecular weight, and so also, as might be expected, does the density.

Cases of **isomerism** in the restricted sense of the word—that is, when, with an identity of composition and molecular weight, the properties of the substances are different—are very numerous among the hydrocarbons and their derivatives. Such cases are particularly important for the comprehension of molecular structure, and they also, like the polymerides, may be predicted from the above-mentioned conceptions, expressing the principles of the structure of the carbon compounds⁴² based on the law of substitution. According to it, for

³⁹ For instance, ethylene, C_2H_4 , combines with Br_2 , HI , H_2SO_4 , as a whole molecule, as also does amylene, C_5H_{10} , and, in general, C_nH_{2n} .

⁴⁰ For instance, ethylene is obtained by removing the water from ethyl alcohol, $C_2H_5(OH)$, and amylene, C_5H_{10} , from amyl alcohol, $C_5H_{11}(OH)$, or in general C_nH_{2n} from $C_nH_{2n+1}(OH)$.

⁴¹ Acetylene and its polymerides have an empirical composition CH , ethylene and its homologues (and polymerides) CH_2 , ethane CH_3 , methane CH_4 . This series presents a good example of the law of multiple proportions, but such diverse proportions are met with between the number of atoms of the carbon and hydrogen in the hydrocarbons already known that the accuracy of Dalton's law might be doubted. Thus the substances $C_{30}H_{62}$ and $C_{30}H_{60}$ have such slight differences in their composition by weight as to be within the limits of experimental error, but their reactions and properties are so distinct that they can, however, be distinguished beyond doubt. Without Dalton's law chemistry could not have been brought to its present condition, but it cannot alone express all those gradations which are quite clearly understood and predicted by the law of Avogadro-Gerhardt.

⁴² The conception of the structure of carbon compounds—that is, the expression of those unions and correlations which their atoms have in the molecules—was for a long time limited to the representation that organic substances contained complex radicles

example, it is evident that there can be no isomerism in the cases of the saturated hydrocarbons C_2H_6 and C_3H_8 , because the former is CH_4 , in which methyl has taken the place of H, and as all the hydrogen atoms of methane must be supposed to have the same relation to the carbon, it is all the same which of them be subjected to the methyl substitution—the resulting product can only be ethane, CH_3CH_3 ; ⁴³ the same argument also applies in the case of propane, $CH_3CH_2CH_3$, where one compound only can be imagined. It is to be expected, however, that there should be two butanes, C_4H_{10} , and this is actually the case. In one, methyl may be considered as replacing the hydrogen of one of the methyls, $CH_3CH_2CH_2CH_3$; and in the other CH_3 may be considered as substituted for H in CH_2 , and there it will consist of $CH_3CH \begin{smallmatrix} CH_3 \\ CH_3 \end{smallmatrix}$. The latter may also be regarded as methane in which three of hydrogen are exchanged for three of methyl. On going further in the series it is evident that the number of possible isomerides will be still greater, but we have limited ourselves to the simplest examples, showing the possibility and actual existence of isomerides. C_2H_4 and CH_2CH_2 are, it is evident, identical; but there ought to be, and are, two hydrocarbons of the composition C_3H_6 , propylene and trimethylene; the first is ethylene,

(for instance, ethyl C_2H_5 , methyl CH_3 , phenyl C_6H_5 , &c.); then about the year 1840 the phenomena of substitution and the correspondence of the products of substitution with the primary bodies (nuclei and types) were observed, but it was not until about the year 1860 and later when, on the one hand, the teaching of Gerhardt about molecules was spreading, and, on the other, the materials had accumulated for discussing the transformations of the simplest hydrocarbon compounds, that conjectures began to appear as to the mutual connection of the atoms of carbon in the molecules of the complex hydrocarbon compounds. Then Kekulé and A. M. Butleroff began to formulate the connection between the separate atoms of carbon, regarding it as a quadrivalent element. Although in their methods of expression and in some of their views they differ from each other and also from the way in which the subject is treated in this work, yet the essence of the matter—namely, the comprehension of the causes of isomerism and of the union between the separate atoms of carbon—remains the same. In addition to this, starting from the year 1870, there appears a tendency, which from year to year increases, to discover the actual spacial distribution of the atoms in the molecules. Thanks to the endeavours of Le-Bel (1874), van't Hoff (1874), and Wislicenus (1887) in observing cases of isomerism—such as the effect of different isomerides on the direction of the rotation of the plane of polarisation of light—this tendency promises much for chemical mechanics, but the details of the still imperfect knowledge in relation to this matter must be sought for in special works devoted to organic chemistry.

⁴³ Direct experiment shows that however CH_3X is prepared (where X=for instance Cl, &c.) it is always one and the same substance.

This was shown in the year 1860, or thereabout, by many methods, and is the fundamental conception of the structure of hydrocarbon compounds. If the atoms of hydrogen in methane were not absolutely identical in value and position (as they are not, for instance, in $CH_3CH_2CH_3$ or CH_3CH_2X), then there would be as many different forms of CH_3X as there were diversities in the atoms of hydrogen in CH_4 .

CH_2CH_2 , in which one atom of hydrogen is exchanged for methyl, CH_2CHCH_3 , and trimethylene is ethane, CH_3CH_3 , with the substitution of methylene for two hydrogen atoms from two methyl groups—that is, $\begin{smallmatrix} \text{CH}_2 \\ \text{CH}_2 \end{smallmatrix} \text{CH}_2$,⁴⁴ where the methylene introduced is united to both the atoms of carbon in CH_3CH_3 . It is evident that the cause of isomerism here is, on the one hand, the difference of the amount of hydrogen in union with the particular atoms of carbon, and, on the other, the different connection between the several atoms of carbon. In the first case they may be said to be chained together (more usually to form an ‘open chain’), and in the second case to be locked together (to form a ‘closed chain’ or ‘ring’). Here also it is easily understood that on increasing the number of carbon atoms the number of possible and existing isomerides will greatly increase. If, at the same time, in addition to the substitution of one of the radicles of methane for hydrogen a further exchange of part of the hydrogen for some of the other groups of elements X, Y . . . occurs, the number of possible isomerides still further increases in a considerable degree. For instance, there are even two possible isomerides for the derivatives of ethane, C_2H_6 : if two atoms of the hydrogen be exchanged for X_2 , one will have the ethylene structure, $\text{CH}_2\text{XCH}_2\text{X}$, and the other an ethylidene structure, CH_3CHX_2 ; such are, for instance, ethylene chloride, $\text{CH}_2\text{ClCH}_2\text{Cl}$, and ethylidene chloride, CH_3CHCl_2 . And as in the place of the hydrogen not only metals may be substituted, but Cl, Br, I, OH (the water radicle), NH_2 (the ammonia radicle), NO_2 (the radicle of nitric acid), &c., so also in exchange for two atoms of hydrogen, O, NH, S, &c., may be substituted; hence it will be understood that the number of isomerides is sometimes very great. It is impossible here to describe how the isomerides are distinguished from each other, in what reactions they occur, how and when one changes into another, &c.; for this, taken together with the description of the hydrocarbons already known, and their derivatives, forms a very extensive and very thoroughly investigated branch of chemistry, called **organic chemistry**. Enriched with a mass of closely observed phenomena and strictly deduced generalisations, this branch of chemistry has been treated separately for the reason that in it the hydrocarbon groups are subjected to transformations which are not met with in such number in dealing with any of the other elements or their hydrogen compounds. It was important for us to show that,

⁴⁴ The union of carbon atoms in closed chains or rings was first suggested by Kekulé as an explanation of the structure and isomerism of the derivatives of benzene, C_6H_6 , forming aromatic compounds (note 26).

notwithstanding the great variety of the hydrocarbons and their products,⁴⁵ they are all of them governed by the law of substitution,^{45a} and, referring our readers for detailed information to works on organic chemistry, we will limit ourselves to a short exposition of the properties of the two simplest unsaturated hydrocarbons: ethylene, CH_2CH_2 , and acetylene, CHCH , and a short acquaintance with petroleum as the natural source of a mass of hydrocarbons.

Ethylene, or olefiant gas, C_2H_4 , is the lowest known member of the unsaturated hydrocarbon series of the composition C_nH_{2n} . As in composition it is equal to two molecules of marsh gas deprived of two molecules of hydrogen, it is evident that it might be, and it actually can be, produced, although but in small quantities, together with hydrogen, by heating marsh gas. On being heated, however, olefiant gas splits up, first into acetylene and methane ($3\text{C}_2\text{H}_4 = 2\text{C}_2\text{H}_2 + 2\text{CH}_4$,

⁴⁵ The following are the most generally known of the oxygenised but non-nitrogenous hydrocarbon derivatives. (1) The *alcohols*. These are hydrocarbons in which hydrogen is exchanged for hydroxyl (OH). The simplest of them is methyl alcohol, $\text{CH}_3(\text{OH})$, or wood spirit, obtained by the dry distillation of wood. The common spirits of wine or ethyl alcohol $\text{C}_2\text{H}_5(\text{OH})$, and glycol, $\text{C}_2\text{H}_4(\text{OH})_2$, correspond with ethane. Normal propyl alcohol $\text{CH}_3\text{CH}_2\text{CH}_2(\text{OH})$, and isopropyl alcohol, $\text{CH}_3\text{CH}(\text{OH})\text{CH}_3$, *propylene-glycol*, $\text{C}_3\text{H}_6(\text{OH})_2$, and glycerol, $\text{C}_3\text{H}_5(\text{OH})_3$ (which, with stearic and other acids, forms fatty substances), correspond with propane, C_3H_8 . All alcohols are capable of forming water and *ethereal salts* with acids, just as alkalies form ordinary salts. (2) *Aldehydes* are alcohols minus hydrogen; for instance, acetaldehyde, $\text{C}_2\text{H}_4\text{O}$, corresponds with ethyl alcohol. (3) It is simplest to regard *organic acids* as hydrocarbons in which hydrogen has been exchanged for carboxyl (CO_2H), as will be explained in the following chapter. There are a number of intermediate compounds; for example, the aldehyde-alcohols, alcohol-acids (or hydroxy-acids), &c. Thus the hydroxy-acids are hydrocarbons in which some of the hydrogen has been replaced by hydroxyl, and some by carboxyl; for instance, lactic acid corresponds with C_2H_6 , and has the constitution $\text{C}_2\text{H}_4(\text{OH})(\text{O}_2\text{H})$. If to these products we add the haloid salts (where H is replaced by Cl, Br, I), the nitro-compounds containing NO_2 in place of H, the amides, cyanides, ketones, and other compounds, it will be readily seen what an immense number of organic compounds there are and what a variety of properties these substances have; this we see also from the composition of plants and animals.

^{45a} In this and other portions of my work I refrain from introducing the usual and, to many chemists, customary notion of the atomicity or equivalency of the elements, and give the law of substitution and its consequences instead. This is done chiefly for two reasons: (1) the equivalency of the elements (for instance, 4 for C, 2 for O, &c.) cannot be regarded as one of their radical, unchangeable properties (see Chapter X., note 1), and the principal object of this work is to embrace the unchanging fundamental properties of the chemical elements; (2) the law of substitution, being a direct application of one of the Newtonian principles of all natural philosophy (action and reaction are equal and opposite), gives the possibility of understanding sufficiently, and without any supplementary hypothesis, all that the conception of equivalency gives, even in such an instance as the carbon (organic) compounds in which it first took rise and was most frequently and successfully applied. Moreover, I think that the student who has grasped the law of substitutions will encounter no difficulty in grasping the conception of atomicity (for instance, of carbon), but will rather regard the matter from a wider and freer point of view by the light cast upon it by the law of substitution.

Lewes, 1894), and at a higher temperature into carbon and hydrogen ; and therefore in those cases where marsh gas is produced by heating, olefiant gas, hydrogen, and charcoal will also be formed, although only in small quantities. The lower the temperature at which complex organic substances are heated, the greater the quantity of olefiant gas found in the gases given off ; at a white heat it is entirely decomposed into charcoal and marsh gas. If coal, wood, and more particularly petroleum, tars, and fatty substances are subjected to dry distillation, they give off illuminating gas, which contains more or less olefiant gas.

Olefiant gas, almost free from other gases,⁴⁶ may be obtained from ordinary alcohol (if possible, free from water) if the latter be mixed with five parts of strong sulphuric acid and the mixture heated to slightly above 100°. Under these conditions, the sulphuric acid removes the elements of water from the alcohol, $C_2H_5(OH)$, and gives olefiant gas : $C_2H_6O = H_2O + C_2H_4$. The greater molecular weight of olefiant gas compared with that of marsh gas indicates that it may be comparatively easily converted into a liquid by means of pressure of great cold ; this may be effected, for example, by the evaporation of liquid nitrous oxide. Its absolute boiling-point is + 10°, it boils at - 103° (1 atmosphere), liquefies at 0°, at a pressure of 43 atmospheres, and solidifies at - 163°. Ethylene is colourless, has a slight ethereal smell, is slightly soluble in water, and somewhat more soluble in alcohol and in ether (in five volumes of spirit or six volumes of ether).⁴⁷

Like other unsaturated hydrocarbons, olefiant gas readily enters into combination with certain substances, such as chlorine, bromine, iodine, fuming sulphuric acid, or sulphuric anhydride, &c. If olefiant gas be sealed up with a small quantity of sulphuric acid in a glass vessel, and constantly agitated (as, for instance, by attaching it to the

⁴⁶ Ethylene bromide, $C_2H_4Br_2$, when gently heated in alcoholic solution with finely divided zinc, yields pure ethylene, the zinc merely taking up the bromine (Sabaneyeff).

⁴⁷ Ethylene decomposes somewhat easily under the influence either of the electric spark or of a high temperature. In this case the volume of the gas formed may remain the same when olefiant gas is decomposed into carbon and marsh gas, or may increase to double its volume when hydrogen and carbon are formed, $C_2H_4 = CH_4 + C = 2C + 2H_2$. A mixture of olefiant gas and oxygen is highly explosive; two volumes of this gas require six volumes of oxygen for their perfect combustion. The eight volumes thus taken then resolve themselves into eight volumes of the products of combustion, a mixture of water and carbonic anhydride, $C_2H_4 + 3O_2 = 2CO_2 + 2H_2O$. On cooling after the explosion diminution of volume occurs because the water becomes liquid. For two volumes of the olefiant gas taken, the diminution will be equal to four volumes, and the same is the case for marsh gas. The quantities of carbonic anhydride formed by the two gases are not the same. Two volumes of marsh gas give only two volumes of carbonic anhydride, whilst two volumes of ethylene give four volumes of carbonic anhydride. In the presence of platinum black, a mixture of C_2H_4 and H_2 contracts owing to the formation of ethane, C_2H_6 (Lunge, 1897).

moving part of a machine), the prolonged contact and repeated mixing causes the olefiant gas, little by little, to combine with the sulphuric acid, forming $C_2H_4H_2SO_4$. If, after this absorption, the sulphuric acid be diluted with water and distilled, alcohol will be produced by the olefiant gas combining with the elements of water, $C_2H_4 + H_2O = C_2H_6O$. In this reaction (Berthelot) we see an excellent example of the fact that if a given substance, like olefiant gas, is produced by the decomposition of another, then in the reverse way this substance, entering into combination, is capable of forming the original substance—in our example, alcohol. In combination with various molecules, X_2 , ethylene gives saturated compounds, $C_2H_4X_2$ or CH_2XCH_2X (for example, $C_2H_4Cl_2$), which correspond with ethane, CH_3CH_3 or C_2H_6 .⁴⁸

Acetylene, $C_2H_2 = CHCH$, is a gas; it was first prepared by Berthelot (1857). It has a very pungent smell, is characterised by its great stability under the action of heat, and is obtained as the only product of the direct combination of carbon with hydrogen when a luminous arc (voltaic) is formed between carbon electrodes in an atmosphere of hydrogen. This arc contains particles of carbon passing from one pole to the other. Acetylene may be formed from olefiant gas if two atoms of hydrogen be taken from it. This may be effected in the following way: the olefiant gas is first made to combine with bromine, giving $C_2H_4Br_2$; from this hydrobromic acid is removed by means of an alcoholic solution of caustic potash, leaving the volatile product C_2H_3Br ; and from this yet another molecule of hydrobromic acid is withdrawn by passing it through anhydrous alcohol in which metallic sodium has been dissolved, or by heating it with a strong alcoholic solution of caustic potash. Under these circumstances (Berthelot, Sawitsch, Miasnikoff) the alkali takes up the hydrobromic acid from $C_nH_{2n-1}Br$, forming C_nH_{2n-2} .

Acetylene is obtained for lighting purposes (for bicycles and carriages) by the action of water on the carbide (carbon compound) of calcium, CaC_2 (Chapter XIV.), formed by the action of charcoal on lime in the electric furnace.^{48a} It is also produced by the imperfect

⁴⁸ The homologues of ethylene, C_nH_{2n} , are also capable of direct combination with halogens, &c., but with various degrees of facility. The composition of these homologues can be expressed thus: $(CH_3)_x(CH_2)_y(CH)_zC_r$, where the sum of x and z is always an even number, and $x + z + r$ is equal to half of $3x + z$, whence $z + 2r = x$; by this means the possible isomerides are determined. For example, for butylenes, C_4H_8 , $(CH_3)_2(CH)_2$, $(CH_3)_2(CH_2)C$, $(CH_3)(CH_2)_2CH$, and $(CH_2)_4$ are possible.

^{48a} It must be remembered in using acetylene that it is poisonous and explosive, not only in admixture with air, but spontaneously ($C_2H_2 = C_2 + H_2$) under the action of electric sparks, a blow, or concussion. The explosion of liquid (absolute boiling-point $+37^\circ$) and compressed acetylene is especially dangerous. It is very soluble in acetone (25 vols.

combustion of olefiant and marsh gases—for example, if the flame of coal gas has not free access to air.⁴⁹

Acetylene, being further removed than ethylene from the limit C_nH_{2n+2} of hydrocarbon compounds, has a still greater faculty of combination than is shown by olefiant gas, and therefore can be more readily separated from any mixture containing it. Actually, acetylene not only combines with one and two molecules of I_2 , HI , H_2SO_4 , Cl_2 , Br_2 , &c. (many other unsaturated hydrocarbons also combine with them), but also with cuprous chloride, $CuCl$, forming a red precipitate. If a gaseous mixture containing acetylene be passed through an ammoniacal solution of cuprous chloride (or silver nitrate), the other gases do not combine, but the acetylene gives a red precipitate (or grey with silver), which detonates when struck with a hammer. This red precipitate gives off acetylene under the action of acids. In this manner pure acetylene may be obtained. Acetylene and its homologues also readily react with corrosive sublimate, $HgCl_2$ (Koucheroff, Favorsky). Acetylene burns with a very brilliant flame, which is accounted for by the comparatively large amount of carbon it contains, and which is taken advantage of in its employment for lighting purposes. For this purpose the acetylene is prepared in a closed vessel by the action of water on C_2Ca , and escapes under pressure through a fine orifice, where it is lighted.⁵⁰

The formation and existence in nature of large masses of **petroleum**, which is a mixture of liquid hydrocarbons, principally of the series C_nH_{2n} , C_nH_{2n+2} is in many respects remarkable.⁵¹ In some mountainous

under the ordinary pressure), and even water dissolves it (up to 50 per cent.) in greater quantity than any other hydrocarbon gas, probably owing to its presenting the germs of an acid character (see Chap. XIV., note 62: C_2H_2 , C_2HNa , C_2Na_2 , C_2Ca).

⁴⁹ This is easily accomplished with those gas burners which are used in laboratories and mentioned in the Introduction. In these burners the gas is first mixed with air in a long tube, above which it is kindled. But if it be lighted inside the pipe, it does not burn completely, but forms acetylene on account of the cooling effect of the walls of the metallic tube; this is detected by the smell, and may be shown by passing the issuing gas (by aid of an aspirator) into an ammoniacal solution of cuprous chloride.

⁵⁰ The area of the orifice for the escape of the gas is 15–25 times smaller than in the ordinary gas burner. Amongst the homologues of acetylene C_nH_{2n-2} , the lowest is C_3H_4 ; the isomerides allylene, CH_3CCH , and allene, CH_2CCH_2 , are known, as well as $CH_2(CH)_2$, having a closed structure.

⁵¹ The saturated hydrocarbons predominate in American petroleum, especially in the more volatile portions; in Baku naphtha, hydrocarbons of the composition C_nH_{2n} form the main part (Lisenko, Markovnikoff, Beilstein), but doubtless (Mendeléeff) it also contains saturated ones, C_nH_{2n+2} . The structure of the naphtha hydrocarbons is only known for the lower homologues, but doubtless the distinction between the hydrocarbons of the Pennsylvania and Baku naphthas, boiling at the same temperature (after the requisite refining by repeated fractional distillation, which can be very conveniently done by means of steam rectification—that is, by passing steam through the dense mass), depends not only on the predominance of saturated hydrocarbons in the former,

districts—as, for instance, by the slopes of the Caucasian chain, on inclines lying in a direction parallel to the range—an oily combustible liquid issues from the earth together with salt water and hot gases (methane and others); it has a tarry smell and dark brown colour, and is lighter than water. This liquid is called naphtha or rock oil (petroleum) and is obtained in large quantities by sinking wells and deep bore-holes in those places where traces of naphtha^{51a} are observed, the naphtha being sometimes thrown up from the wells in fountains of considerable height.⁵² The evolution of naphtha is always accompanied by salt water and marsh gas. Naphtha has from ancient times been worked in Russia in the Apsheron peninsula near Baku, and is also now worked in Burmah (India), in Galicia near the Carpathians, and in America, especially in Pennsylvania and Canada, &c. Naphtha does not consist of one definite hydrocarbon, but of a mixture of several, and its density, external appearance, and other properties vary with the amounts of the different hydrocarbons of which it is composed. The light kinds of naphtha have a specific gravity about 0·8 and the heavy kinds up to 0·98. The former are very mobile liquids, and more volatile; the latter contain less of the volatile hydrocarbons and are less mobile. When the light kinds of naphtha are distilled, the boiling-point taken in the vapours constantly changes, beginning at 0° and going up to above 350°. That which passes over first is a very mobile, colourless ethereal liquid (forming gasolene, ligroin, benzoline, &c.), from which the hydrocarbons whose boiling-points start from 0° may be extracted—namely, the hydrocarbons C_4H_{10} , C_5H_{12} (which boils at 30°), C_6H_{14} (boiling at about 62°), C_7H_{16} (boiling about 90°), &c. Those fractions of the naphtha distillate which boil above 130°, and

and naphthenes, C_nH_{2n} , in the latter, but also on the diversity of composition and structure of the corresponding portions of the distillation. The products of the Baku naphtha are richer in carbon (therefore in a suitably constructed lamp they ought to give a brighter light) and of greater specific gravity, and have greater internal friction (and are therefore more suitable for lubricating machinery) than the American products collected at the same temperature.

^{51a} In all probability deep bore-holes would prove the presence of naphtha where no signs of it are to be seen on the surface, because some mountain chains have been levelled in the course of time, and the naphtha may remain unchanged for any period surrounded by clay strata in the depths of the earth.

⁵² The formation of naphtha fountains (which sometimes burst forth after the higher clay strata covering the layers of sands impregnated with naphtha have been bored through) is without doubt caused by the pressure or tension of the combustible hydrocarbon gases which accompany the naphtha, and are soluble in it under pressure. Sometimes these naphtha fountains reach a height of 100 metres—for instance, the fountain of 1887 near Baku. Naphtha fountains generally act periodically, and their force diminishes with the lapse of time, as might be expected, because the gases which cause the fountains find an outlet, the naphtha issuing from the bore-hole carrying away the sand which was partially choking it up.

contain hydrocarbons with C_9 , C_{10} , C_{11} , &c., enter into the composition of the oily substance, universally used for lighting, called *kerosene*, *photogen*, *photonaphthalene*, and other names. The specific gravity of kerosene is from 0.77 to 0.84, and it smells like naphtha. Those products of the distillation of naphtha which pass off below 130° and have a specific gravity below 0.75, enter into the composition of light petroleum (benzoline, ligroin, petroleum spirit, &c.), which is used as a solvent for india-rubber, for removing grease-spots, and as a fuel for motors (bicycles, &c.) and other purposes. Those portions of naphtha (which can only be distilled without change by means of superheated steam, otherwise they are largely decomposed) which boil above 275° and up to 300° , and have a specific gravity higher than 0.84, form an excellent oil,⁵³ safe as regards inflammability (which is very important, as it diminishes the risks of fire), and may be used in lamps as an effective substitute for kerosene.⁵⁴ Those portions of naphtha which pass over at a still higher temperature and have a higher specific gravity than 0.9, which are found in abundance (about 30 per cent.) in the

⁵³ This is a so-called intermediate oil (between kerosene and lubricating oils), solar oil, or *pyronaphtha*. Lamps are already being manufactured for burning it, but they still require improvement. Above all, however, it requires a more extended market, and this at present is wanting, owing to the two following reasons: (1) Those products of the American petroleum which are the most widely spread and almost universally consumed contain but little of this intermediate oil, and what there is is divided between the kerosene and the lubricating oils; (2) the Baku naphtha, which is capable of yielding a great deal (up to 30 per cent.) of intermediate oil, is produced in enormous quantities, about 500 million poods, but has no regular markets abroad, and for the consumption in Russia (about 35 million poods of kerosene per annum) and for the limited export (80 million poods per annum) into Western Europe (by the Trans-Caucasian Railway) those volatile and more dangerous parts of the naphtha which enter into the composition of the American petroleum are sufficient, although Baku naphtha yields about 25 per cent. of such kerosene. For this reason pyronaphtha is not manufactured in sufficient quantities, and the whole world is consuming the unsafe kerosene. When a pipe line has been laid from Baku to the Black Sea (in America there are many which carry the raw naphtha to the sea-shore, where it is made into kerosene and other products) then the whole mass of the Baku naphtha will furnish safe illuminating oils, which without doubt will find an immense application. A mixture of the intermediate oil with kerosene or Baku oil (specific gravity 0.84 to 0.85) may be considered (on removing the benzoline) to be the best illuminating oil, because it is safe (flashing point from 40° to 60°), cheaper (Baku naphtha gives as much as 60 per cent. of Baku oil), and burns perfectly well in lamps differing but little from those everywhere made for burning American kerosene (unsafe, flashing-point 20° to 30°).

⁵⁴ The substitution of Baku pyronaphtha, or intermediate oil, or Baku oil (see note 53), would not only be a great advantage as regards safety from fire, but would also be highly economical. A ton (61 poods) of American crude petroleum costs at the coast considerably more than 24s. (12 roubles), and yields two-thirds of a ton of kerosene suitable for ordinary lamps. A ton of raw naphtha in Baku costs from 6s. to 12s. (3 to 6 roubles), and with a pipe line to the shore of the Black Sea would not cost more than 8 roubles, or 16s. Moreover, a ton of Baku naphtha will yield as much as two-thirds of a ton of kerosene, Baku oil, and pyronaphtha suitable for illuminating purposes.

Baku naphtha, make excellent lubricating or machine oils. The remaining tar, on distillation with superheated steam (at about 410°), decomposes, giving vaseline (used in pomades, plasters, &c., and forming a kind of cerate). Naphtha has thus many important applications, and the naphtha industry is now of great commercial importance, especially as naphtha and its refuse may be used as fuel.⁵⁵ Whether naphtha was formed from organic matter is very doubtful, as it is found in the most ancient Silurian strata which correspond with epochs of the earth's existence when but little organic matter existed; it could not penetrate from the higher to the lower (more ancient) strata, as it floats on water (and water penetrates through all strata). It therefore tends to rise to the surface of the earth, and it is found in highlands parallel to the direction of the mountains.⁵⁶ Much

⁵⁵ Naphtha has been applied for heating purposes on a large scale in Russia, not only on account of the low cost of naphtha itself and of the *residue* from the preparation of kerosene, but also because the products of all the Baku naphtha do not find an outlet for general consumption, and the only railway across the Caucasus is unable to carry 300–400 million poods a year. Naphtha itself and its various residues form excellent fuel, burning without smoke and giving a high temperature (steel and iron may be easily melted in the flame). A hundred poods of good coal (for instance, Don coal) used as fuel for heating boilers are equivalent to 36 cubic feet (about 250 poods) of dry wood, while only 70 poods of naphtha would be required to give the same effect; and moreover there is no need for stoking, as the liquid can be readily and evenly supplied in the required quantity. The economic and other questions relating to American and Baku petroleum have been discussed more in detail in some separate works of mine (D. Mendeléeff): (1) *The Naphtha Industry of Pennsylvania and the Caucasus*, 1870; (2) *Where to build Naphtha Works*, 1880; (3) *On the Naphtha Question*, 1883; (4) *The Baku Naphtha Question*, 1886; (5) the article on the naphtha industry in the account of the Russian industries printed for the Chicago Exhibition.

⁵⁶ As during the process of the dry distillation of wood, seaweed, and similar vegetable *débris*, and also when fats are decomposed by the action of heat (in closed vessels), hydrocarbons similar to those of naphtha are formed, it was natural that this fact should have been turned to account to explain the formation of the latter. But the hypothesis of the formation of naphtha from vegetable *débris* inevitably assumes coal to be the chief element of decomposition, and naphtha is met with in Pennsylvania and Canada, in the Silurian and Devonian strata, which do not contain coal, and correspond to an epoch not abounding in organic matter. Coal was formed from the vegetable *débris* of the Carboniferous, Jurassic, and other recent strata, but judging more from its composition and structure, it has been subjected to the same kind of decomposition as peat; nor could liquid hydrocarbons have been thus formed to such an extent as we see in naphtha. If we ascribe the derivation of naphtha to the decomposition of fat (adipose, animal fat) we encounter three almost insuperable difficulties: (1) Animal remains would furnish a great deal of nitrogenous matter, whilst there is but very little in naphtha; (2) the enormous quantity of naphtha already discovered as compared with the insignificant amount of fat in the animal carcase; (3) the sources of naphtha always running parallel to mountain chains is completely inexplicable. Being struck with this last-mentioned circumstance in Pennsylvania, and finding that the sources in the Caucasus surround the whole Caucasian range (Baku, Tiflis, Gouria, Kouban, Taman, Groznoe, Dagestan), I developed in 1876 the hypothesis of the mineral origin of naphtha expounded further on. Berthelot even made a suggestion of the same kind, and in recent times Moissan holds

more probably its formation may be attributed to the action of water penetrating through the crevasses formed on the mountain slopes and reaching to the heart of the earth, to that kernel of heated metallic matter which must be accepted as existing in the interior of the earth. And as meteoric iron often contains carbon (like cast iron), so, accepting the existence of such carburetted iron at unattainable depths in the interior of the earth, it may be supposed that naphtha was produced by the action of water penetrating through the crevices of the strata during the upheaval of mountain chains,⁵⁷ because

the same opinion, although there are yet many men of science who ascribe the origin of naphtha to the antediluvian remains of the animal and vegetable world.

⁵⁷ During the upheaval of mountain ranges, crevasses would be formed at the peaks with openings upwards, and at the foot of the mountains with openings downwards. These cracks in course of time fill up, but the younger the mountains the fresher the cracks (the Alleghany Mountains are, without doubt, more ancient than the Caucasian, which were formed during the Tertiary epoch); through them water must gain access deep into the recesses of the earth to an extent that could not occur on the level (on plains). The situation of naphtha at the foot of mountain chains is the principal argument in the following hypothesis.

Another fundamental reason is the consideration of the mean density of the earth. Cavendish, Airy, Cornu, Boys, and many others who have investigated the subject by various methods, found that, taking water as 1, the mean density of the earth is nearly 5.5. As at the surface, water and all rocks (sand, clay, limestone, granite, &c.) have a density less than 3, it is evident (as solid substances are but slightly compressible even under the greatest pressure) that inside the earth there are substances of a greater density—indeed, not less than 7 or 8. What conclusion, then, can be arrived at? Anything heavy contained in the bosom of the earth must be distributed not only on its surface, but throughout the whole solar system, for everything tends to show that the sun and planets are formed from the same material, and according to the hypothesis of Laplace and Kant it is most probable, and indeed must necessarily be held, that the earth and planets are but fragments of the solar atmosphere, which have had time to cool considerably and become masses semi-liquid inside and solid outside, forming both planets and satellites. The sun amongst other heavy elements contains a great deal of iron, as is shown by spectrum analysis. There is also much of it in an oxidised condition on the surface of the earth. Meteoric stones, carried as fragmentary planets in the solar system and sometimes falling upon the earth, consisting of siliceous rocks similar to terrestrial ones, often contain either dense masses of iron (for example, the Pallosovo iron preserved in the St. Petersburg Academy of Sciences) or granular masses (for instance, the Okhansk meteorite of 1886). It is therefore possible that the interior of the earth contains much iron in a metallic state. This might be anticipated from the hypothesis of Laplace, for the iron must have been compressed into a liquid at that period when the other component parts of the earth were still strongly heated, and oxides of iron could not then have been formed. The iron was covered with slags (mixtures of silicates like glass fused with rocky matter) which did not allow it to burn at the expense of the oxygen of the atmosphere or of water, just at that time when the temperature of the earth was very high. Carbon was in the same state; its oxides were also capable of dissociation (Deville); it is also but slightly volatile, and has an affinity for iron, and iron carbide is found in meteoric stones (as also are carbon and even the diamond). Thus the supposition of the existence of iron carbides in the interior of the earth was derived by me from many indications, which are to some extent confirmed by the fact that granular pieces of iron have been found in some basalts (ancient lava) as well as in meteoric stones. The occurrence of iron in contact with carbon during the formation of

water with iron carbide should give iron oxide and hydrocarbons.⁵⁸ Direct experiment (Cloëz, Mendeléeff) proves that the so-called *Spiegel-eisen* (manganiferous iron, rich in chemically combined carbon), when treated with acids, gives liquid hydrocarbons⁵⁹ which in composition, appearance, and properties are completely identical with naphtha,⁶⁰ and

the earth is all the more probable because those elements predominate in nature which have small atomic weights, and among them the most widely diffused, the most difficultly fusible, and therefore the most easily condensed (Chapter XV.), are carbon and iron. They passed into the liquid state when all compounds were at a temperature of dissociation.

The reaction of the iron and carbon would give carbide of iron, which would remain in an incandescent state inside the earth. And the action of water, especially salt-water, on this carbide of iron can give naphtha, C_nH_{2n} .

⁵⁸ The following is the typical equation for this formation :

⁵⁹ Cloëz investigated the hydrocarbons formed when cast iron is dissolved in hydrochloric acid, and found C_nH_{2n} and others. I treated crystalline manganiferous cast iron with the same acid, and obtained a liquid mixture of hydrocarbons exactly similar to natural naphtha in taste, smell, and reaction.

⁶⁰ Naphtha was probably produced during the upheaval of all mountain chains, but only in some cases were the conditions favourable to its being preserved underground. The water penetrating below formed there a mixture of naphtha and aqueous vapours, and this mixture issued through fissures to the cold parts of the earth's crust. The naphtha vapours, on condensing, formed naphtha, which, if there were no obstacles, appeared on the surface of land and water. Here part of it soaked through formations (possibly the bituminous slates, schists, dolomites, &c., were thus formed), another part was carried away on the water, became oxidised, evaporated, and was driven to the shores (the Caucasian naphtha probably in this way, during the existence of the Aralo-Caspian sea, was carried as far as the Sisran banks of the Volga, where many strata are impregnated with naphtha and products of its oxidation resembling asphalt and pitch); a great part of it was burnt in one way or another—that is, gave carbonic anhydride and water. If the mixture of vapours, water, and naphtha formed inside the earth had no free outlet to the surface, it nevertheless would find its way through fissures to the superior and colder strata, and there become condensed. Some of the formations (clays) which do not absorb naphtha were only washed away by the warm water, and formed mud, which we also now observe issuing from the earth in the form of mud volcanoes. The neighbourhood of Baku and the whole of the Caucasus near the naphtha districts are full of such volcanoes, which from time to time are in a state of eruption. In old naphtha beds (such as the Pensylvanian) even these blow-holes are closed, and the mud volcanoes have had time to be washed away. The naphtha and the gaseous hydrocarbons formed with it, under the pressure of the overlying earth and water, impregnated the layers of sand, which are capable of absorbing a great quantity of such liquid, and if above this there were strata impermeable to naphtha (dense, clayey, damp strata) the naphtha would accumulate in them. It is thus preserved from remote geological periods up to the present day, compressed and dissolved under the pressure of the gases which burst out in places forming naphtha fountains. If this be granted, it may be thought that in the comparatively new (geologically speaking) mountain chains, such as the Caucasian, naphtha is even now being formed. Such a supposition may explain the remarkable fact that, in Pennsylvania, localities where naphtha had been rapidly worked for five years, have become exhausted, and it becomes constantly necessary to have recourse to sinking new wells in fresh places. Thus, from the year 1859, the workings were gradually transferred along a line running parallel to the Alleghany Mountains for a distance of more than 200 miles; they are now almost exhausted, and have been trans-

carbide of uranium forms them directly when acted on by water (Moissan).

ferred to Ohio and Texas. In Baku the industry dates from time immemorial (the Persians worked near the village of Ballaghana), and up to the present time keeps to one and the same place. The amounts of the Pennsylvanian and Baku annual outputs are at present equal—namely, about 500 million poods (eight million tons). It may be that the Baku beds, as being of more recent geological formation, are not so exhausted by nature as those of Pennsylvania, and perhaps in the neighbourhood of Baku naphtha is still being formed, as is partially indicated by the continued activity of the mud volcanoes. However, the bearings have also become deeper at Baku in the course of years; thus in the eighties the depth was about 80 fathoms, and in 1902 it had increased to 150 fathoms.

As many varieties of naphtha contain in solution solid slightly volatile hydrocarbons like paraffin and mineral wax, the production of ozokerite, or mountain wax, is accounted for as accompanying that of naphtha. Ozokerite is found in Galicia, also in the neighbourhood of Novorossisk, in the Caucasus, and on the islands of the Caspian Sea (particularly in the Chileken and Holy Islands); it is met with in large masses, and is used for the production of paraffin and *ceresine*, for the manufacture of candles, and similar purposes.

As the naphtha treasures of the Caucasus have hardly been exploited (near Baku and near Kouban and Grosnyi), and as naphtha finds numerous uses, the subject presents most interesting features to chemists and geologists, and is worthy of the close attention of practical men.

CHAPTER IX

COMPOUNDS OF CARBON WITH OXYGEN AND NITROGEN

CARBONIC ANHYDRIDE (or carbonic acid or carbon dioxide, CO_2) was the first of all gases to be distinguished from atmospheric air. Paracelsus and van Helmont, in the sixteenth century, knew that on heating limestone a peculiar gas separated, which is also formed during the alcoholic fermentation of saccharine solutions (for instance, in the manufacture of wine); they knew that it was identical with the gas which is produced by the combustion of charcoal, and that in some

FIG. 70.—Dumas and Stas' apparatus for determining the composition of carbonic anhydride. Carbon, graphite, or a diamond is placed in the tube E in the furnace, and heated in a stream of oxygen displaced from the bottle by water flowing from A. The oxygen is purified from carbonic anhydride and water in the tubes B, C, D. Carbonic anhydride, together with a certain amount of carbon monoxide, is formed in E. The latter is converted into carbonic acid by passing the products of combustion through a tube, F, containing cupric oxide heated in a furnace. The cupric oxide oxidises this CO into CO_2 , forming metallic copper. The potash bulbs H and tubes I, J, K retain the carbonic anhydride. Thus, knowing the weight of carbon taken and the weight of the resultant carbonic anhydride (by weighing H, I, J, K before and after the experiment), the composition of carbonic anhydride and the equivalent of carbon may be determined.

cases it is found in nature. In course of time it was found that this gas is absorbed by alkali, forming a salt which, under the action of acid, again yields this same gas. Priestley found that this gas exists in air, and Lavoisier determined its formation during respiration, combustion, putrefaction, and during the reduction of the oxides of metals by charcoal; he determined its composition, and showed that it contains only oxygen and carbon. Berzelius, Dumas with Stas, and

Roscoe determined its composition, showing that it contains twelve parts of carbon to thirty-two of oxygen. The composition by volume of this gas is determined from the fact that during the combustion of charcoal in oxygen, the volume remains unchanged; that is to say, **carbonic anhydride occupies the same volume as the oxygen which it contains**—the atoms of the carbon being, so to speak, squeezed in between the atoms of the oxygen. O_2 occupies two volumes and is a molecule of ordinary oxygen; CO_2 likewise occupies two volumes, and expresses the composition and molecular weight of the gas. The relation between hydrogen, H_2 , and acetylene, C_2H_2 , is the same, only in that case we have C_2 , and here one atom of carbon.

Carbonic anhydride exists **in nature**, both in a free state and in the most varied compounds. In a free state it is always contained (Chap. V.) in the air, and in solution exists in all kinds of water. It is evolved from volcanoes, from mountain fissures, and in some caves. The well-known Dog grotto, near Agnano on the bay of Baiæ, near Naples, furnishes the best known example of such an evolution. Similar sources of carbonic anhydride are also found in other places. In France, for instance, there is a well-known poisonous fountain in Auvergne. It is a round hole, surrounded with luxurious vegetation and constantly evolving carbonic anhydride. In the woods surrounding the Lacher Lake near the Rhine, in the neighbourhood of extinct volcanoes, there is a depression constantly filled with this same gas. The insects which fly to this place perish, animals being unable to breathe the gas. The birds chasing the insects also die, and this is turned to profit by the local peasantry. Many mineral springs carry into the air enormous quantities of this gas. Vichy in France, Sprüdel in Germany, and Narzan in Russia (in Kislovodsk near Piatigorsk) are known for their carbonated gaseous waters. Much of this gas is also evolved in mines, cellars, diggings, and wells. People descending into such places are suffocated. The combustion, putrefaction, and fermentation of organic substances give rise to the formation of carbonic anhydride. It is also introduced into the atmosphere during the respiration of animals at all times and during the respiration of plants in darkness and also during their growth. Very simple experiments prove the formation of carbonic anhydride under these circumstances; thus, for example, if the air expelled from the lungs be passed through a glass tube into a transparent solution of lime (or baryta) in water a white precipitate will soon be formed consisting of an insoluble compound of lime and carbonic anhydride. By allowing the seeds of plants to grow under a bell-jar, or in a closed vessel, the formation of carbonic anhydride may be similarly confirmed. By confining an animal, a mouse, for

instance, under a bell-jar, the quantity of carbonic acid which it evolves may be exactly determined, and it will be found to be many grams per day for a mouse. Such experiments on the **respiration of animals** have also been made with great exactitude with large animals, such as men, bulls, sheep, &c. By means of enormous hermetically closed bell-receivers and the analysis of the gases evolved during respiration it was found that a man expels about 900 grams (more than two pounds) of carbonic anhydride per diem, and absorbs during this time 700 grams of oxygen.¹ It must be remarked that the carbonic anhydride of the air constitutes the fundamental food of plants (Chapters III., V., and VIII.). Carbonic anhydride in a state of combination with a variety of other substances is perhaps even more widely distributed in nature than in a free state.^{1a} Some of these substances are very stable and form a

¹ The quantity of carbonic acid gas exhaled by a man during the twenty-four hours is not produced uniformly; during the night more oxygen is taken in than during the day (by night, in twelve hours, about 450 grams), and more carbonic anhydride is separated by day than during night-time and repose; thus, of the 900 grams produced during the twenty-four hours about 375 are given out during the night and 525 by day. This depends on the formation of carbonic anhydride during the work performed by the man in the day. Every movement is the result of some change of matter, for force cannot be self-created (in accordance with the law of the conservation of energy). Proportionally to the amount of carbon consumed an amount of energy is stored up in the organism and is consumed in the various movements performed by animals. This is proved by the fact that during work a man exhales 900 grams of carbonic anhydride in twelve hours instead of 525, absorbing the same amount of oxygen as before. The man, as it were, burns. After a working day a man exhales by night almost the same amount of carbonic anhydride as after a day of rest, so that during a total twenty-four hours a man exhales about 1,300 grams of carbonic anhydride and absorbs about 950 grams of oxygen. So that during work the change of matter increases. The carbon expended on the work is obtained from the food; on this account the food of animals ought certainly to contain carbonaceous substances capable of dissolving under the action of the digestive fluids, and of passing into the blood, or, in other words, capable of being digested. Such food for man and all other animals is formed of vegetable matter, or of parts of other animals. The latter in every case obtain their carbonaceous matter from plants, in which it is formed by the separation of the carbon from the carbonic anhydride taken up during the day by the respiration of the plants. The volume of the oxygen exhaled by plants is almost equal to the volume of the carbonic anhydride absorbed; that is to say, nearly all the oxygen entering into the plant in the form of carbonic anhydride is liberated in a free state, whilst the carbon from the carbonic anhydride remains in the plant. At the same time the plant absorbs moisture by its leaves and roots. By a process which is unknown to us, this absorbed moisture and the carbon obtained from the carbonic anhydride enter into the composition of the plants in the form of so-called *carbohydrates*, composing the greater part of the vegetable tissues, starch and cellulose of the composition $C_6H_{10}O_5$ being representatives of them. They may be considered, like all carbohydrates, as compounds of carbon and water, $6C + 5H_2O$. In this way a **circulation** of the carbon in nature goes on by means of vegetable and animal organisms, in which changes the principal factor is the carbonic anhydride of the air.

^{1a} Hence, and from the fact that coal is derived from plants which were nourished by CO_2 , it follows that the amount of CO_2 in the air in former geological periods was greater than now. This would also affect the diathermancy of the atmosphere and the climate of the globe (see Chap. V., note 25)

large portion of the earth's crust. For instance, limestones, calcium carbonate, CaCO_3 , were formed as precipitates in the seas formerly existing on the earth; this is proved by their stratified structure and the number of remains of sea animals which they frequently contain. Chalk, lithographic stone, limestone, marls (a mixture of limestone and clay), and many other rocks are examples of such carboniferous sedimentary formations. Carbonates with various other bases—such as, for instance, magnesia, ferrous oxide, zinc oxide, &c.—are often found in nature. The shells of molluscs also have the composition CaCO_3 , and many limestones were exclusively formed from the shells of minute organisms. As carbonic anhydride (together with water) is produced during the combustion of all organic compounds in a stream of oxygen or by heating them with substances which readily part with their

FIG. 71.—Apparatus for the combustion of organic substances by igniting them with oxide of copper.

oxygen—for instance, with copper oxide—this method is employed for estimating the amount of carbon in organic compounds, more especially as the CO_2 can be easily collected and the amount of carbon calculated from its weight. As a rule, for this purpose a hard glass tube, closed at one end, is filled with a mixture of the organic substance (about 0.2 gram) and copper oxide. The open end of the tube is fitted with a cork and tube containing calcium chloride for absorbing the water formed by the oxidation of the substance. This tube is hermetically connected (by a caoutchouc tube) with potash bulbs or other weighing apparatus (Chapter V.) containing alkali destined to absorb the carbonic anhydride. The increase in weight of this apparatus shows the amount of carbonic anhydride formed during the combustion of the given substance, and the quantity of carbon may be determined from this, because three parts of carbon give eleven parts of carbonic anhydride.

For the preparation of carbonic anhydride in laboratories and often in manufactories, either charcoal is simply burnt or more frequently various kinds of native calcium carbonate are used, being treated with some acid; it is most usual to employ the so-called muriatic acid—that is, an aqueous solution of hydrochloric acid, HCl —because the substance formed, calcium chloride, CaCl_2 , is soluble in water and does not hinder the further action of the acid on the calcium carbonate (sulphuric acid gives insoluble gypsum). For calcium carbonate, either limestone, chalk, or marble is used: ² $\text{CaCO}_3 + 2\text{HCl} = \text{CaCl}_2 + \text{H}_2\text{O} + \text{CO}_2$. The nature of the reaction in this case is the same as in the decomposition of nitre by sulphuric acid; only in the latter case a hydrate is formed, and in the former an anhydride of the acid, because the hydrate, carbonic acid, H_2CO_3 , is unstable, and as soon as it separates decomposes into water and its own anhydride. It is evident from the explanation of the cause of the action of sulphuric acid on nitre that not every acid can be employed for obtaining carbonic anhydride, for those will not set it free which are chemically but slightly energetic, or are insoluble in water, or are themselves as volatile as carbonic anhydride.³ But as many acids are soluble in water and are less volatile than carbonic anhydride, the latter is evolved by the

² If porous limestone—for instance, chalk—be treated with sulphuric acid diluted with an equal volume of water, the liquid is absorbed and acts on the mass of the salt, the evolution of carbonic anhydride continuing evenly for a long time. Instead of calcium carbonate other carbonates may of course be used; for instance, washing-soda, Na_2CO_3 , which is often chosen when it is required to produce a rapid stream of carbonic anhydride (for example, for liquefying it). But natural crystalline magnesium carbonate is with difficulty decomposed by hydrochloric and sulphuric acids. When for manufacturing purposes—for instance, in precipitating lime in sugar-works—a large quantity of carbonic acid gas is required, it is generally obtained by burning charcoal, and the products of combustion, rich in carbonic anhydride, are forced into the liquid containing the lime, and the carbonic anhydride is thus absorbed. Another method which consists in using the carbonic anhydride separated during fermentation, or that evolved from limekilns, is also practised. During the fermentation of sweet-wort, grape-juice, and other similar saccharine solutions, the glucose, $\text{C}_6\text{H}_{12}\text{O}_6$, changes under the influence of the yeast organism, forming alcohol ($2\text{C}_2\text{H}_6\text{O}$), and carbonic anhydride (2CO_2) which separates in the form of gas; if the fermentation proceeds in closed bottles sparkling wine is obtained. When carbonic acid gas is prepared for saturating water and other beverages it is necessary to use it in a pure state; whilst when evolved from ordinary limestone by the aid of acids it contains, besides a certain quantity of acid, the organic matters of the limestone. In order to diminish the quantity of these substances the densest kinds of dolomites are used, which contain less organic matter, and the gas formed is passed through various washing apparatus, and then through a solution of potassium permanganate, which absorbs organic matter and does not take up carbonic anhydride.

³ Hypochlorous acid, HClO , and its anhydride, Cl_2O , do not displace carbonic acid, and hydrogen sulphide has the same relation to carbonic acid as nitric acid to hydrochloric—an excess of either one displaces the other.

action of most acids on its salts, and this reaction takes place at ordinary temperatures.⁴

For the preparation of carbonic anhydride in laboratories, marble is generally used. It is placed in a Woulfe's bottle and treated with hydrochloric acid in an apparatus similar to the one used for the production of hydrogen. The gas evolved carries away through the tube part of the volatile hydrochloric acid, and it is therefore necessary to wash the gas by passing it through another Woulfe's bottle containing water.⁵

Carbonic anhydride may also be prepared by heating many of the salts of carbonic acid; for instance, by heating magnesium carbonate, MgCO_3 (e.g., in the form of dolomite), the separation is easily effected, particularly in the presence of the vapours of water. The acid salts of carbonic acid (for instance, NaHCO_3 , see further on) readily and abundantly give carbonic anhydride when heated.

Carbonic anhydride is colourless, has a slight smell and a faint acid taste; its density in a gaseous state is twenty-two times as great as that of hydrogen, because its molecular weight is forty-four.⁶

⁴ Thus, in preparing the ordinary effervescing powders, sodium bicarbonate (or acid carbonate of soda) is used, and is mixed with powdered citric or tartaric acid. In a dry state these powders do not evolve carbonic anhydride, but when mixed with water the evolution takes place briskly, owing to the substances passing into solution. The salts of carbonic acid may be recognised from the fact that they evolve carbonic acid with a hissing noise when treated with acids. If vinegar, which contains acetic acid, be poured upon limestone, marble, malachite (containing copper carbonate), &c., carbonic anhydride is evolved with a hissing noise. It is noteworthy that neither hydrochloric acid, nor even sulphuric acid, nor acetic acid acts on limestone except in presence of water. We shall refer to this later on.

⁵ The direct observations made (1876) by Messrs. Bogouski and Kayander lead to the conclusion that the quantity of carbonic anhydride evolved by the action of acids on marble (as homogeneous as possible) is directly proportional to the time of action, the extent of surface, and the degree of concentration of the acid, and inversely proportional to the molecular weight of the acid. If the surface of a piece of Carrara marble be equal to one decimetre, the time of action one minute, and one cubic decimetre or litre of the acid contains one gram of hydrochloric acid, then about 0.02 gram of carbonic anhydride will be evolved. If the litre contains n grams of hydrochloric acid, then by experiment the amount will be $n \times 0.02$ of carbonic anhydride. Therefore, if the litre contains 36.5 (= HCl) grams, about 0.73 gram of carbonic anhydride (about half a litre) would be evolved per minute. If nitric acid or hydrobromic acid be used instead of hydrochloric, then, with a combining proportion of the acid, the same quantity of carbonic anhydride will be evolved; thus, if the litre contains 63 (= HNO_3) grams of nitric acid, or 81 (= HBr) grams of hydrobromic acid, the quantity of carbonic anhydride evolved will still be 0.73 gram. Spring (in 1890) made a series of similar determinations.

⁶ As carbonic anhydride is one and a half time **heavier than air**, it diffuses with difficulty, and therefore does not easily mix with air, but sinks in it. This may be shown in various ways; for instance, the gas may be carefully poured from one vessel into another containing air. If a lighted taper be plunged into the vessel containing carbonic anhydride it is extinguished, and then, after pouring the gas into the other cylinder, it will burn in the former and be extinguished in the latter. If a certain quantity of carbonic anhydride be poured into a vessel containing air, and soap-bubbles be introduced, they will only sink as far as the stratum where the atmosphere of carbonic anhydride commences,

It is an example of those gaseous substances which have been long ago transformed into all the three states. In order to obtain **liquid** carbonic anhydride, the gas must be submitted to a pressure of thirty-six atmospheres at 0° .⁷ Its absolute boiling-point (critical temperature) is $+32^{\circ}$.⁸ Liquid carbonic anhydride is colourless and does not mix with water, but it is soluble in alcohol, ether, and oils; at 0° its specific gravity is 0.9.^{8a} The boiling-point of this liquid lies at -78° ; that is to say, the pressure of carbonic acid gas at that temperature is nearly that of the atmosphere. At the ordinary pressure liquid CO_2 remains as such for some time, if it does not exceed 50° , on account of its requiring a considerable amount of heat for its evaporation (latent heat at $0^{\circ}=55$ units). If the evaporation takes place rapidly from a considerable surface—for instance, when the liquid is poured in a thin stream—such a fall of temperature occurs that a part of the carbonic anhydride is transformed into a solid snowy mass melting at about -60° . Water, mercury, and many other liquids freeze on coming into contact with carbonic anhydride snow.⁹ In this form carbonic anhydride may be preserved for a long time in the open air, because it requires still more heat to turn it into a gas than when in a liquid state.^{9a}

as this latter is heavier than the soap-bubbles filled with air. Naturally, after a certain lapse of time, the carbonic anhydride will be diffused throughout the vessel, and form a uniform mixture with the air, just as salt in water.

⁷ This liquefaction was first observed by Faraday, who sealed up a mixture of a carbonate and sulphuric acid in a tube. This method was afterwards very considerably improved by Thilorier and Natterer, whose apparatus is described in Chapter VI. in discussing N_2O . It is, however, necessary to remark that the preparation of liquid carbonic anhydride requires good liquefying apparatus, constant cooling, and a rapid preparation of large masses of carbonic anhydride.

⁸ Carbonic anhydride, having the same molecular weight as nitrous oxide, very much resembles it when in a liquid state.

^{8a} When poured into a tube, which is then sealed up, liquefied carbonic anhydride can be easily preserved, because a thick tube easily supports the pressure (about 50 atmospheres) exerted by the liquid at the ordinary temperature. At -20° the sp. gr. is almost = 1, at $+20^{\circ}$ about 0.77, and at the critical temperature, $+31.4^{\circ}$, about 0.46. At this latter temperature gaseous CO_2 has almost the same density, for the pressure is almost 75 atmospheres.

⁹ When a fine stream of liquid carbonic anhydride is discharged into a closed metallic vessel, about one-third of its mass solidifies and the remainder evaporates. In employing solid carbonic anhydride for making experiments at low temperatures, it is best to use it mixed with ether, otherwise there will be few points of contact. If a stream of air be blown through a mixture of liquid carbonic anhydride and ether, the evaporation proceeds rapidly, and great cold is obtained. At present in some special manufactories (and for making artificial mineral waters) carbonic anhydride is liquefied on the large scale, filled into wrought-iron cylinders provided with a valve, and in this manner it can be transported and preserved safely for a long time. It is used, for instance, in breweries.

^{9a} Solid carbonic anhydride (sp. gr. about 1.4), notwithstanding its very low temperature, can be safely placed on the hand, because it continually evolves gas which prevents its coming into actual contact with the skin; but if a piece be squeezed between

Carbonic anhydride as a liquefiable gas **dissolves** with great facility in **water**, alcohol, and other liquids. Its solubility in water has been already spoken of in the first chapter. Carbonic anhydride is still more soluble in alcohol than in water, one volume of alcohol dissolving 4·3 volumes of this gas at 0° and 2·9 volumes at 20°.

Aqueous solutions of carbonic anhydride, under a pressure of several atmospheres, are now prepared artificially, because water saturated with this gas promotes digestion and quenches thirst. For this purpose the carbonic anhydride is pumped by means of a force-pump into a closed vessel containing the liquid and then bottled off, taking special means to ensure rapid and air-tight corking. Various effervescing drinks and artificially effervescing wines are thus prepared. The presence of carbonic anhydride has an important significance in nature, because by its means water acquires the property of decomposing and dissolving many substances which are not acted on by pure water: for instance, calcium phosphates and carbonates are soluble in water containing carbonic acid. If the water in the interior of the earth be saturated with carbonic acid under pressure, the quantity of calcium carbonate in solution may reach three grams per litre, and on issuing at the surface, as the carbonic anhydride escapes, the calcium carbonate will be deposited.¹⁰ Water charged with carbonic anhydride brings about the destruction of many rocky formations by removing the lime, alkali, &c., from them. This process has been going on, and still continues, on an enormous scale. Rocks contain silica and the oxides of various metals; amongst others, the oxides of aluminium, calcium, and sodium. Water charged with

the fingers, it produces a severe frost-bite similar to a burn. If the snowlike solid be mixed with ether, a semi-liquid mass is obtained, which is employed for artificial refrigeration. This mixture may be used for liquefying many other gases—such as chlorine, nitrous oxide, hydrogen sulphide, and others. The evaporation of such a mixture proceeds with far greater rapidity under the receiver of an air-pump, and consequently the refrigeration is more intense.

¹⁰ If such water trickles through crevices and enters a cavern, the evaporation will be slow, and therefore, in those places from which the water drips, growths of calcium carbonate will be formed, just like the icicles formed on the gutters of roofs in winter-time. Such conical and cylindrical stony growths form the so-called stalactites or pendants hanging from above and stalagmites formed on the bottom of caves. Sometimes these two kinds meet together, forming entire columns filling the cave. Many of these caves are remarkable for their picturesqueness; for instance, the cave of Antiparos, in the Grecian Archipelago. This same action also forms spongy masses of calcium carbonate in those places where the springs come to the surface of the earth. It is therefore very evident that a calcareous solution is sometimes capable of penetrating plants and filling the whole of their mass with calcium carbonate. This is one of the forms of petrified plants. Calcium phosphate in solution in water containing carbonic acid plays an important part in the nourishment of plants, because all plants contain both lime and phosphoric acid.

carbonic acid dissolves both the latter, transforming them into carbonates. The waters of the ocean ought, as the evolution of the carbonic anhydride proceeds, to precipitate salts of lime; these are actually found everywhere on the surface of the ground in those places which formerly formed the bed of the ocean. The presence of carbonic anhydride in solution in water is essential to the nourishment and growth of water plants.

Although carbonic anhydride is soluble in water, no definite hydrate is formed;¹¹ nevertheless an idea of the composition of this hydrate may be formed from that of the salts of carbonic acid, because a hydrate is nothing but a salt in which the metal is replaced by hydrogen. As carbonic anhydride forms salts of the composition K_2CO_3 , Na_2CO_3 , $HNaCO_3$, &c., carbonic acid ought to have the composition H_2CO_3 —that is, it ought to contain $CO_2 + H_2O$. Whenever this substance is formed, it decomposes into its component parts—that is, into water and carbonic anhydride. **The acid properties** of carbonic anhydride^{11a} are demonstrated by its being directly absorbed by alkaline solutions, forming salts with them. Unlike nitric, HNO_3 , and similar monobasic acids which with univalent metals (exchanging one atom for one atom of hydrogen) give salts such as those of potassium, sodium, and silver containing only one atom of the metal ($NaNO_3$, $AgNO_3$), and with bivalent¹² metals (such as calcium, barium, lead) salts containing two acid groups—for example, $Ca(NO_3)_2$, $Pb(NO_3)_2$ —carbonic acid, H_2CO_3 , is **dibasic**, that is, contains two atoms of hydrogen in the hydrate or two atoms of univalent metals in its salts: for example, Na_2CO_3 is washing soda, a normal salt; $NaHCO_3$ is the bicarbonate, an acid salt. Therefore, if M' be a univalent metal, its carbonates in general are the normal carbonate M'_2CO_3 and the acid carbonate, $M'HCO_3$; or if M'' be a bivalent metal (replacing H_2) its normal carbonate will be $M''CO_3$; these metals do not usually form

¹¹ The crystallhydrate, $CO_2 \cdot 8H_2O$ of Wroblewski (Chap. I., note 67), is, in the first place, only formed under special conditions; in the second place, its existence still requires confirmation; and in the third place, it does not correspond with that hydrate H_2CO_3 which should occur, judging from the composition of the salts.

^{11a} It is easy to demonstrate the acid properties of carbonic anhydride by taking a long tube, closed at one end, and filling it with this gas; a test-tube is then filled with a solution of an alkali (for instance, sodium hydroxide), which is then poured into the long tube and the open end corked. The solution is then well shaken in the tube, and the corked end plunged into water. If the cork be now withdrawn under water, the water will fill the tube. The vacuum obtained by the absorption of the carbonic anhydride by an alkali is so complete that even an electric discharge will not pass through it. This method is often applied to produce a vacuum.

¹² The reasons for distinguishing the uni-, bi-, tri-, and quadri-valent metals will be explained hereafter on passing from the univalent metals (Na , K , Li) to the bivalent ones (Mg , Ca , Ba), Chap. XIV.

acid salts in a free state, as we shall see further on. The dibasic character of carbonic acid is akin to that of sulphuric acid, H_2SO_4 ,¹³ but the latter, in distinction from the former, is an example of the energetic or strong acids (such as nitric or hydrochloric), whilst in carbonic acid we observe but feeble development of the acid properties; hence carbonic acid must be considered to be a **weak acid**. This conception must, however, be taken as only comparative.¹⁴ The feeble

¹³ Up to the year 1840, or thereabout, acids were not distinguished by their basicity. Graham, while studying phosphoric acid, H_3PO_4 , and Liebig, while studying many organic acids, distinguished mono-, di-, and tri-basic acids. Gerhardt and Laurent generalised these relations, showing that this distinction extends over many reactions (for instance, to the faculty of dibasic acids of forming neutral and acid salts with alkalies, KHO or NaHO , or with alcohols, RHO , &c.); but now, since a definite conception as to atoms and molecules has been arrived at, *the basicity of an acid is determined by the number of hydrogen atoms, contained in a molecule of the acid, which can be exchanged for metals*. If carbonic acid forms acid salts, NaHCO_3 , and normal salts, Na_2CO_3 , it is evident that the hydrate is H_2CO_3 , a dibasic acid. Otherwise it is at present impossible to account for the composition of these salts. But when $\text{C} = 6$ and $\text{O} = 8$ were taken, then the formula CO_2 expressed the composition, but not the molecular weight, of carbonic anhydride; and the composition of the normal salt would be $\text{Na}_2\text{C}_2\text{O}_6$, or NaCO_3 , so that carbonic acid might have been regarded as a monobasic acid. The acid salt would then have been represented by $\text{NaCO}_3, \text{HCO}_3$. Such questions were the cause of much argument and difference of opinion among chemists about forty years ago. At present there cannot be two opinions on the subject, if the law of Avogadro-Gerhardt and its consequences be strictly adhered to. It may, however, be observed here that the monobasic acids R(OH) were for a long time considered to be incapable of being decomposed into water and anhydride, and this property was ascribed to the dibasic acids R(OH)_2 as containing the elements necessary for the separation of the molecule of water, H_2O . Thus H_2SO_4 or $\text{SO}_2(\text{OH})_2$, H_2CO_3 , or CO(OH)_2 , and other dibasic acids decompose into an anhydride, RO , and water, H_2O . But as nitrous, HNO_2 , iodic, HIO_3 , hypochlorous, HClO , and other monobasic acids easily give their anhydrides N_2O_3 , I_2O_5 , Cl_2O , &c., that method of distinguishing the basicity of acids, although it fairly well satisfies the requirements of organic chemistry, cannot be considered correct. It may also be remarked that up to the present time not one of the dibasic acids has been found to have the faculty of being distilled without being decomposed into anhydride and water (even H_2SO_4 , on being evaporated and distilled, gives $\text{SO}_3 + \text{H}_2\text{O}$), and the decomposition of acids into water and anhydride proceeds particularly easily with feebly energetic acids, such as carbonic, nitrous, boric, and hypochlorous. Let us add that carbonic acid, as a hydrate corresponding to marsh gas, $\text{C(HO)}_4 = \text{CO}_2 + 2\text{H}_2\text{O}$, ought to be tetrabasic. But in general it does not form such salts. Basic salts, however, such as $\text{CuCO}_3, \text{CuO}$, may be regarded in this sense, for CCu_2O_4 corresponds with CH_4O_4 , since Cu corresponds with H_2 . Amongst the ethereal salts (alcoholic derivatives) of carbonic acid corresponding cases are, however, observed; for instance, ethylic orthocarbonate, $\text{C(C}_2\text{H}_5\text{O)}_4$ (obtained by the action of chloropicrin, $\text{C(NO}_2\text{)Cl}_3$, on sodium ethoxide, $\text{C}_2\text{H}_5\text{ONa}$; boiling-point 158° ; specific gravity, 0.92). The name *orthocarbonic acid* for CH_4O_4 is taken from *orthophosphoric acid*, PH_3O_4 , which corresponds with PH_3 (see Chap. XIX.).

¹⁴ Long ago endeavours were made to find a *measure of the affinity* of acids and bases, because some of the acids, such as sulphuric or nitric, form comparatively stable salts, decomposed with difficulty by heat and water, whilst others, like carbonic and hypochlorous acids, do not combine with feeble bases, and with most of the other bases form salts which are easily decomposed. The same may be said with regard to bases, among which those of potassium, K_2O , sodium, Na_2O , and barium, BaO , may serve as examples of the most powerful, because they combine with the most feeble acids and form a number of salts of

acid properties of carbonic acid may, however, be judged from the *joint evidence* of many properties. With such energetic alkalies as soda and great stability, whilst as examples of the feeblest bases alumina, Al_2O_3 , or bismuth oxide, Bi_2O_3 , may be taken, because these form salts easily decomposed by water or heat if the acid be volatile. Efforts have long since been made to endow the conception of the relative affinity of acids and bases with a measurable degree of exactitude. The most varied methods have been employed for this purpose, and we shall become acquainted with some of them in the following chapter. A wider acquaintance with all these methods must be looked for in works on physical and theoretical chemistry, as the matter cannot yet be considered as fully explained and it comprises much which relates more closely to the province of those physico-chemical phenomena which are of such vital interest at the present time. For my part I think that neither the thermo-chemical investigation of aqueous solutions, nor the changes in volume (see Chap. X., note 27) which take place in the mixing together of solutions of acids and bases, nor the determination of the electro-conductivity of dilute solutions, nor the study of 'distribution,' nor many others of the methods used for determining the measure of the affinity of bases and acids in their solutions, are exempt from the radical defect of neglecting from their consideration the water serving for the solution and having its own chemical reaction on the original and resultant substances. The determination of the so-called 'rate of reaction,' which seems best fitted to give trustworthy results directly related to affinity, is unfortunately not directly applicable to the reaction of acids with bases, as these reactions proceed exceedingly rapidly, although the reaction of alcohols with acids, for instance, proceeds so slowly that the rate can be easily measured. The fact that such acids as HCl , HNO_3 and H_2SO_4 react with far greater rapidity than acetic and formic acids, &c., already shows that the former are more energetic than the latter, but still it seems to me that the measure of 'affinity' cannot in general be identified in this case with the measure of 'time.' Nevertheless the numerous observations made during the nineties, especially in the laboratory of Prof. Ostwald, on these subjects have not only given a vast store of experimental data to science, but also deserve our best attention from a theoretical point of view owing more especially to the fact that the numerical data obtained by various methods are found to be in close agreement. From the following table it is evident that the relations between the so-called molecular electrical conductivity (I) of dilute solutions of different acids coincide with those in which these acids stand as regards distribution (II), and also with the relations existing between their velocities of reaction (III), measured, for example, by the rate of decomposition of methyl acetate (into acid and alcohol) or by the rate of the so-called inversion of cane-sugar, i.e., its transformation into dextrose and levulose; the energy of hydrochloric acid is taken as equal to 100:—

			I.	II.	III.
Hydrochloric acid,	HCl	. .	100	100	100
Hydrobromic acid,	HBr	. .	101	89	105
Nitric acid,	HNO_3	. .	100	100	96
Sulphuric acid,	H_2SO_4	. .	65	49	74
Formic acid,	CH_2O_2	. .	2	4	1
Acetic acid,	$\text{C}_2\text{H}_4\text{O}_2$. .	1	2	1
Oxalic acid,	$\text{C}_2\text{H}_2\text{O}_4$. .	20	24	18
Phosphoric acid,	PH_3O_4	. .	7	—	6

The coincidence of these figures, obtained by so many various methods, indicates a most important and instructive relation between phenomena of different kinds, but in my opinion it does not permit us to assert that the degree of affinity existing between bases and various acids is determined by all these various methods, because the influence of the water must be taken into consideration. On this account, until the theory of solution is more thoroughly worked out, these coincidences (which for the present ought to be treated of in special treatises on chemical mechanics) must be received with great caution.

potash, carbonic acid forms normal salts, soluble in water, but having an alkaline reaction and in many cases themselves acting as alkalies.¹⁵ Only the acid salts of these energetic alkalies, NaHCO_3 and KHCO_3 , have a neutral reaction on litmus, although they, like acids, contain hydrogen, which may be exchanged for metals. The acid salts of such acids as, for instance, sulphuric acid— NaHSO_4 —have a clearly defined acid reaction, and therefore carbonic acid is unable to neutralise the powerful basic properties of such alkalies as potash or soda. Carbonic acid does not even combine at all with feeble bases, such as alumina, Al_2O_3 , so that, if a strong solution of sodium carbonate, Na_2CO_3 , be added to a strong solution of aluminium sulphate, $\text{Al}_2(\text{SO}_4)_3$, instead of aluminium carbonate, $\text{Al}_2(\text{CO}_3)_3$, being formed, carbonic acid separates, for this salt splits up in the presence of water into aluminium hydroxide and carbonic anhydride: $\text{Al}_2(\text{CO}_3)_3 + 3\text{H}_2\text{O} = \text{Al}_2(\text{OH})_6 + 3\text{CO}_2$. Thus feeble bases are unable to retain carbonic acid even at ordinary temperatures. For the same reason, in the case of bases of medium energy, although they form carbonates, the latter are comparatively easily decomposed by heating, as is shown by the decomposition of copper carbonate, CuCO_3 (see Introduction), and even of calcium carbonate, CaCO_3 . Only the normal (not the acid) salts of such powerful bases as potassium and sodium are capable of withstanding a red heat without decomposition. The acid salts—for instance, NaHCO_3 —decompose even on heating their solutions ($2\text{NaHCO}_3 = \text{Na}_2\text{CO}_3 + \text{H}_2\text{O} + \text{CO}_2$), evolving carbonic anhydride. The amount of heat given out by the combination of carbonic acid with bases also shows its feeble acid properties, being considerably less than with energetic acids. Thus if a weak solution of forty grams of sodium hydroxide be saturated (up to the formation of a normal salt) with sulphuric or nitric acid or another powerful acid, from thirteen to fifteen thousand calories are given out, but with carbonic acid the heat evolution is only about ten thousand calories.¹⁶

¹⁵ Thus, for instance, in the washing of fabrics the caustic alkalies, such as sodium hydroxide, in weak solutions, act in removing the fatty matter just in the same way as carbonate solutions, for instance, a solution of soda crystals, Na_2CO_3 . Soap acts in the same way, being composed of feeble acids, either fatty or resinous, combined with alkali. On this account all such substances are applied in manufacturing processes, and answer equally well in practice for bleaching and washing fabrics. Soda crystals or soap are preferred to caustic alkali, because an excess of the latter may have a destructive effect on the fabrics. It may be supposed that in aqueous solutions of soap or soda crystals, part of the base forms caustic alkali; that is to say, the water will compete with the weak acids, and the alkali will be distributed between the latter and the water.

¹⁶ Although carbonic acid is reckoned among the feeble acids, yet there are evidently many others still feebler—for instance, prussic acid, hypochlorous acid, many organic acids, &c. Bases like alumina, or such feeble acids as silica, when in combination with alkalies, are decomposed in aqueous solutions by carbonic acid, but on fusion—that is, without the presence of water—they displace it, clearly showing how much depends,

The majority of carbonates are insoluble in water, and therefore such soluble ones as sodium, potassium, and ammonium carbonates form, in solutions of most other salts, MX or $M''X_2$, insoluble precipitates of the carbonates, M_2CO_3 or $M''CO_3$. Thus, a solution of barium chloride gives with sodium carbonate a precipitate of barium carbonate, $BaCO_3$. For this reason rocks, especially those of aqueous origin, very often contain carbonates; for example, calcium, ferrous, magnesium carbonates, &c.

Carbonic anhydride—which, like water, is formed with the development of a large amount of heat—is very stable. Hence only very few substances are capable of depriving it of its oxygen. However, certain metals, such as magnesium, potassium, and the like, burn in it, depositing carbon and forming oxides. If a mixture of carbonic anhydride and hydrogen be passed through a heated tube, formation of water and carbonic oxide will be observed; $CO_2 + H_2 = CO + H_2O$. But only a portion of the carbonic acid gas undergoes this change, and the result will therefore be a mixture of carbonic anhydride, carbonic oxide, hydrogen, and water, which does not suffer further change under the action of heat.¹⁷ Although, like water, carbonic anhydride is ex-

in phenomena of this kind, upon the conditions of reaction and the properties of the substances formed.

¹⁷ Hydrogen and carbon are near akin as regards affinity towards oxygen, but it must be assumed that the affinity of hydrogen is slightly greater than that of carbon, because during the combustion of hydrocarbons the hydrogen usually burns first. Some idea of this similarity of affinity may be formed by the quantity of heat evolved. Gaseous hydrogen, H_2 , on combining with an atom of oxygen, $O = 16$, develops 69,000 heat-units if the water formed be condensed to a liquid state. If the water remains in the form of a gas (steam), the latent heat of evaporation must be subtracted, and then 58,000 calories will be developed. Carbon, C , as a solid, on combining with $O_2 = 32$, develops about 97,000 calories, forming gaseous CO_2 . If it were gaseous like hydrogen, and only contained C_2 in its molecule, much more heat would be developed, and judging by other substances, whose molecules on passing from the solid to the gaseous state absorb about 10,000 to 15,000 calories, it must be held that gaseous carbon on forming gaseous carbonic anhydride would develop not less than 110,000 calories—that is, approximately twice as much as is developed in the formation of water. And since there is twice as much oxygen in a molecule of carbonic anhydride as in a molecule of water, the oxygen develops approximately the same quantity of heat on combining with hydrogen as with carbon. That is to say, that here we find the same close affinity (see Chap. II., note 7), determined by the quantity of heat, as between hydrogen, zinc, and iron. For this reason here also, as in the case of hydrogen and iron, we ought to expect an equal distribution of oxygen between hydrogen and carbon, if they are both in excess compared with the amount of oxygen; but if there be an excess of carbon, it will decompose water, whilst an excess of hydrogen will decompose carbonic anhydride. P. Sabatier and Senderens (1902) showed that at 350° finely powdered nickel (reduced from the oxide) entirely converts a mixture of carbonic acid gas and hydrogen into methane and water, if the proportion of hydrogen be not less than is required by the equation: $CO_2 + 4H_2 = CH_4 + 2H_2O$. This is another instance in which hydrogen takes up the oxygen from CO_2 , but the affinity of carbon for hydrogen also probably influences the course of the reaction.

ceedingly stable, still on being heated it partially decomposes into carbonic oxide and oxygen. Deville showed that such is the case if carbonic anhydride be passed through a long tube containing pieces of porcelain and heated to 1300° . If the products of decomposition—namely, the carbonic oxide and oxygen—be suddenly cooled, they can, to some extent, be collected separately, although they partly reunite. A similar decomposition of carbonic anhydride into carbonic oxide and oxygen takes place on passing a series of electric sparks through it (for instance, in the eudiometer). Under these conditions an increase of volume occurs, because two volumes of CO_2 give two volumes of CO and one volume of O . The decomposition reaches a certain limit (less than one-third) and does not proceed further, so that the result is a mixture of carbonic anhydride, carbonic oxide, and oxygen, which is not altered in composition by the continued action of the sparks. This is readily understood, as it is a reversible reaction. If the carbonic anhydride be removed, then the residual mixture explodes when a spark is passed and forms carbonic anhydride.^{17a} If from a similar mixture the oxygen (and not the carbonic anhydride) be removed (by means of phosphorus), and a series of sparks be again passed, the decomposition is renewed. In these examples we see that a definite mixture of changeable substances is capable of arriving at a state of stable equilibrium, destroyed, however, by the removal of one of the substances composing the mixture. This is one of the instances of the influence of mass.

Although carbonic anhydride is decomposed on heating, it is nevertheless very stable at ordinary temperatures. Its decomposition, as

^{17a} The degree or relative magnitude of the dissociation of CO_2 varies with the temperature and pressure—that is, it increases with the temperature and as the pressure decreases. Deville found that in the flame of carbonic oxide burning in oxygen at a pressure of 1 atmosphere, about 40 per cent. of the CO_2 is decomposed when the temperature is about 3000° , but less than 1 per cent. at 1500° (Krafts); whilst under a pressure of 10 atmospheres about 34 per cent. is decomposed at 3300° (Mallard and Le Chatelier). It follows therefore that, under very small pressures, the dissociation of CO_2 will be considerable even at comparatively moderate temperatures, but at the temperature of ordinary furnaces (about 1000°) even under the small partial pressure of the carbonic acid, there are only small traces of decomposition which may be neglected in a practical estimation of the combustion of fuels. We may here give the molecular specific heat of CO_2 (i.e. the amount of heat required to raise the temperature of 44 units of weight of CO_2 by 1°), according to the determinations and calculations of Mallard and Le Chatelier. At constant volume the value is $C_v = 6.26 + 0.0037t$, and at constant pressure, $C_p = C_v + 2$ (see Chap. XIV., note 7). So that the specific heat of CO_2 increases rapidly with a rise of temperature: for example, at 0° (for 1 part by weight), it has at a constant pressure the value 0.188; at 1000° , 0.272; at 2000° , about 0.356. The cause of this must be looked for in dissociation. T. M. Cheltzoff, however, upon the basis of his researches upon explosives considers that it must be admitted that a maximum is reached at a certain temperature (about 2500°), beyond which the specific heat begins to fall.

effected by plants, is on this account all the more remarkable ; in this case the whole of the oxygen of the carbonic anhydride is separated in the free state. The mechanism of this change is that the heat and light absorbed by the plants are expended in the decomposition of the carbonic anhydride. This accounts for the enormous influence of temperature and light on the growth of plants. But it is at present not clearly understood how this takes place, or by what separate intermediate reactions the whole process of decomposition of carbonic anhydride in plants into oxygen and the carbohydrates (note 1) remaining in them, takes place. It is known that sulphurous anhydride (in many ways resembling carbonic anhydride) under the action of light (and also of heat) forms sulphur and sulphuric anhydride, SO_3 , and in the presence of water, sulphuric acid. But no similar decomposition has been obtained directly with carbonic anhydride, although it forms an exceedingly easily decomposable higher oxide—percarbonic acid ;¹⁸ and it is perhaps for this reason that the oxygen separates. On the other hand, it is known that plants always form and contain **organic acids**, and these must be regarded as derivatives of carbonic acid, as is shown by all their reactions, of which we shall shortly treat. For this reason it might be thought that the carbonic acid absorbed by the plants first forms (according to Baeyer) formic aldehyde, CH_2O , and from this organic acids, and that these latter in their final transformation yield all the other complex organic substances of plants. Many organic acids are found in plants in considerable quantity ; for instance, tartaric acid, $\text{C}_4\text{H}_6\text{O}_6$, found in grape-juice and in the acid juice of many plants ; malic acid, $\text{C}_4\text{H}_6\text{O}_5$, found not only in unripe apples but in still larger quantities in mountain-ash berries ; citric acid, $\text{C}_6\text{H}_8\text{O}_7$, found in the acid juice of lemons, in gooseberries, cranberries, &c. ; oxalic acid, $\text{C}_2\text{H}_2\text{O}_4$, found in wood-sorrel and

¹⁸ Percarbonic acid, H_2CO_4 ($= \text{H}_2\text{CO}_3 + \text{O}$) is supposed by A. Bach (1893) to be formed from carbonic acid in the action of light upon plants (in the same manner as, according to the above scheme, sulphuric acid is formed from sulphurous) with the formation of carbon, which remains in the form of hydrates of carbon : $3\text{H}_2\text{CO}_3 = 2\text{H}_2\text{CO}_4 + \text{CH}_2\text{O}$. This substance CH_2O expresses the composition of formic aldehyde which, according to Baeyer, by polymerisation and further changes, gives other hydrates of carbon and forms the first product formed in plants from CO_2 . And Berthelot (1872) had already, at the time of the discovery of persulphuric (Chap. XX.) and pernitric (Chap. VI., note 26) acids, pointed out the formation of the unstable percarbonic anhydride, CO_3 . Thus, notwithstanding the hypothetical nature of the above equation, it may be admitted, all the more readily because it explains the comparative abundance of peroxide of hydrogen (Schöne, Chap. IV.) in the air, and this also at the period of the most energetic growth of plants (in July), because percarbonic acid should, like all peroxides, easily give H_2O_2 . Percarbonic acid as such probably cannot exist, but it may be regarded as a compound of H_2O_2 and CO_2 ; its salts apparently do exist as unstable products of the action of H_2O_2 on carbonates, but our knowledge of them is incomplete.

many other plants. Sometimes these acids exist in a free state in the plants, and sometimes in the form of salts; for instance, tartaric acid is met with in grapes as the salt known as cream of tartar, but in the impure state called argol, or tartar, $C_4H_5KO_6$. There is a very clear connection between carbonic anhydride and the above-mentioned organic acids—namely, the latter, under one condition or another, all yield carbonic anhydride, and can all be formed by means of it from substances destitute of acid properties. The following examples afford the best demonstration of this fact; if acetic acid, $C_2H_4O_2$, the acid of vinegar, be passed in the form of vapour through a heated tube, it splits up into carbonic anhydride and marsh gas $= CO_2 + CH_4$. But conversely it can also be obtained from those components into which it decomposes. If one equivalent of hydrogen in marsh gas is replaced (by indirect means) by sodium, the compound CH_3Na is obtained, and this directly absorbs carbonic anhydride, forming a salt of acetic acid, $CH_3Na + CO_2 = C_2H_3NaO_2$. The hydrogen of marsh gas does not, like that in acids, show the property of being directly replaced by metals; i.e., CH_4 does not show any acid character whatever, but on combining with the elements of carbonic anhydride it acquires the properties of an acid. The investigation of all other organic acids shows similarly that their acid character depends on their containing the elements of carbonic anhydride. For this reason there is no organic acid containing less oxygen in its molecule than is present in carbonic anhydride; every organic acid, like carbonic acid, contains in its molecule at least two atoms of oxygen. If the addition of CO_2 raises the basicity, the removal of CO_2 lowers it. Thus from the dibasic oxalic acid, $C_2H_2O_4$, and phthalic acid, $C_8H_6O_4$, by eliminating CO_2 (easily effected experimentally) we obtain monobasic formic acid, CH_2O_2 , and benzoic acid, $C_7H_6O_2$ respectively. This shows that a group, HCO_2 , or **carboxyl**, must be recognised in organic acids. If we take a hydrocarbon compound A, not having the properties of an acid, but containing hydrogen united to carbon, as in the hydrocarbons, then ACO_2 will be a monobasic organic acid, A_2CO_2 a dibasic acid, A_3CO_2 a tribasic acid, and so on. That is, each molecule of CO_2 converts one hydrogen into the form in which it is capable of being replaced by metals, as in acids. The nature of carboxyl is directly explained by the law of substitution. Judging from what has been stated in Chapters VI. and VIII. concerning this law, it is evident that CO_2 is CH_4 with the H_4 exchanged for O_2 , and that the hydrate of carbonic anhydride, H_2CO_3 , is $CO(OH)_2$, that is, methane, in which two parts of hydrogen are replaced by two parts of the water radicle (OH, hydroxyl) and the other two by oxygen. Therefore the group $CO(OH)$, or carboxyl, HCO_2 ,

is a part of carbonic acid, and is equivalent to (OH), and therefore also to H. That is, it is a univalent residue of carbonic acid capable of replacing one atom of hydrogen. Carbonic acid itself is a dibasic acid, both hydrogen atoms in it being replaceable by metals, so that carboxyl, which contains one of the hydrogen atoms of carbonic acid, represents a group in which the hydrogen is exchangeable for metals. And therefore if 1, 2 . . . n atoms of non-metallic hydrogen are exchanged 1, 2 . . . n times for carboxyl, we ought to obtain 1-, 2- . . . n -basic acids. *Organic acids are the products of carboxyl substitution in hydrocarbons.*^{18a} If in the saturated hydrocarbons, C_nH_{2n+2} , one part of hydrogen be replaced by carboxyl, the monobasic saturated (or fatty) acids, $C_nH_{2n+1}(CO_2H)$, will be obtained, as, for instance, formic acid, HCO_2H , acetic acid, CH_3CO_2H , . . . stearic acid, $C_{17}H_{35}CO_2H$, &c. The double substitution will give dibasic acids, $C_nH_{2n}(CO_2H)(CO_2H)$; for instance, in oxalic acid $n = 0$, in malonic acid $n = 1$, and in succinic acid $n = 2$, &c. To benzene, C_6H_6 , correspond benzoic acid, $C_6H_5(CO_2H)$, phthalic acid (and its isomerides), $C_6H_4(CO_2H)_2$, and so on, up to mellitic acid, $C_6(CO_2H)_6$, in all of which the basicity is equal to the number of carboxyl groups. As many isomerides exist in hydrocarbons, it is readily understood not only that such can exist also in organic acids, but that their number and structure may be foreseen. This complex and most interesting branch is treated of separately in organic chemistry.

Carbonic Oxide.—This gas is formed whenever the combustion of

^{18a} If CO_2 is the anhydride of a dibasic acid, and carboxyl corresponds with it, replacing the hydrogen of hydrocarbons, and giving them the character of comparatively feeble acids, then SO_3 is the anhydride of an energetic dibasic acid, and *sulphoxyl*, $SO_2(OH)$, corresponds with it, being capable of replacing the hydrogen of hydrocarbons, and forming comparatively energetic *sulphur oxyacids* (*sulphonic acids*); for instance, $C_6H_5(COOH)$, benzoic acid, and $C_6H_5(SO_2OH)$, benzenesulphonic acid, are derived from C_6H_6 . Just as the exchange of H for methyl, CH_3 , is equivalent to the addition of CH_2 , so the exchange of carboxyl, $COOH$, is equivalent to the addition of CO_2 ; also the replacement of H by sulphoxyl is equivalent to the addition of SO_3 . The latter proceeds directly, for instance: $C_6H_6 + SO_3 = C_6H_5(SO_2OH)$.

As, according to the determinations of Thomsen, the heat of combustion of the *vapours* of acids RCO_2 is known where R is a hydrocarbon, and also the heats of combustion of the hydrocarbons R themselves, it can be shown that the formation of acids, RCO_2 , from $R + CO_2$ is always accompanied by a *small* absorption or development of heat. We give the heats of combustion in thousands of calories, referred to the molecular weights of the substances:—

	R		
	H ₂	CH ₄	C ₂ H ₆
Hydrocarbon	68·4	212	370
Acid RCO_2	69·4	225	387

Benzene, C_6H_6 , gives 777 and benzoic acid, $C_7H_6O_2$, 766 thousands of calories. The data for the latter are taken from Stohmann, and refer to the solid condition.

organic substances takes place in the presence of a large excess of incandescent charcoal; the air first burns the carbon into carbonic anhydride, but this in penetrating through the red-hot charcoal is transformed into carbonic oxide, $\text{CO}_2 + \text{C} = 2\text{CO}$. By this reaction carbonic oxide is prepared by passing carbonic anhydride through charcoal at a red heat. (The reaction does not proceed to the end.) It may be separated from the excess of carbonic anhydride by passing it through a solution of alkali, which does not absorb carbonic oxide. This reduction of carbonic anhydride explains why carbonic oxide is formed in ordinary clear fires, where the incoming air passes over a large surface of heated coal. A blue flame is then observed burning above the coal; this is the burning carbonic oxide. When charcoal is burnt in stacks, when a thick layer of coal is burning in a brazier, and under many similar circumstances, carbonic oxide is also formed. In metallurgical processes, for instance, when iron is smelted from the ore, very often the same process of conversion of carbonic anhydride into carbonic oxide occurs, especially if the combustion of the coal be effected in tall, so-called blast, furnaces and ovens, where the air enters at the lower part and is compelled to pass through a thick layer of incandescent coal. In this way, also, combustion with flame may be obtained from those kinds of fuel which under ordinary conditions burn without flame; for instance, anthracite, coke, charcoal. Heating by means of a **gas-producer**—that is, an apparatus producing combustible carbonic oxide from fuel—is carried on in the same manner.¹⁹ In transforming one part of charcoal into carbonic oxide 2,420 heat units are given out, and on burning to carbonic anhydride 8,080 heat units. It is evident that on transforming the charcoal first into carbonic oxide we obtain a gas which in burning is capable of giving out 5,660 heat units for one part of charcoal. This preparatory transformation of fuel into carbonic oxide, or producer gas containing a mixture of carbonic oxide (about $\frac{1}{3}$ by volume) and nitrogen ($\frac{2}{3}$ volume), in many cases presents most important advantages,

¹⁹ In gas-producers all carbonaceous fuels are transformed into inflammable gas. In those which (on account of their slight density and large amount of water, or combustible admixtures which absorb heat) are not as capable of giving a high temperature in ordinary furnaces—for instance, fir cones, peat, the lower kinds of coal, &c.—the same gas is obtained as with the best kinds of coal, because the water condenses on cooling, and the ashes and earthy matter remain in the gas producer. The construction of a gas-producer is seen from the accompanying drawing. The fuel lies on the fire-bars O, through which and the ash-hole the air enters (drawn by the draught of the chimney of the stove where the gas burns, or else forced by a blowing apparatus), the quantity of air being regulated exactly by means of valves. The gases formed are then led by the pipe V, provided with a valve, into the gas main U. The addition of fuel ought to proceed in such a way as to prevent the generated gas escaping; hence the space A is kept filled with the combustible material and covered with a lid.

as it is easy to completely burn gaseous fuel without an excess of air, which would lower the temperature.²⁰ In stoves where solid fuel is burnt it is impossible to effect the complete combustion of the various kinds of fuel without admitting an excess of air. Gaseous fuel, such as carbonic oxide, is easily completely mixed with air and burnt without excess of it. If, in addition to this, the air and gas required for the combustion be previously heated by means of the heat which would otherwise be uselessly carried off in the products of combustion (smoke)²¹, it is easy to reach a high temperature, so high (about 1800°) that platinum may be melted. Such an arrangement is known as a *regenerator furnace*.²² By means of this process not only may the high temperatures indispensable in many industries be obtained (for instance, glass-working, steel-melting, &c.), but a great advantage is also ²³ gained as regards the quantity of fuel, because the transmission of heat to the

²⁰ An excess of air lowers the temperature of combustion, because it becomes heated itself, as explained in Chap. III. In ordinary furnaces the excess of air is three or four times greater than the quantity required for perfect combustion. In the best furnaces (with fire-bars, regulated air supply, and corresponding chimney draught) it is necessary to introduce $1\frac{1}{2}$ time as much air as is necessary, otherwise the smoke contains much carbonic oxide.

²¹ If in manufactories it is necessary, for instance, to maintain the temperature in a furnace at 1000°, the flame passes out at this or a higher temperature, and therefore much heat is lost in the smoke. For the draught of the chimney a temperature of 100° to 150° is sufficient, and therefore the remaining heat ought to be utilised. For this purpose the flues are carried under boilers or other heating apparatus. The preparatory heating of the air is the best means of utilisation when a high temperature is desired (see note 22).

²² Regenerator furnaces were introduced into many industries by the Brothers Siemens about the year 1860, and mark a most important progress in the use of fuel, especially in obtaining high temperatures. The principle is as follows: The products of combustion from the furnace are led into a chamber, I, and heat up the bricks in it, and then pass into the outlet flue; when the bricks are at a red heat the products of combustion are passed (by altering the valves) into another adjoining chamber, II, and air requisite for the combustion of the generator gases is passed through I. In passing round about the incandescent bricks the air is heated, and the bricks cooled—that is, the heat of the smoke is returned into the furnace. The air is then passed through II, and the smoke through I. The regenerator burners for illuminating gas are based on this same principle; the products of combustion heat the incoming air and gas, the temperature is higher, the light brighter, and an economy of gas is effected.

²³ At first sight it appears absurd, useless, and paradoxical to lose nearly one-third of the heat which fuel can develop, by turning it into gas. In reality, however, the advantage is enormous, especially for producing high temperatures, as is already seen from the fact that fuels rich in oxygen (for instance, wood) when damp are unable, with any kind of hearth whatsoever, to give the temperature required for glass-melting or steel-casting, whilst in the gas-producer they furnish exactly the same gas as the driest and most carbonaceous fuel. In order to understand the principle which is here involved, it is sufficient to remember that a large amount of heat at a low temperature is in many cases of no use whatever. We are unable here to enter into all the details of the complicated matter of the application of fuel, and further particulars must be sought for in special technical treatises.

object to be heated, other conditions being equal, is determined by the difference of temperatures.

The transformation of carbonic anhydride, by means of charcoal, into carbonic oxide ($C + CO_2 = CO + CO$) is considered a reversible reaction, because at a high temperature the carbonic oxide splits up into carbon and carbonic anhydride, as Sainte-Claire Deville showed by using the method of the 'cold and hot tube.' Inside a tube heated in a furnace is fitted another thin metallic (silver copper) tube, through which a constant stream of cold water flows. The carbonic oxide coming into contact with the heated walls of the exterior tube forms charcoal, the minute particles of which settle in the form of lampblack on the lower side of the cold tube, and, since they are cooled, do not act further on the oxygen or carbonic anhydride formed.²⁴

²⁴ The first product of combustion of charcoal is always carbonic anhydride, and not carbonic oxide. This is seen from the fact that with a shallow layer of charcoal (less than a decimetre if the charcoal be closely packed) carbonic oxide is not formed at all. It is not even produced with a deep layer of charcoal if the temperature is not above 500° and the current of air or oxygen is very slow. With a rapid current of air the charcoal becomes red-hot, and the temperature rises, and then carbonic oxide appears (Lang, 1888). Ernst (1891) found that below 995° carbonic oxide is always accompanied by CO_2 , and that the formation of CO_2 begins about 400° . Naumann and Pistor determined that the reaction of carbonic anhydride with carbon commences at about 550° , and that between water and carbon at about 500° . At the

latter temperature carbonic anhydride is formed, and only with a rise of temperature is carbonic oxide formed (Lang) from the action of the carbonic anhydride on the carbon, and also from the reaction $CO_2 + H_2 = CO + H_2O$. Rathke (1881) showed that at no temperature whatever is the reaction as expressed by the equation, $CO_2 + C = 2CO$, complete; a part of the carbonic anhydride remains, and Lang determined that at about 1000° not less than 3 per cent. of the carbonic anhydride remains untransformed into carbonic oxide, even after the action has been continued for several hours. The endothermic reactions, $C + 2H_2O = CO_2 + 2H_2$, and $CO + H_2O = CO_2 + H_2$, are just as incomplete. This is made clear if we note, on the one hand, that the above-mentioned reactions are all *reversible*, and therefore bounded by a limit; and, on the other, that at about 500° oxygen begins to combine with hydrogen and carbon and also that the lower limits of dissociation of water, carbonic anhydride, and carbonic oxide lie near one another between 500° and $1,200^\circ$. For water and carbonic oxide the lower limit of the commencement of dissociation is unknown, but judging from the published data

FIG. 72.—Gas-producer for the formation of carbon monoxide for heating purposes.

A series of electric sparks also decomposes carbonic oxide into carbonic anhydride and carbon, and, if the carbonic anhydride be removed by alkali, complete decomposition may be obtained (Dewille).^{24a} Aqueous vapour, which is so similar to carbonic anhydride in many respects, acts, at a high temperature, on charcoal in an exactly similar way, $C + H_2O = H_2 + CO$. From 2 volumes of carbonic anhydride with charcoal 4 volumes of carbonic oxide (2 molecules) are obtained, and so also from 2 volumes of water vapour with charcoal 4 volumes of a gas consisting of hydrogen and carbonic oxide ($H_2 + CO$) are formed. This mixture of combustible gases is called **water gas**.²⁵ But aqueous vapour (and only when strongly superheated, otherwise it cools the charcoal) only acts on charcoal to form a large amount of carbonic oxide at a very

(according to Le Chatelier, 1888) that of carbonic anhydride may be taken as about 1050° . Even at about 2000° half the carbonic anhydride dissociates if the pressure be small,—about 0.001 atmosphere. At the atmospheric pressure, not more than 0.05 per cent. of the carbonic anhydride decomposes. The reason of the influence of pressure is here evidently that the splitting up of carbonic anhydride into carbonic oxide and oxygen is accompanied by the increase in volume (as in the case of the dissociation of nitric peroxide. See Chap. VI., note 46). As in stoves and lamps, and also with explosive substances, the temperature is not higher than 2000° to 2500° , it is evident that although the partial pressure of carbonic anhydride is small, still its dissociation cannot here be considerable, and probably does not exceed 5 per cent.

^{24a} Besides which, L. Mond (1890) showed that the powder of freshly reduced metallic nickel (obtained by heating the oxide to redness in a stream of hydrogen) is able, when heated even to 350° , to *completely* decompose carbonic oxide into CO_2 and carbon, which remains with the nickel and is easily removed from it by heating in a stream of air. Here $2CO = CO_2 + C$. It should be remarked that heat is evolved in this reaction (note 25), and therefore that the influence of 'contact' may here play a part. Indeed, this reaction must be classed among the most remarkable instances of the influence of contact, especially as metals analogous to Ni (Fe and Co) do not effect this reaction (see Chap. II., note 17).

²⁵ A molecular weight of this gas, or 2 volumes of CO (28 grams), on combustion (forming CO_2) gives out 68,000 heat units (Thomsen 67,960 calories). A molecular weight of hydrogen, H_2 (or 2 volumes), develops on burning into *liquid* water 69,999 heat units (according to Thomsen 68,300), but if it forms aqueous *vapour*, 58,000 heat units. Charcoal, resolving itself by combustion into the molecular quantity of CO_2 (2 volumes), develops 97,000 heat units. From the data furnished by the exothermic reactions it follows: (1) that the oxidation of charcoal into carbonic oxide develops 29,000 heat units; (2) that the reaction $C + CO_2 = 2CO$ *absorbs* 39,000 heat units; (3) $C + H_2O = H_2 + CO$ *absorbs* (if the water be in a state of vapour) 29,000 calories, but if the water be liquid, 40,000 calories (almost as much as $C + CO_2$); (4) $C + H_2O = CO_2 + 2H_2$ *absorbs* (if the water be in a state of vapour) 19,000 heat units; (5) the reaction $CO + H_2O = CO_2 + H_2$ *develops* 10,000 heat units if the water be in the state of vapour; and (6) the decomposition expressed by the equation $2CO = C + CO_2$ (note 24a) is accompanied by the *evolution* of 39,000 units of heat.

Hence it follows that 2 volumes of CO or H_2 burning into CO_2 or H_2O develop almost the same amount of heat, just as also the heat effects corresponding with the equations:

re nearly equal.

high temperature (at which carbonic anhydride dissociates); it begins to react at about 500° , forming carbonic anhydride according to the equation: $C + 2H_2O = CO_2 + 2H_2$. Besides this, carbonic oxide on splitting up forms carbonic anhydride, and therefore water gas always contains a mixture ²⁶ in which hydrogen predominates, the volume of carbonic oxide being comparatively less, whilst the amount of carbonic anhydride increases as the temperature of the reaction decreases (generally it is more than 3 per cent.).

Metals like iron and zinc, which at a red heat are capable of decomposing water with the formation of hydrogen, also decompose carbonic anhydride with the formation of carbonic oxide; thus both the ordinary products of complete combustion, water and carbonic anhydride, are very similar in their reactions. The metallic oxides of the above-mentioned metals, when reduced by charcoal, also give carbonic oxide.

²⁶ **Water gas**, obtained from steam and charcoal at a white heat, contains about 50 per cent. (by volume) of hydrogen, about 40 of carbonic oxide, and about 5 of carbonic anhydride, the remainder being nitrogen from the charcoal and air. Compared with producer gas, which contains much nitrogen, this is a gas much richer in combustible matter, and therefore capable of giving high temperatures, and is for this reason of the greatest utility. If carbonic anhydride could be as readily obtained in as pure a state as water, then CO might be prepared directly from $CO_2 + C$, and in that case the utilisation of the heat of the carbon would be the same as in water gas, because CO evolves as much heat as H_2 , and even more if the temperature of the products formed is over 100° , and the water remains in the form of vapour (note 25). But producer gas contains a large proportion of nitrogen, so that its effective temperature is below that given by water gas; therefore in places where a particularly high temperature is required (for instance for lighting by means of incandescent lime or magnesia, or for melting steel, &c.), and where the gas can be easily distributed through pipes, water gas is at present held in high estimation, but when (in ordinary furnaces, re-heating, glass-melting, and other furnaces) a very high temperature is not required, and there is no need to convey the gas in pipes, producer gas is generally preferred on account of the simplicity of its preparation, especially as for water gas such a high temperature is required that the plant soon becomes damaged.

There are numerous systems for making water gas, but the American patent of T. Lowe is generally used. The gas is prepared in a cylindrical generator, into which hot air is introduced, in order to raise the coke in it to a white heat. The products of combustion containing carbonic oxide are utilised for superheating steam, which is then passed over the white hot coke. Water gas, or a mixture of hydrogen and carbonic oxide, is thus obtained.

Water gas is sometimes called the '*fuel of the future*,' because it is applicable to all purposes, develops a high temperature, and is therefore available, not only for domestic and industrial uses, but also for gas-motors and for lighting. For the latter purpose platinum, lime, magnesia, zirconia, and similar substances (as in the Drummond light (Chap. III.) are rendered incandescent in the flame, or else the gas is **carburetted**—that is, mixed with the vapours of volatile hydrocarbons (generally benzene or naphtha, naphthalene, or simply naphtha gas), which communicate to the pale flame of carbonic oxide and hydrogen a great brilliancy, owing to the high temperature developed by the combustion of the non-luminous gases. In some cases *Dowson gas* is prepared in producers. This is a mixture of water and producer gases obtained by passing steam into an ordinary producer (note 19), when the temperature of the carbon has become sufficiently high for the reaction, $C + H_2O = CO + H_2$.

Priestley obtained it by heating charcoal with zinc oxide. As free carbonic anhydride may be transformed into carbonic oxide, so, in precisely the same way, may that carbonic acid which is in a state of combination; hence, if magnesium or barium carbonate (MgCO_3 or BaCO_3) be heated to redness with charcoal, or iron, or zinc, carbonic oxide will be produced—it is obtained, for instance, by heating an intimate mixture of 9 parts of chalk and 1 part of charcoal in a clay retort, or by passing carbonic acid gas over hot zinc dust: $\text{Zn} + \text{CO}_2 = \text{ZnO} + \text{CO}$.

Many organic substances²⁷ on being heated, or under the action of various reagents, yield carbonic oxide; amongst these are many organic or carboxylic acids, the simplest being formic and oxalic acids. Formic acid, CH_2O_2 , on being heated to 200° , readily decomposes into carbonic oxide and water, $\text{CH}_2\text{O}_2 = \text{CO} + \text{H}_2\text{O}$.^{27a} Usually, however, carbonic oxide is prepared in laboratories, not from formic but from oxalic acid, $\text{C}_2\text{H}_2\text{O}_4$, which is easily obtained by the action of nitric acid on starch, sugar, &c.; it is also found in nature, and is used in the arts. Oxalic acid is easily decomposed by heat; its crystals first lose water, then partly volatilise, but the greater part is decomposed. In this decomposition the acid splits up into water, carbonic oxide, and carbonic anhydride,²⁸ $\text{C}_2\text{H}_2\text{O}_4 = \text{H}_2\text{O} + \text{CO}_2 + \text{CO}$. This decomposition is generally effected practically by mixing oxalic acid with strong sulphuric acid, because the latter assists the decomposition by taking up the water. On heating a mixture of oxalic and sulphuric acids a mixture of carbonic oxide and carbonic anhydride is evolved. This mixture is passed through a solution of an alkali in order to absorb the carbonic anhydride, the carbonic oxide passing on.

In its physical **properties** carbonic oxide resembles nitrogen; this is explained by the equality of their molecular weights. The absence

²⁷ The so-called yellow prussiate of potash, $\text{K}_4\text{FeC}_6\text{N}_6$, on being heated with ten parts of strong sulphuric acid yields a considerable quantity of very pure carbonic oxide quite free from carbonic anhydride. Greshoff (1888) showed that iodoform, CHI_3 , and a solution of nitrate of silver directly give CO *in toto* according to the equation, $\text{CHI}_3 + 3\text{AgNO}_3 + \text{H}_2\text{O} = 3\text{AgI} + 3\text{HNO}_3 + \text{CO}$, and Thiele and Dent obtained CO by the action of a strong solution of caustic potash on chloroform, $\text{CHCl}_3 + 3\text{KHO} = 3\text{KCl} + 2\text{H}_2\text{O} + \text{CO}$.

^{27a} To perform this reaction, the formic acid is mixed with glycerine, because when heated alone it volatilises much below its temperature of decomposition. When heated with sulphuric acid the salts of formic acid yield carbonic oxide.

²⁸ The decomposition of formic and oxalic acids, with the formation of carbonic oxide, considering these acids as carboxyl derivatives, may be explained as follows:—The first is $\text{H}(\text{CO}_2\text{H})$ and the second $(\text{CO}_2\text{H})_2$, or H_2 , in which one or both halves of the hydrogen are exchanged for carboxyl; therefore they are equal to $\text{H}_2 + \text{CO}_2$ and $\text{H}_2 + 2\text{CO}_2$; but H_2 reacts with CO_2 , as has been stated above, forming CO and H_2O . From this it is also evident that oxalic acid on losing CO_2 forms formic acid, and also that the latter may proceed from $\text{CO} + \text{H}_2\text{O}$, as we shall see further on. Citric acid, $\text{C}_6\text{H}_8\text{O}_7$, also gives CO when heated with strong sulphuric acid.

of colour and smell, the low temperature of the absolute boiling-point, -140° (nitrogen, -146°), the property of solidifying at -200° (nitrogen, -202°), the boiling-point of -190° (nitrogen, -203°), and the slight solubility (Chapter I., note 30) of carbonic oxide are almost the same as with nitrogen. The chemical properties of the two gases are, however, very different, and in these carbonic oxide resembles hydrogen. Carbonic oxide burns with a blue flame like hydrogen, and it explodes with oxygen, in the eudiometer.²⁹ When breathed it acts as a strong poison, being absorbed by the blood; ³⁰ this explains the action of charcoal fumes, the products of the incomplete combustion of charcoal and other carbonaceous fuels.

Owing to its power of combining with oxygen, carbonic oxide acts as a powerful **reducing agent**, taking up the oxygen from many compounds at a red heat, and being itself transformed into carbonic anhydride. The reducing action of carbonic oxide, however, is (like that of hydrogen, Chapter II.) naturally confined to those oxides which readily part with their oxygen—as, for instance, copper oxide—whilst the oxides of magnesium or potassium are not reduced. Metallic iron itself is capable of reducing carbonic anhydride to carbonic oxide, just as it liberates the hydrogen from water. Copper, however, which does not decompose water, does not decompose carbonic oxide. If a platinum wire heated to 300° , or spongy platinum at the ordinary temperature,

²⁹ It is remarkable that, according to the investigations of Dixon, perfectly dry carbonic oxide does not explode with oxygen when a spark of low intensity is used, but an explosion takes place if there is the slightest admixture of moisture. L. Meyer, however, showed that sparks of an electric discharge of considerable intensity produce an explosion. I think that this may be explained by the fact that water with carbonic oxide gives carbonic anhydride and hydrogen, but hydrogen with oxygen gives hydrogen peroxide (Chap. VII.), which with carbonic oxide forms carbonic anhydride and water. The water, therefore, is renewed, and again serves the same purpose. But it may be that here it is necessary to acknowledge a simple contact influence. After Dixon had shown the influence of traces of moisture upon the reaction $\text{CO} + \text{O}$, many researches of a similar nature were made. The fullest investigation into the influence of moisture upon the course of many chemical reactions was made by Baker in 1894. He showed that with perfect dryness many chemical transformations (for example, the formation of ozone from oxygen, the decomposition of HgO , KClO_3 under the action of heat, &c.) proceed in exactly the same manner as in the presence of moisture; but that in many cases traces of moisture have an evident influence. We may mention the following instances: (1) Dry SO_3 does not act upon dry CaO or CuO ; (2) perfectly dry sal-ammoniac does not give NH_3 with dry CaO , but simply volatilises; (3) dry NO and O do not react; (4) perfectly dry NH_3 and HCl do not combine; (5) perfectly dry sal-ammoniac does not dissociate at 350° (Chap. VII., note 15a); and (6) perfectly dry chlorine does not act upon metals, &c.

³⁰ Carbonic oxide is very rapid in its action, because it is absorbed by the blood in the same way as oxygen. In addition to this, the absorption spectrum of the blood changes, so that by the help of blood it is easy to detect the slightest traces of carbonic oxide in the air. M. A. Kapoustin found that linseed oil, and therefore oil paints, are capable of giving off carbonic oxide while drying (absorbing oxygen).

be plunged into a mixture of carbonic oxide and oxygen, the mixture explodes like a mixture of $H_2 + O$. These reactions are very similar to those peculiar to hydrogen.^{30a} The following important distinction, however, exists between them—namely: the molecule of hydrogen is composed of H_2 , a group of elements divisible into two like parts, whilst, as the molecule of carbonic oxide, CO , contains unlike atoms of carbon and oxygen, in none of its reactions of combination can it give two molecules of matter containing its elements. This is particularly noticeable in the action of chlorine on hydrogen and on carbonic oxide respectively; with the former chlorine forms hydrogen chloride, and with the latter it produces the so-called carbonyl chloride, $COCl_2$; that is to say, the molecule of hydrogen, H_2 , under the action of chlorine divides, forming two molecules of hydrochloric acid, whilst the molecule of carbonic oxide enters in its entirety into the molecule of carbonyl chloride. This characterises the reactions of so-called **diatomic** or **bivalent** radicles or **residues**. H is a monatomic residue or radicle, like K , Cl , and others, whilst carbonic oxide, CO , is an indivisible (without decomposition) bivalent radicle, equivalent to H_2 and not to H , and therefore combining with X_2 and interchangeable with H_2 . This distinction is evident from the annexed comparison:—

HH , hydrogen.	CO , carbonic oxide.
HCl , hydrochloric acid.	$COCl_2$, carbonyl chloride.
HKO , potash.	$CO(KO)_2$, potassium carbonate.
HNH_2 , ammonia.	$CO(NH_2)_2$, urea.
HCH_3 , methane.	$CO(CH_3)_2$, acetone.
HHO , water.	$CO(HO)_2$, carbonic acid.
H_2O , water.	COO , carbonic acid gas.

Such monatomic (univalent) residues, X , as H , Cl , Na , NO_2 , NH_4 , CH_3 , CO_2H (carboxyl), OH , and others, in accordance with the law of substitution, combine together, forming compounds, XX' ; and with oxygen, or in general with diatomic (bivalent) residues, Y —for instance, O , CO , CH_2 , S , Ca , &c. forming compounds $XX'Y$; but diatomic residues, Y , sometimes capable of existing separately may combine together, forming YY' and with X_2 or XX' , as we see from the transition of CO into CO_2 and $COCl_2$. This combining power of carbonic oxide appears in many of its reactions. Thus it is very easily absorbed by cuprous chloride, $CuCl$, dissolved in fuming hydrochloric acid, forming a crystalline compound, $COCu_2Cl_2 \cdot 2H_2O$, decomposable by

^{30a} Formaldehyde (the aldehyde of formic acid), CH_2O , which is obtained by oxidising methyl alcohol, and readily yields solid polymerides, acts as a powerful reducing agent owing to the fact that it contains the elements $CO + H_2$, just as phosgene contains $CO + Cl_2$.

water; it combines directly with potassium (at 90°), forming $(\text{KCO})_n$,³¹ with platinum dichloride, PtCl_2 , with chlorine, Cl_2 , &c.

But the most remarkable compounds are: (1) the compound of CO with metallic nickel, a colourless volatile liquid, $\text{Ni}(\text{CO})_4$, obtained by L. Mond (and described in Chap. XXII.) and (2) the compounds of carbonic oxide with the alkalis, for instance, with potassium or barium hydroxide, &c.—although it is not directly absorbed by them, as it has no acid properties. Berthelot (1861) showed that potash in the presence of water is capable of absorbing carbonic oxide, but the absorption takes place very gradually, and it is only after being heated for many hours that the whole of the carbonic oxide is absorbed by the potash. The salt CHKO_2 is obtained by this absorption; it corresponds with an acid found in nature—namely, the simplest organic (carboxylic) acid, **formic acid**, CH_2O_2 . It can be extracted from the potassium salt by means of distillation with dilute sulphuric acid, just as nitric acid is prepared from sodium nitrate. This same acid is found in ants and in nettles (when the stings of the nettles puncture the skin they break, and the corrosive formic acid enters into the body); it is also obtained during the action of oxidising agents on many organic substances; it is formed from oxalic acid, and under many conditions splits up into carbonic oxide and water. In the formation of formic acid from carbonic oxide we observe an example of the synthesis of organic compounds, such as are now very numerous, and are treated of in detail in works on organic chemistry. Moissan (1901) accomplished this synthesis by means of CO_2 , as he showed that sodium hydride, NaH (Chap. XII.), directly forms sodium formate, CNaHO_2 with CO_2 .

Formic acid, $\text{H}(\text{CHO}_2)$, carbonic acid, $\text{HO}(\text{CHO}_2)$, and oxalic acid, $(\text{CHO}_2)_2$, are the simplest organic or carboxylic acids, $\text{R}(\text{CHO}_2)$ corresponding with HH and HOH . Commencing with carbonic oxide, CO , the formation of carboxylic acids is clearly seen from the fact that CO is capable of combining with X_2 , that is, of forming COX_2 . If, for instance, one X is an aqueous residue, OH (hydroxyl), and the other X hydrogen, then the simplest organic acid—formic acid, $\text{H}(\text{COOH})$ —is obtained. As all hydrocarbons (Chap. VIII.) correspond with the simplest, CH_4 , so all organic acids may be considered to proceed from formic acid.

In a similar way it is easy to explain the relation to other

³¹ The black mass formed by the combination of carbonic oxide with potassium explodes with great ease, and oxidises in the air. Although Brodie, Lerch, and Joannis (who obtained it in 1893 in a colourless form by means of NH_3K , described in Chap. VI., note 14) have greatly extended our knowledge of this compound, much still remains unexplained. It probably exists in various polymeric and isomeric forms, having the composition $(\text{KCO})_n$.

compounds of carbon of those compounds which contain nitrogen. By way of an example, we will take one of the carboxyl acids, $R(\text{CO}_2\text{H})$, where R is a hydrocarbon radicle (residue). Such an acid, like all others, will give by combination with NH_3 an ammoniacal salt, $R(\text{CO}_2\text{NH}_4)$. This salt contains the elements for the formation of two molecules of water, and under suitable conditions by the action of bodies capable of taking it up, water may in fact be separated from $R(\text{CO}_2\text{NH}_4)$, forming by the loss of one molecule of water, **amides**, $R\text{CONH}_2$,³² and by the loss of two molecules of water, **nitriles**, RCN , otherwise known as **cyanogen compounds** or **cyanides**.³³ If all the carboxyl acids are united not only by many common reactions but also by mutual conversion into each other (an instance of which we saw above in the conversion of oxalic acid into formic and carbonic acids), one would expect the same for all the cyanogen compounds also. The common character of their reactions and the reciprocity of their transformation were long ago observed by Gay-Lussac, who recognised a common group or radicle (residue) cyanogen, CN , in all of them. The simplest compounds are hydrocyanic or prussic acid, HCN , cyanic acid, OHCN , and free cyanogen, $(\text{CN})_2$, which correspond to the three simplest carboxylic acids: formic, HCO_2H , carbonic, $\text{OHC}_2\text{O}_2\text{H}$, and oxalic, $(\text{CO}_2\text{H})_2$. Cyanogen, like carboxyl, is evidently a monatomic residue and of an acid nature, like chlorine.

The reactions and properties of the amides and nitriles of the organic acids are described in detail in books on organic chemistry; we will here only touch upon the simplest of them, and to clearly explain the derivative compounds will first consider the ammoniacal salts and amides of carbonic acid.

As carbonic acid is dibasic, its ammonium salts ought to have the following composition: **acid carbonate of ammonium**, $\text{H}(\text{NH}_4)\text{CO}_3$, and

³² Thus, for instance, *oxamide*, or the amide of oxalic acid, $(\text{CNH}_2\text{O})_2$, is obtained in the form of an insoluble precipitate on adding a solution of ammonia to an alcoholic solution of ethyl oxalate $(\text{CO}_2\text{C}_2\text{H}_5)_2$, which is formed by the action of oxalic acid on alcohol: $(\text{CHO}_2)_2 + 2(\text{C}_2\text{H}_5)\text{OH} = 2\text{HOH} + (\text{CO}_2\text{C}_2\text{H}_5)_2$. As the nearest derivatives of ammonia, the amides treated with alkalis yield ammonia and form the salt of the acid. The nitriles do not, however, give similar reactions so readily. The majority of amides corresponding to acids have a composition RNH_2 , and therefore recombine with water with great ease even when simply boiled with it, and with still greater facility in presence of acids or alkalis. Thus in the majority of cases amides easily pass into ammoniacal salts, but they differ essentially from them. No ammoniacal salt sublimes or volatilises unchanged, and generally when heated it gives off water and yields an amide, whilst many amides volatilise without alteration, and are frequently volatile crystalline substances which may be easily sublimed. Such, for instance, are the amides of benzoic, formic, and many other organic acids.

³³ The connection of the cyanogen compounds with the rest of the hydrocarbons by means of carboxyl was enunciated by me, about the year 1860, at the first Annual Meeting of the Russian Naturalists.

normal carbonate, $(\text{NH}_4)_2\text{CO}_3$; they represent compounds of one or two molecules of ammonia with carbonic acid. The acid salt appears in the form of a non-odoriferous and (when tested with litmus) neutral substance, soluble at the ordinary temperature in six parts of water and insoluble in alcohol. If an aqueous solution of ammonia be saturated with an excess of carbonic anhydride, and then evaporated over sulphuric acid in the bell-jar of an air-pump, crystals of this salt are separated. Solutions of all other ammonium carbonates, when evaporated under the air-pump, yield crystals of this salt. A solution of this salt, even at the ordinary temperature, gives off carbonic anhydride, as do all the acid salts of carbonic acid (for instance, NaHCO_3), and at 38° the separation of carbonic anhydride takes place with great rapidity. *On losing carbonic anhydride* and water, the acid salt is converted into the normal salt: $2(\text{NH}_4)\text{HCO}_3 = \text{H}_2\text{O} + \text{CO}_2 + (\text{NH}_4)_2\text{CO}_3$; the latter, however, decomposes in solution, with *the evolution of ammonia* and formation of the acid salt, and can therefore only be obtained in crystals, $(\text{NH}_4)_2\text{CO}_3 \cdot \text{H}_2\text{O}$, at low temperatures, and from solutions containing an *excess of ammonia*, which is one of the products of dissociation of this salt: $(\text{NH}_4)_2\text{CO}_3 = \text{NH}_3 + (\text{NH}_4)\text{HCO}_3$. But the normal salt,³⁴ according to the general type, is capable of decomposing *with separation of water*, and forming **ammonium carbamate**, $\text{NH}_4\text{O}(\text{CONH}_2) = (\text{NH}_4)_2\text{CO}_3 - \text{H}_2\text{O}$; this still further complicates the chemical transformations of the carbonates of ammonium. It is in fact evident that, by changing the ratios of water, ammonia, and carbonic acid, various intermediate salts will be formed containing mixtures or combinations of those mentioned above. Thus the ordinary commercial **carbonate of ammonia** is obtained by heating a mixture of chalk and either sulphate of ammonia (Chapter VI.) or sal-ammoniac: $2\text{NH}_4\text{Cl} + \text{CaCO}_3 = \text{CaCl}_2 + (\text{NH}_4)_2\text{CO}_3$. The normal salt, however, through loss of part of the ammonia, partly forms the acid salt, and, through loss of water, the carbamate, and most frequently presents the composition $\text{NH}_4\text{O}(\text{CONH}_2) + 2\text{OH}(\text{CO}_2\text{NH}_4) = 4\text{NH}_3 + 3\text{CO}_2 + 2\text{H}_2\text{O}$. This salt, in parting under various conditions with ammonia, carbonic anhydride, and water, does not present a constant composition, and ought rather to be regarded as a mixture of acid salt and amide salt. The latter must be recognised as entering into the composition of the ordinary carbonate of ammonia, because it contains less water than is required for the normal or acid salt;³⁵ but

³⁴ The acid salt, $(\text{NH}_4)\text{HCO}_3$, on losing water ought to form the *carbamic acid* $\text{OH}(\text{CNH}_2\text{O})$; but this is not formed, owing to the instability of the acid salt itself. Carbonic anhydride is given off and ammonia is produced, which gives ammonium carbamate.

³⁵ In the normal salt, $2\text{NH}_3 + \text{CO}_2 + \text{H}_2\text{O}$, in the acid salt, $\text{NH}_3 + \text{CO}_2 + \text{H}_2\text{O}$, in the carbamate, $2\text{NH}_3 + \text{CO}_2$, but in the commercial salt only $2\text{H}_2\text{O}$ to 3CO_2 .

on being dissolved in water this salt gives a mixture of acid and normal salts.

Each of the two ammoniacal salts of carbonic acid has its corresponding amide. That of the acid salt is OHCONH_2 , or **carbamic acid**. This acid is not known in a free state, but its corresponding ammoniacal salt or **ammonium carbamate** is known. The latter is easily and immediately formed by mixing 2 volumes of *dry* ammonia with 1 volume of dry carbonic anhydride, $2\text{NH}_3 + \text{CO}_2 = \text{NH}_4\text{O}(\text{CONH}_2)$; it is a solid substance, smells strongly of ammonia, attracts moisture from the air, and decomposes completely at 60° . The fact of this decomposition may be proved³⁶ by the density of its vapour, which is 13 ($\text{H}=1$); this exactly corresponds with the density of a mixture of 2 volumes of ammonia and 1 volume of carbonic anhydride. It is easily understood that such a combination will take place with any ammonium carbonate under the action of salts which take up the water—for instance, sodium or potassium carbonate³⁷—as in an anhydrous state ammonia and carbonic anhydride only form one compound, $\text{CO}_2, 2\text{NH}_3$.³⁸ As the normal ammonium carbonate contains two ammonias, and as the amides are formed with the separation of water at the expense of the hydrogen of the ammonias, so this salt has its symmetrical amide, $\text{CO}(\text{NH}_2)_2$. This must be termed **carbamide**. It is **identical with urea**, $\text{CN}_2\text{H}_4\text{O}$, which, contained in the urine (about 2 per cent. in human urine), is for the higher animals (especially the carnivora) the ordinary product of excretion³⁹ and oxidation of the nitrogenous substances found in the organism. If ammonium carbamate be heated to 140° (in a sealed tube, Bazaroff), or if carbonyl

³⁶ Naumann determined the following dissociation pressures of the vapour of ammonium carbamate (in millimetres of mercury):—

-10°	0°	$+10^\circ$	20°	30°	40°	50°	60°
5	12	30	62	124	248	470	770

With excess of either NH_3 or CO_2 (Horstmann and Isambert), the mass of the salt formed (in a solid state) increases and the vapour pressure decreases.

³⁷ Calcium chloride enters into double decomposition with ammonium carbamate. Acids (for instance, sulphuric) take up ammonia, and set free carbonic anhydride; whilst alkalies (such as potash) take up carbonic anhydride and set free ammonia, so that in this case only sodium or potassium carbonate can be used for removing water. An aqueous solution of ammonium carbamate does not entirely precipitate a solution of CaCl_2 , probably because calcium carbamate is soluble in water, and all the $(\text{NH}_3)_2\text{CO}_2$ is not converted, on dissolving, into the normal salt, $(\text{NH}_4\text{O})_2\text{CO}_2$.

³⁸ It must be imagined that the reaction takes place at first between equal volumes (Chap. VII.); but then carbamic acid, $\text{HO}(\text{CNH}_2\text{O})$, is produced, which, as an acid, immediately combines with the ammonia, forming $\text{NH}_4\text{O}(\text{CNH}_2\text{O})$.

³⁹ Urea is undoubtedly a product of the oxidation of the complex nitrogenous matters (albumin) of the animal body. It is found in the blood and is absorbed from the blood by the kidneys. A man excretes about 30 grams of urea per day. As a derivative of carbonic anhydride, urea is a product of oxidation just as CO_2 is.

chloride, COCl_2 , be treated with ammonia (Natanson), urea will be obtained, which shows its direct connection with carbonic acid—that is, the presence of carbonic acid and ammonia in it. From this it will be understood how, during the putrefaction of urine, urea is converted into ammonium carbonate: $\text{CN}_2\text{H}_4\text{O} + \text{H}_2\text{O} = \text{CO}_2 + 2\text{NH}_3$.

Thus urea, both by its origin and decomposition, is an amide of carbonic acid. Representing as it does ammonia (two molecules) in which hydrogen (two atoms) is replaced by the bivalent radicle of carbonic acid, urea retains the property of ammonia of entering into combination with acids (thus nitric acid forms $\text{CN}_2\text{H}_4\text{O}, \text{HNO}_3$), with bases (for instance, with mercuric oxide), and with salts (such as sodium chloride, ammonium chloride), but containing an acid residue it has no alkaline properties. It is soluble in water without change, but at a red heat loses ammonia and forms **cyanic acid**, CNHO , which is a nitrile of carbonic acid—that is to say, a cyanogen compound, corresponding to the acid ammonium carbonate, $\text{OH}(\text{CNH}_4\text{O}_2)$, which on parting with $2\text{H}_2\text{O}$ ought to form cyanic acid, CNOH . Liquid cyanic acid, exceedingly unstable at the ordinary temperatures, easily and frequently gives its stable solid polymeride, cyanuric acid, $\text{O}_3\text{H}_3\text{C}_3\text{N}_3$.^{39a} Both have the same composition, and they pass one into another at different temperatures. If crystals of cyanuric acid be heated to a temperature t° , then the vapour pressure, p , in millimetres of mercury (Troost and Hautefeuille) will be :

$t.$	160° ,	170° ,	200° ,	250° ,	300° ,	350°
$p.$	56,	68,	130,	220,	430,	1,200

The vapour contains cyanic acid, and, if it be *rapidly* cooled, it condenses into a mobile volatile liquid (specific gravity at $0^\circ = 1.14$). If the liquid cyanic acid be gradually heated, it passes into a new amorphous polymeride (cyamelide), which, on being heated, like cyanuric acid, forms vapours of cyanic acid. Hence, the above-mentioned figures give the pressure of dissociation of cyanuric acid, or the greatest pressure which the vapours of HOCN are able to attain at a given temperature, whilst at a greater pressure, or by the introduction of a larger mass of the substance into a given volume, the whole of the excess is converted into cyanuric acid. The properties of cyanic acid which we have described were observed principally by Wöhler, and clearly show the *faculty of polymerisation of cyanogen compounds*. This is observed in many other cyanogen derivatives, and is to be regarded as the consequence of the above-mentioned explanation of their nature. All cyanogen compounds are ammonium salts, $\text{R}(\text{CNH}_4\text{O}_2)$, deprived of

^{39a} Cyanic acid is a very unstable, readily changeable liquid, while cyanuric acid is a crystalline solid which is very stable at the ordinary temperature.

water, $2\text{H}_2\text{O}$; therefore the molecules, RCN , ought to possess the faculty of combining with two molecules of water or with other molecules in exchange for it (for instance, with H_2S , or HCl , or 2H_2 , &c.), and are therefore capable of combining together. The combination of molecules of the same kind to form more complex ones is what is meant by polymerisation.⁴⁰

Besides being a substance very prone to form polymerides, cyanic acid presents many other features of interest, expounded in greater detail in works on organic chemistry. However we may mention here the production of the cyanates by the oxidation of the metallic cyanides. Potassium cyanate, KCNO , is most often obtained in this way. Solutions of cyanates by the addition of sulphuric acid yield cyanic acid, which, however, immediately decomposes: $\text{CNHO} + \text{H}_2\text{O} = \text{CO}_2 + \text{NH}_3$. A solution of ammonium cyanate, $\text{CN}(\text{NH}_4)\text{O}$, behaves in the same manner, but only in the cold. On being heated it completely changes, as it is transformed into urea. The composition of the two substances is the same, namely, $\text{CN}_2\text{H}_4\text{O}$, but the structure, or the disposition of, and connection between, the elements, is different: in the ammonium cyanate one atom of nitrogen exists in the form of cyanogen, CN —that is, united with carbon—and the other as ammonium, NH_4 . The composition of this salt is best expressed by supposing one atom of the hydrogen in water to be replaced by ammonium and the other by cyanogen—i.e., that its composition is not symmetrical—whilst in urea both the nitrogen atoms are symmetrically and uniformly disposed as regards the radicle CO of carbonic acid: $\text{CO}(\text{NH}_2)_2$. For this reason, urea is much more stable than ammonium cyanate, and therefore the latter, on being slightly heated in solution, is converted into urea. This remarkable isomeric transformation was discovered by Wöhler in 1828 and formed an epoch in our science, being the first instance of the synthesis of an organic compound.⁴¹ Formamide, HCONH_2 , and **hydrocyanic acid**, HCN , as a nitrile, correspond with formic acid, HCOOH , and therefore ammonium formate, HCOONH_4 , and formamide, when acted on by heat and by substances which take up water

⁴⁰ Just as the aldehydes (such as $\text{C}_2\text{H}_4\text{O}$) are alcohols (like $\text{C}_2\text{H}_6\text{O}$) which have lost hydrogen and are also capable of entering into combination with many substances, and of polymerising, forming slightly volatile polymerides, which depolymerise on heating.

⁴¹ It has an important historical interest, more especially as at that time such an easy preparation of substances occurring in organisms without the aid of organic life was quite unexpected, for they were supposed to be formed under the influence of the forces acting in organisms, and without the latter their formation was considered impossible. And in addition to destroying this illusion, the easy transition of NH_4OCN into $\text{CO}(\text{NH}_2)_2$ is the best example of the passage of one system of equilibrium of atoms into another more stable system.

(phosphoric anhydride), form hydrocyanic acid, HCN, whilst, under many conditions (for instance, on combining with hydrochloric acid in presence of water), this hydrocyanic acid forms formic acid and ammonia. Although containing hydrogen in the presence of two acid-forming elements—namely, carbon and nitrogen⁴²—hydrocyanic acid does not give an acid reaction with litmus (cyanic acid has very marked acid properties); **but it forms salts, MCN**, thus presenting the properties of a feeble acid, and for this reason is called an **acid**. The small amount of energy which it has is shown by the fact that the cyanides of the alkali metals—for instance, potassium cyanide ($\text{KHO} + \text{HCN} = \text{H}_2\text{O} + \text{KCN}$) in solution—have a strongly alkaline reaction.⁴³ If ammonia be passed over charcoal at a red heat, especially in the presence of an alkali, or if gaseous nitrogen be passed through a mixture of charcoal and an alkali (especially potash, KHO), and also if a mixture of nitrogenous organic substances and alkali be heated to a red heat, the alkali metal combines with the carbon and nitrogen, forming a metallic cyanide, MCN—for example, KCN.^{43a} Potassium cyanide is much used in the arts, and is obtained, as above stated, under many circumstances—as, for instance, in iron smelting, especially with the assistance of wood charcoal, the ash of which contains much potash. The nitrogen of the air, the alkali of the ash, and the charcoal are brought into contact at a high temperature during iron smelting, and therefore, under these conditions, a considerable quantity of potassium cyanide

⁴² That ammonia and methane (marsh gas) do not show any acid properties is due to the presence of a large amount of hydrogen in both; but in hydrocyanic acid one atom of hydrogen is under the influence of two acid-forming elements. Acetylene, C_2H_2 , which contains but little hydrogen, presents acid properties in certain respects, for its hydrogen is replaced by metals. Hydrazoic acid, HN_3 , which contains little hydrogen also has the properties of an acid.

⁴³ Solutions of cyanides—for instance, those of potassium and barium—are decomposed by carbonic acid. Even the carbonic anhydride of the air acts in a similar way, and for this reason these solutions do not keep, because, in the first place, free hydrocyanic acid itself decomposes and polymerises, and, in the second place, with alkaline liquids it forms ammonia and formic acid. Hydrocyanic acid does not liberate carbonic anhydride from solutions of sodium or potassium carbonates. But a mixture of solutions of potassium carbonate and hydrocyanic acid yields carbonic anhydride on the addition of oxides like zinc oxide, mercuric oxide, &c. This is due to the great inclination which the cyanides exhibit of forming double salts. For instance, $\text{ZnK}_2(\text{CN})_4$ is formed, which is a soluble double salt.

^{43a} The conversion of the atmospheric nitrogen into cyanogen compounds, although possible, has not yet been carried out on a large scale, and one of the problems for future research should be the discovery of a practical and economical means of converting this nitrogen into metallic cyanides, not only because potassium cyanide has found an extensive and important use for the extraction of gold from even the poorest ores, but more especially because the cyanides furnish the means for effecting the synthesis of many complex carbon compounds, and the nitrogen contained in cyanogen passes easily into other forms of combination such as ammonia, which is of great importance in agriculture.

is formed. In practice it is not usual to prepare potassium cyanide directly, but a peculiar compound of it containing potassium, iron, and cyanogen. This compound is potassium ferrocyanide, and is also known as **yellow prussiate of potash**. This saline substance (see Chap. XXII.) has the composition $K_4FeC_6N_6 + 2H_2O$. The name of cyanogen (*κύανος*) is derived from the property which this yellow prussiate possesses of forming, with a solution of a ferric salt, FeX_3 , the familiar pigment, Prussian blue. The yellow prussiate is manufactured on a large scale, and is generally used as the source of the other cyanogen compounds.

If four parts of yellow prussiate are mixed with eight parts of water and three parts of sulphuric acid, and the mixture heated, it decomposes, volatile hydrocyanic acid separating. This was obtained for the first time by Scheele in 1782, but it was only known to him in solution. In 1809 Ittner prepared anhydrous prussic acid, and in 1815 Gay-Lussac finally settled its properties and showed that it contains only hydrogen, carbon, and nitrogen, CNH . If the distillate (a weak solution of HCN) be redistilled, and the first part collected, the anhydrous acid may be prepared from this stronger solution. In order to do this, pieces of calcium chloride are added to the concentrated solution, when the anhydrous acid floats as a separate layer, because it is not soluble in an aqueous solution of calcium chloride. If this layer be then distilled over a new portion of calcium chloride at the lowest temperature possible, the prussic acid may be obtained completely free from water. It is, however, necessary to use the greatest caution in work of this kind, because prussic acid, besides being extremely poisonous, is exceedingly volatile.⁴⁴ It is formed by the action of a silent electric discharge on a mixture of acetylene and nitrogen: $C_2H_2 + N_2 = 2CNH$.

⁴⁴ The mixture of the vapours of water and hydrocyanic acid, evolved on heating yellow prussiate with sulphuric acid, may be passed directly through vessels or tubes filled with calcium chloride. These tubes must be cooled, because, in the first place, hydrocyanic acid readily changes on being heated, and, in the second place, the calcium chloride, if warm, would absorb less water. The mixture of hydrocyanic acid and aqueous vapour on passing over a long layer of calcium chloride gives up water, and hydrocyanic acid alone remains in the vapour. It ought to be cooled as carefully as possible in order to bring it into a liquid condition. The method which Gay-Lussac employed for obtaining pure hydrocyanic acid consisted in the action of hydrochloric acid gas on mercuric cyanide. The latter may be obtained in a pure state if a solution of yellow prussiate be boiled with a solution of mercuric nitrate and the liquid filtered, and crystallised by cooling; the mercuric cyanide is then obtained in the form of colourless crystals, $Hg(CN)_2$.

In order to obtain hydrocyanic acid in an anhydrous form, the decomposition of heated mercuric cyanide by hydrogen sulphide may be made use of. Here the sulphur and cyanogen change places, and hydrocyanic acid and mercuric sulphide are formed: $Hg(CN)_2 + H_2S = 2HCN + HgS$.

Anhydrous prussic acid is a very mobile and volatile liquid; its specific gravity is 0.697 at 18°; at lower temperatures, especially when mixed with a small quantity of water, it readily solidifies; it boils at 26°. ^{44a} It is soluble in all proportions in water, alcohol, or ether; weak aqueous solutions are used in medicine. ⁴⁵

The salts of potassium, sodium, ammonium, barium, calcium, and mercury are soluble in water, but the cyanides of manganese, zinc, lead, and many other metals are insoluble. They form double salts with potassium cyanide and similar metallic cyanides, an example of which we shall consider in a further description of the yellow prussiate. Not only are some of the double salts remarkable for their constancy and comparative stability, but so also are the soluble salt HgC_2N_2 , the insoluble silver cyanide AgCN , and even potassium cyanide in the absence of water. The last salt, ⁴⁶ when fused, acts as a reducing agent by means of the elements K and C, and oxidises when fused with lead oxide, forming potassium cyanate, KOCN , which establishes the connection between HCN and OHCN —that is, between the nitriles of formic and carbonic acids—and this connection is the same as that between the acids themselves, since formic acid, on oxidation, yields carbonic acid. Free cyanogen, $(\text{CN})_2$ or CNCN , corresponds with hydrocyanic acid in the same manner as free chlorine, Cl_2 or ClCl , corresponds with hydrochloric acid. This composition, judging from what has been already stated, exactly expresses that of the nitrile

^{44a} Weak solutions of peroxide of hydrogen may, it is said, be used as an antidote, because oxamide $(\text{CONOH})_2$ is formed by the action of H_2O_2 on HCN .

⁴⁵ A weak (up to 2 per cent.) aqueous solution of hydrocyanic acid is obtained by the distillation of certain vegetable substances. The so-called laurel water in particular enjoys considerable notoriety from its containing hydrocyanic acid. It is obtained by the steeping and distillation of laurel leaves. A similar kind of water is formed by the infusion and distillation of bitter almonds. It is well known that bitter almonds are poisonous, and have a peculiar bitter taste. This bitter taste is due to the presence of a certain substance called amygdalin, which can be extracted by alcohol. This amygdalin decomposes in an infusion of bruised almonds, forming the so-called bitter-almond oil, glucose, and hydrocyanic acid:

If an aqueous infusion of bitter almonds be distilled with water, the hydrocyanic acid and the volatile bitter almond oil are carried over with the aqueous vapour. The oil is insoluble in water, or only sparingly soluble, while the hydrocyanic acid remains as an aqueous solution. Bitter-almond water and laurel water are used in medicine, naturally only in small quantities, because any considerable amount has poisonous effects. Pure anhydrous hydrocyanic acid keeps without change, just like the weak solutions, but the strong solutions only keep in the presence of other acids. In the presence of many admixtures these solutions easily give a brown polymeric substance, which is also formed in a solution of potassium cyanide.

⁴⁶ This salt will be described in Chap. XIII.

of oxalic acid, and, as a matter of fact, oxalate of ammonia and the amide corresponding with it (oxamide, note 33), on being heated with phosphoric anhydride, which takes up the water, yield **cyanogen**, $(\text{CN})_2$. This substance is also produced by simply heating some of the metallic cyanides. Mercuric cyanide is particularly adapted for this purpose, because it is easily obtained in a pure state, and is then very stable. If mercuric cyanide be heated, it decomposes, in like manner to mercury oxide, into metallic mercury and cyanogen: $\text{HgC}_2\text{N}_2 = \text{Hg} + \text{C}_2\text{N}_2$.⁴⁷ When cyanogen is formed, part of it always polymerises into a dark brown insoluble substance called **paracyanogen**, capable of forming cyanogen when heated to redness.⁴⁸ Cyanogen is a colourless, poisonous gas, with a peculiar smell, and is easily condensed, by cooling, into a colourless liquid, insoluble in water and having a specific gravity of 0.86. It boils at about -21° , and therefore cyanogen may be easily condensed into a liquid by a strong freezing mixture. At -35° liquid cyanogen solidifies. The gas is soluble in water and in alcohol to a considerable extent—namely, 1 volume of water absorbs as much as $4\frac{1}{2}$ volumes, and 1 of alcohol 23 volumes. Cyanogen resists the action of a tolerably high temperature without decomposing, but under the action of the electric spark the carbon is separated, leaving a volume of nitrogen equal to the volume of the gas taken. As it contains carbon it burns, and the colour of the flame is reddish-violet, owing to the presence of nitrogen, all compounds of which impart more or less of this reddish-violet hue to the flame. During the combustion of

⁴⁷ For the preparation it is necessary to take completely dry mercuric cyanide, because when heated in the presence of moisture it gives ammonia, carbonic anhydride, and hydrocyanic acid. Instead of mercuric cyanide, a mixture of perfectly dry yellow prussiate and mercuric chloride may be used, double decomposition and the formation of mercuric cyanide then taking place in the retort. Silver cyanide also disengages cyanogen, on being heated.

⁴⁸ **Paracyanogen** is a brown substance (having the composition of cyanogen) which is formed during the preparation of cyanogen by all methods, and remains as a residue. Silver cyanide, on being slightly heated, fuses, and on being further heated evolves cyanogen, a considerable quantity of paracyanogen remaining in the residue. It is remarkable that here exactly half the cyanogen becomes gaseous, and the other half is transformed into paracyanogen. Metallic silver will be found in the residue with the paracyanogen; it may be extracted with mercury or nitric acid, which does not act on paracyanogen. If paracyanogen is heated in a vacuum it dissociates, forming cyanogen; Troost and Hautefeuille (1868) found the **dissociation pressures** at different temperatures to be—

$t = 530^\circ$	581°	600°	635°
$p = 90$	143	296	1,089 mm.

However, even at 550° , part of the cyanogen decomposes into carbon and nitrogen. The reverse transition of cyanogen into paracyanogen commences at 350° , and at 600° proceeds rapidly. And if the transition of the first kind is likened to evaporation, then the reverse transition, or polymerisation, presents a likeness to the transformation of vapours into the solid state.

cyanogen, carbonic anhydride and nitrogen are formed. The same products are obtained in the eudiometer with oxygen or by the action of cyanogen on many oxides at a red heat.

The relation of cyanogen to the metallic cyanides is seen not only in the fact that it is formed from mercuric cyanide, but also by the formation of cyanide of sodium or potassium when it is heated with either of those metals, the sodium or potassium taking fire in the cyanogen. When a mixture of hydrogen and cyanogen is heated to 500° (Berthelot),⁴⁹ or exposed to the action of the silent discharge (Boillot), hydrocyanic acid is formed, so that the reciprocity of the transitions leaves no doubt that all the nitriles of the organic acids contain cyanogen, just as all the organic acids contain carboxyl and in it the elements of carbonic anhydride. Besides the amides, the nitriles (or cyanogen compounds, RCN), and nitro-compounds (containing the radicle of nitric acid, RNO_2), there are a great number of other substances containing at the same time carbon and nitrogen, particulars of which must be sought for in special works on organic chemistry.

⁴⁹ Cyanogen (like chlorine) is absorbed by a solution of sodium hydroxide, sodium cyanide and cyanate being produced: $\text{C}_2\text{N}_2 + 2\text{NaHO} = \text{NaCN} + \text{CNNaO} + \text{H}_2\text{O}$. But the latter salt decomposes relatively easily, and moreover part of the cyanogen liberated by heat from its compounds undergoes a more complex transformation.

CHAPTER X

SODIUM CHLORIDE—BERTHOLLET'S LAWS—HYDROCHLORIC ACID

IN the preceding chapters we have become acquainted with the most important properties of the four elements, hydrogen, oxygen, nitrogen, and carbon. They are sometimes termed the **organogens**, because they enter into the composition of organic substances. Their mutual combinations may serve as types for all others—that is, they present types (forms) of the combinations in which the other elements also combine together.

Hydrogen,	HH,	or, in general,	HR.
Water,	H ₂ O,	„ „	H ₂ R.
Ammonia,	H ₃ N,	„ „	H ₃ R.
Marsh gas,	H ₄ C,	„ „	H ₄ R.

One, two, three, and four atoms of hydrogen enter into these molecules for one atom of another element. No compounds of one atom of oxygen with three or four atoms of hydrogen are known; hence the atom of oxygen does not possess certain properties which are found in the atoms of carbon and nitrogen.

The power of an element to form a compound of definite composition with hydrogen, as we have already seen, gives the possibility of foretelling the composition of many others of its compounds. Thus, if we know that an element, M, combines with hydrogen, forming only HM, but not forming H₂M, H₃M, &c., then we must conclude, on the basis of the law of substitution, that this element will give compounds M₂O, M₃N, MHO, MH₃C, &c. Chlorine is an example of this kind. If we know that another element, R, like oxygen, gives with hydrogen a molecule H₂R, then we may expect that it will form compounds similar to hydrogen peroxide, the metallic oxides, carbonic anhydride or carbonic oxide, and others. Sulphur is an instance of this kind. Hence the elements may be classified according to their resemblance to hydrogen, oxygen, nitrogen, and carbon, and in conformity with this analogy it is possible to foretell, if not the properties (for example, the

acidity or basicity), at any rate the composition,¹ of many of their compounds. This forms the substance of **the conception of the valency or atomicity of the elements**. Hydrogen is taken as the representative of the univalent elements, giving compounds RH , $R(OH)$, R_2O , RCl , R_3N , R_4C , &c. Oxygen, in that form in which it gives water, is the representative of the bivalent elements, forming RH_2 , RO , RCl_2 , $RHCl$, $R(OH)_2$, R_2C , RCN , &c. In carbon are exemplified the properties of the quadrivalent elements, forming RH_4 , RO_2 , $RO(OH)_2$, $R(OH)_4$, RHN , RCl_4 , $RHCl_3$, &c. We meet with these **forms of combination**, or degrees of union of atoms, in all other elements, some being analogous to hydrogen, others to oxygen,

¹ But it is impossible to foretell all the compounds formed by an element from its atomicity or valency, because the atomicity of the elements is variable. In CO_2 , COX_2 , CH_4 , and the multitude of carbon compounds corresponding with them, the carbon C is quadrivalent, but in CO either the carbon must be taken as bivalent or the atomicity of oxygen be regarded as variable. Moreover, carbon is an example of an element which preserves its atomicity to a greater degree than most of the other elements. Nitrogen in NH_3 , $NH_2(OH)$, N_2O_3 , and even in CNH , must be considered as trivalent, but in NH_4Cl , $NO_2(OH)$, and in all their corresponding compounds it is necessarily pentavalent. In N_2O , if the atomicity of oxygen is 2, nitrogen has an uneven atomicity (1, 3, 5), whilst in NO it is bivalent. If sulphur be bivalent, like oxygen, in many of its compounds (for example, H_2S , SCl_2 , KHS , &c.), then it could not be foreseen from this that it would form SO_2 , SO_3 , SCl_4 , $SOCl_2$, and a series of similar compounds in which its atomicity must be acknowledged as greater than 2. Thus SO_2 , sulphurous anhydride, has many points in common with CO_2 , and if carbon be quadrivalent then the S in SO_2 is quadrivalent. Therefore the principle of atomicity (valency) of the elements cannot be considered established as the basis for the study of the elements, although it gives an easy method of grasping many analogies. I consider the four following as the chief obstacles to acknowledging the atomicity of the elements as a primary conception for the consideration of the properties of the elements: 1. Such univalent elements as H, Cl, &c., appear in a free state as molecules H_2 , Cl_2 , &c., while others, e.g., K, Na, contain only one atom in the molecule in a free state. Hence it follows that *free affinities* may exist. Granting this, nothing prevents the assumption that free affinities exist in all unsaturated compounds; for example, we might consider nitrogen as pentavalent in NH_3 with two free affinities. If such instances of free affinities be admitted, then all the possible advantages to be gained by the application of the doctrine of atomicity (valency) are lost. 2. There are instances—for example, ICl_3 , $KICl_4$ (Chap. IV., note 3), &c.—where univalent elements are combined in molecules which are more complex than R_2 , and form molecules, R_3 , &c.; this necessitates the primary univalent elements being considered as variable in their atomicity. 3. The periodic system of the elements, with which we shall afterwards become acquainted, shows that there is a law or rule for the variation of the forms of oxygen and hydrogen compounds; chlorine is univalent with respect to hydrogen, and septavalent with respect to oxygen; sulphur is bivalent towards hydrogen, and sexavalent as regards oxygen; phosphorus is trivalent to hydrogen and pentavalent in respect to oxygen—the sum is in every case being equal to 8. Hence the power of the elements to change their atomicity is an essential part of their nature, so that constant valency cannot be considered as a fundamental property. 4. Crystallohydrates (for instance, $NaCl \cdot 2H_2O$, or $NaBr \cdot 2H_2O$), double salts (such as $PtCl_4 \cdot 2KCl$, H_2SiF_6 , &c.) and similar complex compounds (and, according to Chap. I., solutions also) demonstrate the capacity not only of the elements themselves, but also of their saturated and limiting compounds, of entering into further combinations.

and others to nitrogen or to carbon. But besides these quantitative analogies or resemblances, there exist among the elements qualitative analogies and relations which are not fully seen in the compounds of the elements which have been considered, but are most distinctly exhibited in the formation of bases, acids, and salts of different types and properties. Therefore, for a complete study of the elements and their compounds it is especially important to become closely acquainted with the salts, as substances of a peculiar character, and with the corresponding acids and bases. Common table salt, or sodium chloride, NaCl , may in every respect be taken as a type of salts in general, and we will therefore pass to the consideration of this substance (and of hydrochloric acid and the base sodium hydroxide corresponding with it) formed by the non-metal chlorine and the metal sodium.

Sodium chloride, NaCl , the familiar table salt, occurs, although in very small quantities, in all the primary formations of the earth's crust,² from which it is washed away by the atmospheric waters; it is contained in small quantities in all flowing waters, and is in this manner conveyed to the oceans and seas. The immense mass of salt in the ocean has been accumulated by this process which has been carried on from the remote ages of the earth's creation, because the water has evaporated from them while the salt has remained in solution. The salt of sea water serves as the source not only for its direct extraction, but also for the formation of other masses of workable salt, such as rock salt, and of saline springs and lakes.^{2a}

The extraction of salt **from sea water** is carried on in several ways. In southern climes, especially on the shores of the Atlantic Ocean and the Mediterranean and Black Seas, the summer heats are taken advantage of. A convenient low-lying sea shore is chosen, and a

² The primary formations are those which do not bear any distinct traces of having been deposited from water (have not a stratified formation and contain no remains of animal or vegetable life), occur under the sedimentary formations of the earth, and are everywhere uniform in composition and structure, the latter being generally distinctly crystalline. If it be assumed that the earth was originally in a molten condition, the first primary formations formed the first solid crust of the earth. It is from the products of decomposition (mostly by atmospheric, aqueous, and organic agencies, &c.), that all the rocks and substances of the earth's surface have arisen. In speaking of the origin of one or another substance, we can only, on the basis of facts, descend to the primary formations, of which granite, gneiss, and trachyte may be taken as examples.

^{2a} Chloride of sodium has been found to occur in the atmosphere in the form of a fine dust; in the lower strata it is present in larger quantities than in the upper, so that the rain water falling on mountains contains less NaCl than that falling in valleys. Müntz (1891) found that a litre of rain water collected on the summit of the Pic du Midi (2,877 metres above the sea level) contained 0.34 milligram of chloride of sodium, while a litre of rain collected from the valley contained 2.5–7.6 milligrams.

whole series of basins, communicating with each other, are constructed along it. The upper of these basins are filled with sea water by pumping, or else advantage is taken of high tides. These basins are sometimes separated from the sea by natural sand-banks (limans) or by artificial means, and in spring the water already begins to evaporate considerably. As the solution becomes more concentrated, it is run into the succeeding basins, and the upper ones are supplied with a fresh quantity of sea water, or else an arrangement is made enabling the salt water to flow gradually through the series of basins. It is evident that the beds of the basins should be as far as possible impervious to water, and for this purpose they are made of beaten clay. Crystals of salt begin to separate out when the concentration attains 28 per cent. of salt (which corresponds to 28° of Baumé's hydrometer). These are raked off, and employed for all those purposes to which table salt is applicable. In the majority of cases only the first half of the sodium chloride which can be separated from the sea water is extracted, because the second half has a bitter taste owing to the presence of magnesium salts which separate out together with the sodium salt. But in certain localities—as, for instance, in the estuary of the Rhone, on the island of Camarga³—the evaporation is carried on to the very end, in order to obtain those magnesium and potassium salts which separate out at the end of the evaporation of sea water. From 100 parts of sea water there separates out (by natural and artificial evaporation) at the very commencement of the operation, about one part of tolerably pure table salt, the total amount held in solution being about $2\frac{1}{2}$ per cent. The remaining portion separates out intermixed with the bitter salts of magnesium, which, owing to their solubility and the small amount in which they are present (less than 1 per cent.), only separate out in traces in the first crystallisations. A certain amount of gypsum, or calcium sulphate, $\text{CaSO}_4, 2\text{H}_2\text{O}$, separates together with or even before the table salt. On still further evaporation (after the separation of NaCl with MgSO_4) the chlorides of potassium and magnesium begin to separate in a state of combination, forming the double salt $\text{KMgCl}_3, 6\text{H}_2\text{O}$, which occurs in nature as **carnallite**.⁴ After the separation of this salt from sea water, there

³ The extraction of the potassium salts (or so-called summer salts) was carried on at the isle of Camarga (at the mouth of the Rhone) about 1870, when I had occasion to visit that spot. At the present time the deposits of Stassfurt provide a much cheaper salt, owing to the evaporation and separation of the salt being carried on there by natural means and requiring only such treatment and refining as are also necessary for the 'summer salt' obtained from sea water. The Stassfurt deposits present a most wonderful instance of industrial activity.

⁴ The double salt $\text{KCl}, \text{MgCl}_2$ is a crystallohydrate of KCl and MgCl_2 , and is only

remains a mother liquor containing a large amount of magnesium chloride in admixture with various other salts.⁵ The extraction of sea salt is usually carried on for the purpose of procuring table salt, and therefore directly it begins to separate mixed with a considerable proportion ⁶ of magnesium salts the remaining liquor is run back into the sea.

The same process as is employed for artificially obtaining salt in a crystalline form from sea water has been repeatedly accomplished on a gigantic scale during the geological evolution of the earth; upheavals of the earth have cut off portions of the sea from the remainder (the Dead Sea being formerly a part of the Mediterranean, and the Sea of Aral of the Caspian), and their water has evaporated and formed (if the mass of the inflowing fresh water were less than that of the mass evaporated) deposits of **rock salt**. It is always accompanied by gypsum, because the latter is separated from sea water with or before the sodium chloride. For this reason rock salt may always be looked for in those localities where there are deposits of gypsum. But inasmuch as the gypsum remains on the spot where it has been deposited (as it is a sparingly soluble salt), whilst the rock salt (as one which is very soluble) may be washed away by rain or fresh running water, it may sometimes happen that although gypsum is still found there may be no salt; but, on the other hand, where there is rock salt there will always be gypsum. As the geological changes of the earth's surface are still proceeding at the present day, so in the midst of the dry land salt lakes are met with, which are sometimes scattered over vast districts formerly covered by seas now dried up. Such is the

formed from solutions containing an excess of magnesium chloride, because water decomposes this double salt, extracting the more soluble magnesium chloride from it. Van't Hoff studied all the conditions (temperatures), indicating the relative amounts of KCl, MgCl₂, and H₂O, which lead to the formation of carnallite.

⁵ Owing to the fundamental property of salts of interchanging their metals, it cannot be said that sea water contains this or that salt, but only that it contains definite amounts of certain metals M (univalent like Na and K, and bivalent like Mg and Ca), and haloids X (univalent like Cl, Br, and bivalent like SO₄, CO₃), which are disposed in every possible kind of grouping; for instance, K as KCl, KBr, K₂SO₄, Mg as MgCl₂, MgBr₂, MgSO₄, and so on for all the other metals. On evaporation different salts separate out consecutively only as they reach saturation. A proof of this may be seen in the fact that a solution of a mixture of sodium chloride and magnesium sulphate (both of which salts are obtained from sea water, as was mentioned above), when evaporated, deposits crystals of these salts, but when refrigerated (if the solution be sufficiently saturated) the salt Na₂SO₄·10H₂O is first deposited because it is the first to arrive at saturation at low temperatures. Consequently this solution contains MgCl₂ and Na₂SO₄, besides MgSO₄ and NaCl. So it is with sea water.

⁶ The salt extracted from water is piled up in heaps and left exposed to the action of rain water, which purifies it, as the water becomes saturated with sodium chloride and then no longer dissolves it, but washes out the impurities.

origin of the salt deposited in the Karabuga Bay of the Caspian Sea, and of many of the salt lakes about the lower portions of the Volga and in the Kirghiz steppes, where at a geological epoch preceding the present the Aralo-Caspian Sea extended. Such are the Baskunchaksky (in the Government of Astrakhan, 112 square kilometres superficial area), the Eltonsky (140 versts from the left bank of the Volga, and 200 square kilometres in superficial area), and upwards of 700 other salt lakes lying about the lower portions of the Volga. In those in which the annual inflow of fresh water is less than that evaporated yearly, and in which the concentration of the solution has reached saturation, the **self-deposited** salt is found already deposited on their beds, or is being yearly deposited during the summer months. Certain limans, or seaside lakes, of the Azoff Sea are essentially of the same character—as, for instance, those in the neighbourhood of Henichesk and Berdiansk. The saline soils of certain Central Asian steppes, which suffer from a want of atmospheric fresh water, have a similar origin. Their salt originally proceeded from seas previously covering these localities, and has not yet been washed away by fresh water. The main result of the above-described process of nature is the formation of masses of rock salt, which are, however, being gradually washed away by the subsoil waters flowing in their neighbourhood, and afterwards rising to the surface in certain places as **saline springs**, which indicate the presence of masses of deposited **rock salt** in the depths of the earth. If the subsoil water flows along a stratum of salt for a sufficient length of time it becomes saturated; but in flowing, in its further course, along an impervious stratum (clay) it becomes diluted by the fresh water leaking through the upper soil, and therefore the greater the distance of a saline spring from the deposit of rock salt, the poorer will it be in salt. A perfectly saturated brine, however, may be procured from the depths of the earth by means of bore-holes. The deposits of rock salt themselves, which are sometimes hidden at great depths below the earth's strata, may be discovered by the guidance of bore-holes and of the direction of the strata of the district. Deposits of rock salt, about 35 metres thick and 20 metres below the surface, were discovered in this manner in the neighbourhood of Brianstcheffky and Dekonoffky, in the Bakhmut district of the Government of Ekaterinoslav. Large quantities of most excellent rock salt are now (since 1880) obtained from these deposits, the presence of which was indicated by the neighbouring salt springs (near Slaviansk and Bakhmut) and by bore-holes which had been sunk in these localities for procuring strong (saturated) brines. The Stassfurt deposits of rock salt near Magdeburg in Germany are celebrated for their many remarkable

peculiarities.⁷ The plentiful distribution of saline springs in this and the neighbouring districts suggested the presence of deposits of rock salt in the vicinity. Deep bore-holes sunk in this locality did in fact give a richer brine—even quite saturated with salt. On sinking to a still greater depth, the deposits of salt themselves were at last arrived at. But the first deposit which was met with consisted of a bitter salt unfit for consumption, and was therefore called refuse salt (*Abraumsalz*). On sinking still deeper vast beds of real rock salt were struck. In this instance the presence of these upper strata containing salts of potassium, magnesium, and sodium is an excellent proof of the formation of rock salt from sea water. It is very evident that not only a case of evaporation to the end—as far, for instance, as the separation of carnallite—but also the preservation of such soluble salts as separate out from sea water after the sodium chloride, must be a very exceptional phenomenon, which is not repeated in all deposits of rock salt. The Stassfurt deposits form a rich source of potassium salts which have many practical uses.^{7a}

A saturated brine, formed by the continued contact of subsoil water with rock salt, is extracted by means of bore-holes, as, for instance, in the Governments of Perm, Kharkoff, and Ekaterinoslav. Sometimes, as at Berchtesgaden (and at Hallein) in Austria, spring water is run on to underground beds of rock salt containing much clay.

If a saline spring, or the salt water pumped from bore-holes, contains but little salt, then the first concentration of the natural solution is not carried on by the costly consumption of fuel, but by the cheaper method of evaporation by means of the wind. For this purpose

⁷ When the German savants pointed out the exact locality of the Stassfurt salt-beds and their depth below the surface, on the basis of information collected from various quarters respecting bore-holes and the direction of the strata, and when the borings, conducted by the Government, struck a salt-bed which was bitter and unfit for use, there was a great outcry against science, and the doubtful result even caused the cessation of the further work of deepening the shafts. It required a great effort to persuade the Government to continue the work. Now, when the pure salt encountered below forms one of the important riches of Germany, and when those 'refuse salts' have proved to be most valuable (as a source of potassium and magnesium), we should see in the utilisation of the Stassfurt deposits one of the conquests of science for the common welfare.

^{7a} In Western Europe, deposits of rock salt have long been known at Wieliczka, near Cracow, and at Cardona in Spain. In Russia the following deposits are known: (a) the vast masses of rock salt (3 square kilometres area and up to 140 metres thick) lying directly on the surface of the earth at Iletzky Zastchit, on the left bank of the river Ural, in the Government of Orenburg; (b) the Chingaksky deposit, 90 versts from the river Volga, in the Enotaeffsky district of the Government of Astrakhan; (c) the Kulepinsky deposits (whose thickness attains 150 metres), on the Araks, in the Government of Erivan in the Caucasus; (d) the Katchiezmansky deposit in the province of Kars; (e) the Krasnovodsky deposit in the Trans-Caspian province.

so-called *graduators* are constructed; these consist of long sheds, which are sometimes several versts long, and extend in a direction at right angles to that of the usual course of the wind in the district. The sheds are open at the sides, and are filled with brushwood, as shown in fig. 73. Troughs, AB, CD, into which the salt water is pumped, run along the top. On flowing through the openings, *a*, the water spreads over the brushwood and presents a very large surface for evaporation, in conse-

FIG. 73.—Graduator for the evaporation of the water of saline springs.

quence of which it rapidly becomes concentrated in warm or windy weather. After trickling over the brushwood, the solution is pumped up by the pumps *P P'*, and run a second and a third time through the graduator, until it reaches a concentration of 12 to 15 parts of salt in 100 parts of solution. Strong natural solutions of salt, and also the graduated solutions, are evaporated in large shallow metallic vessels, which are either heated by the direct action of the flame from below or from above. These vessels are made of boiler plate, and are called

salt-pans. The first portions of the salt crystallising out in the salt-pans are invariably contaminated with gypsum, but the portions separating later are distinguished by their purity. Since it has become possible to discover the saline deposits themselves, the extraction of table salt from saline springs has fallen somewhat into disuse, and is only able to hold its ground in places where fuel is cheap.

On the average, 20 lb. of table salt are consumed yearly per head of population, either directly in food or for cattle. In those countries where common salt is employed in technical processes, and especially in England, almost an equal quantity is consumed in the production of substances containing chlorine and sodium, and especially in the manufacture of washing soda, &c., and of chlorine compounds (bleaching powder and hydrochloric acid). The yearly production of salt on the globe amounts to ten million tons.

Although certain lumps of rock salt and crystals of bay salt sometimes consist of almost pure sodium chloride, yet the ordinary commercial salt contains various impurities, the most common of which are magnesium salts. If the salt is pure, its solution gives no precipitate with sodium carbonate, Na_2CO_3 , showing the absence of magnesium salts, because magnesium carbonate, MgCO_3 , is insoluble in water.⁸ For ordinary use the bulk of the salt obtained can be employed directly without further purification; but some salts are purified by solution and crystallisation of the solution after standing, in which case the evaporation is not carried on to dryness, and the impurities remain in the *mother liquor* or in the sediment. When perfectly pure salt is required for chemical purposes it is best obtained as follows: A saturated solution of table salt is prepared, and hydrochloric acid gas is passed through it; this precipitates the sodium chloride (which is not soluble in a strong solution of hydrochloric acid), whilst the impurities remain in solution. By repeating the operation and fusing the salt (when adhering hydrochloric acid is volatilised) a pure salt is obtained, which is again crystallised from its solution by evaporation.⁹

Pure sodium chloride, in well-defined crystals (slowly deposited at the bottom of the liquid), is a colourless and transparent substance

⁸ The fracture of rock salt generally shows the presence of interlayers of impurities which are sometimes very small in weight, but visible owing to their different refraction. In the excellently laid-out salt mines of Briansk I counted (1888) on an average ten interlayers per metre of thickness, and between these the salt was in general very pure, and in places quite transparent. If this be the case, then for the whole thickness (about 35 metres) of the bed there would be 350 interlayers. These probably correspond with the yearly deposition of the salt. In this case the deposition would have extended over more than 300 years.

⁹ My own investigations have shown that not only the sulphates, but also the potassium salts, are entirely removed by this method.

resembling glass, but brittle and fragile.¹⁰ Common salt always crystallises in the cubic system, most frequently in **cubes**, and more rarely in octahedra. Large transparent cubes having edges up to 10 centimetres long are sometimes found in masses of rock salt.¹¹ When evaporated in the open the salt often separates out on the surface¹² as cubes, which grow on to each other in the form of square pyramidal funnels. In still weather, these clusters are able to support themselves on the surface of the water for a long time, and sometimes go on increasing to a considerable extent, but they sink directly the water penetrates to their interior. Salt fuses to a colourless liquid (sp. gr. 1.602, according to Quincke) at 851° (V. Meyer); if pure it solidifies to a non-crystalline mass, and if impure to an opaque mass having a rough surface. In fusing, sodium chloride commences to volatilise (its weight decreases) and at a white heat it vaporises completely and with great ease, but at the ordinary temperature it may, like all ordinary salts, be considered as non-volatile, although as yet no exact experiments have been made in this direction.

¹⁰ According to the determinations of Klodt, the Briansk rock salt withstands a pressure of 340 kilograms per square centimetre, whilst glass withstands 1,700 kilos. In this respect salt is twice as secure as bricks, and therefore immense masses may be extracted from underground workings with perfect safety, without having recourse to brickwork supports, merely taking advantage of the properties of the salt itself.

¹¹ To obtain well-formed crystals, a saturated solution is mixed with ferric chloride, several small crystals of sodium chloride being placed at the bottom, and the solution then allowed to evaporate slowly in a vessel with a loose-fitting cover. Octahedral crystals are obtained by the addition of borax, urea, &c. to the solution. Very fine crystals are formed in a mass of gelatinous silica.

¹² If a solution of sodium chloride be slowly heated from above, where the evaporation takes place, then the upper layer will become saturated before the lower and cooler layers, and therefore crystallisation will begin on the surface, and the crystals first formed will float—having also dried from above—on the surface until they become quite soaked. Being heavier than the solution the crystals are partially immersed in it, and the following crystallisation, also proceeding on the surface, will only form crystals by the side of the original crystals. A funnel is formed in this manner. It will be borne on the surface like a boat (if the liquid be quiescent), because it will grow more from the upper edges. We can thus understand this, at first sight, strange funnel form of crystallised salt. To explain why the crystallisation under the above conditions begins at the surface and not at the lower layers, it must be mentioned that the specific gravity of a crystal of sodium chloride is 2.16, and that a solution saturated at 25° contains 26.7 per cent. of salt and has a sp. gr. 1.2004 at 25°/4°; at 15° a saturated solution contains 26.5 per cent. of salt and has a sp. gr. 1.203 at 15°/4°. Hence a solution saturated at a higher temperature is specifically lighter, notwithstanding the greater amount of salt it contains. With many substances *surface crystallisation* cannot take place, because their solubility increases more rapidly with the temperature than their specific gravity decreases. In this case the saturated solution will always be in the lower layers, where also the crystallisation will take place. Besides which it may be added that as a consequence of the properties of water and solutions, when they are heated from above (for instance, by the sun's rays) the warmer layers, being the lightest, remain above, whilst when heated from below they rise to the top.

A saturated ¹³ solution of table salt (containing 26·4 per cent.) has at the ordinary temperature a specific gravity of about 1·2. The specific gravity of the crystals is 2·167 (17°). The salt which separates out at the ordinary and higher temperatures contains no water of crystallisation; ¹⁴ but if the crystals are formed at a low temperature, especially from a saturated solution cooled to -12° , they then present a prismatic form, and contain two equivalents of water, $\text{NaCl}\cdot 2\text{H}_2\text{O}$. At the ordinary temperature these crystals split up into sodium chloride and its solution.¹⁵ Unsaturated solutions of table salt when cooled below 0° give ¹⁶ crystals of ice, but when the solution has a com-

¹³ By combining the results of Poggiale, Müller, and Karsten, we find that a saturated solution at t° , from 0° to 108° , contains $35\cdot7 + 0\cdot024t + 0\cdot0002t^2$ grams of salt per 100 grams of water. But I think that at low temperatures (for instance, -15°) the solubility will be different, because $\text{NaCl}\cdot 2\text{H}_2\text{O}$ is then formed. Perfect confidence cannot be placed in the figures.

¹⁴ Perfectly pure *fused* salt is not hygroscopic, according to Karsten, whilst the crystallised salt, even when quite pure, attracts as much as 0·6 per cent. of water from moist air, according to Stas.

If the salt contains impurities—such as magnesium sulphate, &c.—it is more hygroscopic. If it contains any magnesium chloride, it partially deliquesces in a damp atmosphere. The crystallised and not perfectly pure salt decrepitates when heated, owing to its containing water. The pure salt, and also the transparent rock salt, or that which has been once fused, does not decrepitate. Fused sodium chloride shows a faint alkaline reaction to litmus, which has been noticed by many observers, and is due to the presence of sodium oxide (probably formed by the action of the oxygen of the atmosphere). According to A. Stcherbakoff very sensitive litmus (washed in alcohol and neutralised with oxalic acid) shows a faint alkaline reaction even with the crystallised salt.

From the fact that the action of Na upon molten NaCl gives a blue coloration, and apparently leads to the formation of a lower state of combination, Na_2Cl , which dissolves in water giving NaHO, it may be gathered that the native salt also contains traces of this compound, particularly as pieces of rock salt of a blue tint are sometimes met with.

It may be observed that rock salt sometimes contains cavities filled with a colourless liquid. Certain kinds of rock salt emit an odour like that of hydrocarbons. These phenomena have as yet received very little attention.

¹⁵ By cooling a solution of table salt saturated at the ordinary temperature to -15° , I obtained, first of all, well-formed tabular (six-sided) crystals, which when warmed to the ordinary temperature disintegrated (with the separation of anhydrous sodium chloride), and later prismatic needles up to 20 mm. long were formed from the same solution. I have not yet investigated the reason of the difference in crystalline form.

¹⁶ Notwithstanding the great simplicity (Chap. I., note 49) of the observations on the formation of ice from solution, still, even for sodium chloride they cannot yet be considered as sufficiently harmonious. According to Blagden and Raoult, the temperature of the formation of ice from a solution containing c grams of salt per 100 grams of water is $-0\cdot6c^{\circ}$ to $c=10$; according to Rosetti, $-0\cdot649c^{\circ}$ to $c=8\cdot7$; according to De Coppet (to $c=10$), $-0\cdot55c - 0\cdot006c^2$, and according to Karsten (to $c=10$) $-0\cdot762c + 0\cdot0084c^2$, whilst Guthrie gives a much lower figure.

The data for strong solutions are not less contradictory. Thus with 20 per cent. of salt, ice is formed at $-14\cdot4^{\circ}$ according to Karsten, at -17° according to Guthrie, and at

position of nearly $\text{NaCl}, 10\text{H}_2\text{O}$ it solidifies completely at a temperature of about -23° . A solution of table salt saturated at its boiling-point boils at about 109° , and contains about 42 parts of salt per 100 parts of water.

Of all their physical properties the specific gravity of solutions of sodium chloride is the one which has been the most fully investigated. A comparison of all the existing determinations of the specific gravity, S , of solutions of NaCl ¹⁷ at 15° (*in vacuo*, taking water at 4° as 10,000), with regard to the percentage amount, p , of the salt in solution shows that it is expressed with sufficient accuracy by the equation: $S_{15} = 9991.6 + 71.17p + 0.2140p^2$. For instance, for a solution of the composition $200\text{H}_2\text{O} + \text{NaCl}$, $p = 1.6$, and $S_{15} = 1.0106$. It is seen from the formula that the addition of water produces a contraction.¹⁸ The specific gravity ¹⁹ at certain temperatures and concentrations *in vacuo* referred to that of water at 4° as 10,000 ²⁰ is as follows:

	0°	15°	30°	100°
$p = 5$	10372	10353	10307	9922
10	10768	10728	10669	10278
15	11164	11107	11043	10652
20	11568	11501	11429	11043

It should be remarked that Baumé's hydrometer is graduated by taking a 10 per cent. solution of sodium chloride as 10° on the scale, and therefore gives approximately the percentage amount of the salt in

-17.6° according to De Coppet. Rüdorff states that for strong solutions the temperature of the formation of ice falls in proportion to the content of the compound, $\text{NaCl}, 2\text{H}_2\text{O}$ (per 100 grams of water) by 0.342° per 1 gram of salt, while De Coppet shows that there is no proportionality, in a strict sense, for either a percentage of NaCl or of $\text{NaCl}, 2\text{H}_2\text{O}$.

¹⁷ A collection of observations on the specific gravity of solutions of sodium chloride is given in my work cited in Chapter I., note 50.

¹⁸ If S_0 be the specific gravity of water, and S the specific gravity of a solution containing p per cent. of salt, then by mixing equal weights of water and the solution, we shall obtain a solution containing $\frac{1}{2}p$ of the salt, and if it be formed without contraction, then its specific gravity x will be determined by the equation: $\frac{2}{x} = \frac{1}{S_0} + \frac{1}{S}$, because the volume is equal to the weight divided by the density. In reality, the specific gravity is always found to be greater than that calculated on the supposition of an absence of contraction.

¹⁹ If the specific gravity is observed by weighing in air without making corrections for the expansion of the vessel, &c., a different result is naturally obtained. This must not be lost sight of in very exact researches.

²⁰ If the sp. gr. S_2 be found directly by dividing the weight of a solution by the weight of water at the same temperature and in the same volume, then the true sp. gr. S referred to water at 4° is found by multiplying S_2 by the sp. gr. of water at the temperature of observation.

a solution. Common salt is somewhat soluble in alcohol,²¹ but it is insoluble in ether or oils.

Common salt gives very few compounds²² or double salts; it is also decomposed with great difficulty and its dissociation is unknown.²³ But it is easily decomposed, both when fused and in solution, by the action of a galvanic current. If the dry salt is fused in a crucible and an electric current passed through it by immersing carbon or platinum electrodes in it (the positive electrode is made of carbon and the negative of platinum or mercury), it is **decomposed**, the suffocating gas, chlorine, being liberated at the positive pole and metallic sodium at the negative. Both of these act on water at the moment of their evolution; the sodium evolves hydrogen and forms caustic soda, and the chlorine may yield oxygen and form hydrochloric acid, so that on passing a current through a solution of common salt oxygen, chlorine, and hydrochloric acid will appear at the positive pole (anode), and hydrogen and caustic soda at the negative pole.^{23a} Thus salt, like other salts, is decomposed by the action of an electric current into its ions, a metal and a haloid (Chap. III.).

With respect to the double decompositions of sodium chloride it should be observed that they are most varied, and serve as the means for obtaining nearly all the other compounds of sodium and chlorine. **The double decompositions of sodium chloride** are almost exclusively based on the possibility of the metal sodium being exchanged for hydrogen and other metals. But neither hydrogen nor any other metal can directly displace the sodium from sodium chloride, and the replacement of the sodium in sodium chloride by hydrogen and various

²¹ According to Schiff, 100 grams of alcohol, containing p per cent. by weight of C_2H_5O , dissolves at 15° —

$p = 10$	20	40	60	80
28.5	22.6	13.2	5.9	1.2 gram NaCl

²² Amongst the double salts formed by sodium chloride, that obtained by Ditte (1870) by the evaporation of the solution remaining after heating sodium iodate with hydrochloric acid until chlorine ceases to be liberated, is a remarkable one. Its composition is $NaIO_3, NaCl, 14H_2O$. Rammelsberg obtained a similar (perhaps the same) salt in well-formed crystals by the direct interaction of the two salts.

²³ In the flame of a Bunsen's burner (see Chap. XIII.), $NaCl$ gives sodium, doubtless under the reducing action of the elements carbon and hydrogen. In the presence of an excess of hydrochloric acid in the flame (when the sodium would form sodium chloride), no sodium is formed in the flame and the salt does not communicate its usual coloration.

^{23a} There is no doubt, however, but that chloride of sodium is also decomposed in its aqueous solutions with the separation of sodium, and that it does not simply enter into double decomposition with the water ($NaCl + H_2O = NaHO + HCl$). This is seen from the fact that when a saturated solution of $NaCl$ is rapidly decomposed by an electric current, a large amount of chlorine appears at the anode and a sodium amalgam forms at the mercury cathode, which acts but slowly upon the strong solution of salt. Salt is now converted into chlorine and caustic soda on an industrial scale by this method.

metals can only take place by the transference of the sodium into some other combination. If hydrogen or a metal, M, be combined with an element X, then the double decomposition, $\text{NaCl} + \text{MX} = \text{NaX} + \text{MCl}$ takes place. Such double decompositions take place under special conditions, sometimes completely and sometimes only partially, as we shall endeavour to explain. In order to acquaint ourselves with the double decompositions of sodium chloride, we shall follow the methods employed in practice to procure compounds of sodium and of chlorine from common salt. For this purpose we shall first describe the treatment of sodium chloride with sulphuric acid for the preparation of hydrochloric acid and sodium sulphate. We shall then describe the substances obtained from hydrochloric acid and sodium sulphate. Chlorine itself, and nearly all the compounds of this element, may be procured from hydrochloric acid, whilst sodium carbonate, caustic soda, metallic sodium itself, and all its compounds may be obtained from sodium sulphate.

Even in the animal organism salt undergoes similar changes, furnishing the sodium, alkali, and hydrochloric acid which take part in the processes of animal life.

Its necessity as a constituent in the food both of human beings and of animals becomes evident when we consider that both hydrochloric acid and salts of sodium are found in the substances which are separated out from the blood into the stomach and intestines. Sodium salts are found in the blood and in the bile which is elaborated in the liver and acts on the food in the alimentary canal, whilst hydrochloric acid is found in the acid juices of the stomach (over 4 per cent.). Chlorides of the metals are always found in considerable quantities in the urine, and if they are excreted they must be replenished in the organism; and for the replenishment of the loss, substances containing chlorine compounds must be taken in food. Not only do animals consume those small amounts of sodium chloride which are found in drinking water or in plants or other animals, but many wild animals travel long distances in search of salt springs, and domestic animals which in their natural condition do not require salt, willingly take it, the functions of their organisms becoming much more regular from their doing so.

The action of sulphuric acid on sodium chloride.—If sulphuric acid is poured over common salt, even at the ordinary temperature, as Glauber observed, an odorous gas, hydrochloric acid, is evolved. The reaction which takes place consists in the sodium of the salt and the hydrogen of the sulphuric acid changing places:

At the ordinary temperature this reaction is not complete, but soon ceases (with the formation of the compound $\text{NaHSO}_4, \text{H}_2\text{SO}_4$). When the mixture is heated, the decomposition proceeds until, if there be sufficient salt present, all the sulphuric acid taken is converted into acid sodium sulphate. Any excess of acid will remain unaltered. If 2 molecules of sodium chloride (117 parts) be taken per molecule of sulphuric acid (98 parts), then on heating the mixture to a moderate temperature only one-half (58.5) of the salt will undergo change. Complete decomposition, after which no chlorine is left in the residue, proceeds *at a red heat only*. Then—

This double decomposition is the result of the action of the acid salt, NaHSO_4 , first formed, on sodium chloride, for the acid salt, since it contains hydrogen, itself acts like an acid, $\text{NaCl} + \text{NaHSO}_4 = \text{HCl} + \text{Na}_2\text{SO}_4$. By adding this equation to the first we obtain the second, which expresses the ultimate reaction. Hence in the above reaction, non-volatile or sparingly volatile table salt and sparingly volatile sulphuric acid are taken, and as the result of their reaction, after the hydrogen and sodium have exchanged places, there is obtained non-volatile sodium sulphate and gaseous hydrochloric acid. The fact of the latter being a gaseous substance forms the main reason for the reaction proceeding to the end. The HCl evolved is soluble in water, and its solution is usually called **hydrochloric** or **muriatic acid**. The mechanism of this kind of double decomposition, and the cause of the course of the reaction, are exactly the same as those we found in the decomposition of nitre (Chap. VI.) by the action of sulphuric acid. The sulphuric acid in each case displaces the other, volatile, acid.

Not only in these two instances, but in every instance, if a volatile acid can be formed by the substitution of the hydrogen of sulphuric acid for a metal, then this volatile acid will be formed. From this it may be concluded that the volatility of the acid should be considered as one of the causes of the progress of the reaction; and indeed if the acid be soluble but not volatile, or if the reaction take place in an enclosed space where the resulting acid cannot volatilise, or at the ordinary temperature when it does not pass into the state of elastic vapour—then the decomposition does not proceed to the end, but only up to a certain limit. In this respect the explanations given at the beginning of the nineteenth century by the French chemist Berthollet in his work ‘*Essai de Statique Chimique*,’ and elaborated and generalised

at the close of the nineteenth century, are very important. **The doctrine of Berthollet** starts from the supposition that the chemical reaction of substances is determined not only by the degrees of affinity between the different parts, but also by the relative masses of the reacting substances and by those physical conditions under which the reaction takes place. Two substances, containing the elements MX and NY, being brought into contact with each other, form by double decomposition the compounds MY and NX; but the formation of these two new compounds will not proceed to the end unless one of them is removed from the sphere of action. But it can only be removed if it possesses different physical properties from those of the other substances which are present with it. Either it must be a gas while the others are liquid or solid, or an insoluble solid while the others are liquid or soluble. The relative amounts of the resultant substances, if nothing separates out from their intermixture, depend only on the relative quantities of the substances MX and NY, and upon the degrees of attraction existing between the elements M, N, X, and Y; but however great their mass may be, and however considerable the attractions, still in any case, if nothing separates out from the sphere of action the decomposition will presently cease, **a state of equilibrium** will be established, and instead of two there will remain four substances in the mass: namely, a portion of the original bodies MX and NY, and a certain quantity of the newly formed substances MY and NX, it being assumed that neither MN nor XY nor any other substances are produced, as may for the present ²⁴ be admitted in the case of the double decomposition of salts in which M and N are metals and X and Y haloids. The sum total of existing data concerning the double decomposition of salts leads to the conclusion that from salts $MX + NY$ there always arises a certain quantity of NX and MY, as should be the case according to Berthollet's doctrine. In order that what is said in the following pages about the *modus operandi* of double saline decompositions may acquire its proper connection with other now prevalent chemical views, it is indispensable that some slight

²⁴ If MX and NY represent the molecules of two salts, and if there be *no third substance* present (such as water in a solution), the formation of XY would also be possible; for instance, chlorine and iodine are capable of combining together and with metals. Besides which the salts MX and NY or MY with NX may form double salts, and in general the matter may be complicated by the formation of other compounds besides MY and NX, and when a solvent participates in the action, and especially if present in large proportion, the phenomena must evidently become still more complex. Hence while placing before the reader a certain portion of the existing store of knowledge concerning the phenomena of double saline decompositions, I cannot consider the theory of the subject as complete, and have therefore limited myself to a few data, the completion of which must be sought in more detailed works on the subject of theoretical chemistry, without losing sight of what has been said above.

mention at least should be made of the reversibility of many reactions ^{24a} and of the phenomena of dissociation ^{24b}, as it is only in this way that the true unity of the principles acting in every chemical reaction stands forth. If a salt MX and a salt NY give salts MY + NX, and at the same time MY and NX are able to give MX + NY, it is evident that a state of equilibrium must somewhere ensue between the two opposite reactions, and be attained in equal degree from whichever side we start, if all the substances MX, NY, MY, and NX occur in one homogeneous medium such as a solution. In this lies the point of junction of Bergmann and Berthollet's different views. The first held that the measure of the affinities determines the ultimate reaction with the formation of MY + NX *in toto* if the affinities of the resultant bodies, i.e., of M to Y and N to X, be greater than the affinities in the original bodies, i.e., of M to X and N to Y, and that the reverse reaction is impossible—that is, that MY + NX cannot give any MX + NY, for the weaker cannot overcome the stronger. According to Berthollet, on the other hand, the only part played by affinity is that of distribution, the weaker affinities also playing their part in the general conflict. And although, from the essence of the matter, there are no means of directly measuring the force of affinity, yet logical sequence and the phenomena observed oblige us now to give preference to Berthollet's doctrine; and if there be no reaction between two given substances—for instance, oxygen and hydrogen—it does not indicate that there is no chemical affinity between the elements composing these substances, or that the affinity is too small to overcome the existing state of equilibrium, but only that there are not the necessary conditions for reaction; and that when these conditions are fulfilled a state of equilibrium and distribution will ensue, which will finish in one way or another according to the properties of the participating substances and the conditions in which they are placed. Thus oxygen and hydrogen react at high temperatures forming water, but the water then also

^{24a} The reversibility of many reactions, under certain conditions, is frequently expressed by the sign \rightleftharpoons (for instance $AB \rightleftharpoons A + B$ signifies that AB is able to split up into A and B, but that at the same time A is able, under the same conditions, to combine with B and give AB), which clearly shows that the thermo-chemical data of the evolution or absorption of heat are alone insufficient to determine the direction of a reaction, because if heat is evolved in one direction, it will be absorbed when the reaction proceeds in the opposite direction.

^{24b} As every double decomposition may be mentally reduced to a sum of decompositions and combinations, the fundamental principle of chemical mechanics is expressed in dissociation. In the sense in which it was enunciated by St. Claire-Deville, it throws light directly upon the influence of mass, the conditions of environment, of temperature, pressure, affinity and equilibrium, and hence the doctrine of Berthelot only acquired its true importance and meaning after the conception of dissociation had been established.

decomposes and dissociates to a certain degree. The matter evidently becomes far more complicated in this case, but all facts appear more complex when they become better known than they do at first sight.

It must be remembered that at the time when Berthollet, conjecturing much that was then unknown, understood the essence of chemical reactions in the case of salts, the modern conceptions of the atomic composition of bodies and of molecules were not known, but in expounding his theory we have made use of these fundamental conceptions in order to render the subject more easily understood.

And since, according to Berthollet's doctrine, when mMX of one salt comes into contact with nNY of another salt, there are formed certain quantities xMY and xNX , and there remains $m-x$ of the salt MX , and $n-x$ of the salt NY , if m be greater than n , then the maximum interchange could lead to $x=n$, whilst from the salts taken there would be formed $nMY + nNX + (m-n)MX$ —that is, a portion of one of the salts (MX) taken would remain unchanged because the reaction could only proceed (according to the conception of atoms) between nMX and nNY . If x were actually equal to n , the mass of the salt MX would not have any influence on the *modus operandi* of the reaction, which is equally in accordance with the teaching of Bergmann, who supposed double reactions to be independent of the mass and determined by affinity only. If M had more affinity for X than for Y , and N more affinity for Y than for X , then according to Bergmann there would be no decomposition whatever, and x would equal 0. If the affinity of M for Y and of N for X were greater than those in the original grouping, then the affinity of M for X and of N for Y would be overcome, and, according to Bergmann's doctrine, complete interchange would take place—i.e., x would equal n . According to Berthollet's teaching, if nothing be separated out and all the conditions (temperature, contact) for reaction be present, a distribution of M and N between X and Y will take place in every case, not only in proportion to the degrees of affinity, but also in proportion to the masses, so that with a small affinity and a large mass the same action can be produced as with a large affinity and a small mass. Therefore, (1) x will always be less than n and their ratio $\frac{x}{n}$ less than unity—that is, the decomposition will be expressed by the equation, $mMX + nNY = (m-x)MX + (n-x)NY + xMY + xNX$; (2) by increasing the mass m we increase the decomposition—that is, we increase x and the ratio $\frac{x}{(n-x)}$, until with an infinitely large quantity m the fraction $\frac{x}{n}$ will equal 1, and the

decomposition will be complete, however small the affinities uniting MY and NX may be ; and (3) by taking MX and NY or MY and NX we arrive at one and the same system *in either case*. These direct consequences of Berthollet's teaching are verified by experience. Thus, for example, a mixture of solutions of sodium nitrate and potassium chloride in all cases has exactly the same properties as a mixture of solutions of potassium nitrate and sodium chloride, of course on condition that the mixed solutions are of identical elementary composition, and have the same temperature, pressure, &c. But this identity of properties might either proceed from one system of salts passing entirely into the other (Bergmann's hypothesis) in conformity with the predominating affinities (for instance, from $\text{KCl} + \text{NaNO}_3$ there might arise $\text{KNO}_3 + \text{NaCl}$, if it be admitted that the affinities of the elements as combined in the latter system are greater than in the former) ; or, on the other hand, it might be because both systems by the interchange of a portion of their elements give one and the same state of equilibrium, as according to Berthollet's teaching. Experiment proves the latter hypothesis to be the true one. But before citing the historically most important experiments verifying Berthollet's doctrine, we must stop to consider the **conception of the mass** of the reacting substances. Berthollet understood by mass the actual relative quantity of a substance ; but now it is impossible to understand this term otherwise than as the number of molecules, for these act as chemical units, and in the special case of double saline decompositions it is better to take it as the number of equivalents. Thus in the reaction $\text{NaCl} + \text{H}_2\text{SO}_4$, the salt is taken in one equivalent and the acid in two. If $2\text{NaCl} + \text{H}_2\text{SO}_4$ react, then the numbers of equivalents of the two are equal, and so on. The **influence of mass** on the amount of decomposition $\frac{x}{n}$ forms the root of

Berthollet's doctrine, and we shall therefore first of all turn our attention to the establishment of this principle in relation to the double decomposition of salts.

About 1840 H. Rose²⁵ showed that water decomposes metallic sulphides like calcium sulphide, CaS , forming hydrogen sulphide, H_2S , notwithstanding the fact that the affinity of hydrogen sulphide, as an acid, for lime, CaH_2O_2 , as a base, causes them to react on each other, forming calcium sulphide and water, $\text{CaS} + 2\text{H}_2\text{O}$. Furthermore, Rose showed that the greater the amount of water acting on the calcium sulphide, the more complete is the decomposition. The results of this

²⁵ H. Rose is more especially known for having carefully studied and perfected several methods for the exact chemical analysis of many mineral substances. His predecessor in this branch of research was Berzelius, and his successor Fresenius.

reaction are evident from the fact that the hydrogen sulphide formed may be expelled from the solution by heating, and that the resulting lime is sparingly soluble in water. Rose clearly saw from this that such feeble agents, in a chemical sense, as carbonic anhydride and water, by acting in mass and for long periods of time in nature on the durable rocks, which resist the action of the most powerful acids, are able to bring about chemical change—to extract, for example, from rocks the bases, lime, soda, and potash. The influence of water in mass on antimonious chloride, bismuth nitrate, &c., is essentially of the same character. These substances give up to the water a quantity of acid which is greater in proportion as the mass of the water acting on them is greater.^{25a}

Barium sulphate, BaSO_4 , which is insoluble in water, when fused with sodium carbonate, Na_2CO_3 , gives, but not completely, barium carbonate, BaCO_3 (also insoluble), and sodium sulphate, Na_2SO_4 . If a solution of sodium carbonate acts on precipitated barium sulphate, the same decomposition is also effected (Dulong, Rose), but it is restricted by a limit and requires time. A mixture of sodium carbonate and sulphate is obtained in the solution and a mixture of barium carbonate and sulphate in the precipitate. If the solution be decanted off and a fresh solution of sodium carbonate be poured over the precipitate, then a fresh portion of the barium sulphate passes into barium carbonate, and so, by increasing the mass of the sodium carbonate, it is possible to entirely convert the barium sulphate into barium carbonate. If a definite quantity of sodium sulphate be added to the solution of sodium carbonate, then the latter will have no action whatever on the barium sulphate, because then a system in equilibrium, determined by the reverse action of the sodium sulphate on the barium carbonate and by the presence of both sodium carbonate and sulphate in the solution, is at once arrived at. On the other hand, if the mass of the sodium sulphate in the solution be great, then the barium carbonate is reconverted into sulphate until a definite state of equilibrium is attained between the two opposite reactions, producing barium carbonate by the action of the sodium carbonate and barium sulphate by the action of the sodium sulphate. The influence of mass is here evident.

^{25a} Historically the influence of the mass of water was the first well-observed phenomenon in support of Berthollet's teaching, and it should not now be forgotten. In double decompositions taking place in dilute solutions where the mass of water is large, its influence, notwithstanding the weakness of affinities, must be great, according to the very essence of Berthollet's doctrine.

As explaining the action of the mass of water, the experiments of Pattison Muir (1879) are very instructive. These experiments demonstrate that the decomposition of bismuth chloride is the more complete the greater the relative quantity of water, and the less the mass of the hydrochloric acid which forms one of the products of the reaction.

Another most important principle of Berthollet's teaching is the existence of **a limit of exchange decomposition, or the attainment of a state of equilibrium**. In this respect the determinations of Malaguti (1857) are historically the most important. He took a mixture of solutions of equivalent quantities of two salts, MX and NY, and judged the amount of the resulting exchange from the composition of the precipitate produced by the addition of alcohol. When, for example, zinc sulphate and sodium chloride (ZnSO_4 and 2NaCl) were taken, there were produced by exchange sodium sulphate and zinc chloride. A mixture of zinc sulphate and sodium sulphate was precipitated by an excess of alcohol, and it appeared from the composition of the precipitate that 72 per cent. of the salts taken had been decomposed. When, however, a mixture of solutions of sodium sulphate and zinc chloride was taken, the precipitate presented the same composition as before—that is, about 28 per cent. of the salts taken had been subjected to decomposition. In a similar experiment with a mixture of sodium chloride and magnesium sulphate, $2\text{NaCl} + \text{MgSO}_4$ or $\text{MgCl}_2 + \text{Na}_2\text{SO}_4$, about half of the metals underwent the decomposition, which may be expressed by the equation $4\text{NaCl} + 2\text{MgSO}_4 = 2\text{NaCl} + \text{MgSO}_4 + \text{Na}_2\text{SO}_4 + \text{MgCl}_2$. A no less clear limit expressed itself in another of Malaguti's researches in which he investigated the above-mentioned reversible reactions of the insoluble salts of barium. When, for example, barium carbonate and sodium sulphate ($\text{BaCO}_3 + \text{Na}_2\text{SO}_4$) were taken, about 72 per cent. of the salts were decomposed, that is, were converted into barium sulphate and sodium carbonate. But when the two latter salts were taken, about 19 per cent. of them passed into barium carbonate and sodium sulphate. Probably the end of the reaction was not reached in either case, because this would require a considerable time and a uniformity of conditions attainable with difficulty.

Gladstone (1855) took advantage of the colour of solutions of different ferric salts for determining the measure of exchange between metals, and this is better because then everything remains in solution. A solution of ferric thiocyanate has a most intense red colour, and by making a comparison between the colour of the resulting solutions and the colour of solutions of known strength it was possible to judge very closely the quantity of the thiocyanate formed. This colorimetric method of determination has an important significance as being the first in which a method was applied for determining the composition of a solution without the removal of any of its component parts. When Gladstone took equivalent quantities of ferric nitrate and potassium thiocyanate— $\text{Fe}(\text{NO}_3)_3 + 3\text{KCNS}$ —only 13 per cent. of the salts underwent decomposition. On increasing the mass of the latter salt the

quantity of ferric thiocyanate formed increased, but even when more than 300 equivalents of potassium thiocyanate were taken a portion of the iron still remained as nitrate. It is evident (according to Berthollet's theory) that the affinity acting between Fe and NO_3 and between K and CNS on the one hand is greater than the affinity acting between Fe and CNS, together with the affinity of K for NO_3 , on the other hand. The investigation of the variation of the fluorescence of quinine sulphate, as well as the variation of the rotation of the plane of polarisation of nicotine, gave in the hands of Gladstone many proofs of the entire applicability of Berthollet's doctrine, and in particular demonstrated the influence of mass which forms the chief distinctive feature of the doctrine of Berthollet, a doctrine but little appreciated in his own time. (Determinations showing the influence of the mass of the water are, however, wanting.)

At the beginning of the year 1860 the doctrine of the limit of reaction and of the influence of mass on the process of chemical transformations received very important support in the researches of Berthelot and Peau de Saint-Gilles on the formation of the ethereal salts RX from the alcohols ROH and acids HX, when water is also formed. This conversion is essentially very similar to the formation of salts, but differs in that it proceeds slowly at the ordinary temperature, extending over whole years, and is not complete, that is, it has a distinct limit determined by a reverse reaction; thus an ethereal salt RX with water gives an alcohol ROH and an acid HX—up to the limit generally corresponding with two-thirds of the alcohol taken, if the action proceed between molecular quantities of alcohol and acid. Thus ordinary alcohol, $\text{C}_2\text{H}_5\text{OH}$, with acetic acid, $\text{HC}_2\text{H}_3\text{O}_2$, gives rapidly when heated, or slowly at the ordinary temperature, the system $\text{ROH} + \text{HX} + 2\text{RX} + 2\text{H}_2\text{O}$, whether we start from $3\text{RHO} + 3\text{HX}$ or from $3\text{RX} + 3\text{H}_2\text{O}$. The process and completion of the reaction in this instance are very easily observed, because the quantity of free acid is easily determined from the amount of alkali requisite for its saturation, as neither the alcohol nor the ethereal salt acts on litmus or other reagents for detecting acids. Under the influence of an increased mass of alcohol the reaction proceeds further. If two molecules of alcohol, RHO, be taken for every one molecule of acetic acid, HX, then instead of 66 per cent., 83 per cent. of the acid passes into ethereal salt, and with fifty molecules of RHO nearly all the acid is etherised. The researches of N. A. Menschutkin touched in detail on many important aspects of the same subject, such as the influence of the composition of the alcohol and acid on the limit and rate of exchange—but these, as well as other details, must be looked for in special treatises on organic

and theoretical chemistry. In any case the study of etherification has supplied chemical mechanics with clear and valuable data, which directly confirm the two fundamental propositions of Berthollet; the influence of mass, and the limit of reaction—that is, the equilibrium between opposite reactions.²⁶

A very important epoch in the history of Berthollet's doctrine was attained when, in 1867, the Norwegian chemists, Guldberg and Waage, expressed it as an algebraical formula. They defined the active mass as the number of molecules contained in a given volume, and assumed, as follows from the spirit of Berthollet's teaching, that the action between the substances was equal to the *product* of the masses of the reacting substances. Hence if the salts MX and NY be taken in equivalent quantities ($m = 1$ and $n = 1$) and the salts MY and NX are not added to the mixture but proceed from it, and if k represent the coefficient of the rate of the action of MX on NY and k' the same coefficient for the pair MY and NX, then we shall have at the moment when the decomposition equals x a measure of action for the first pair: $k(1 - x)(1 - x)$, and for the second pair $k'xx$, and a state of equilibrium or limit will be reached when $k(1 - x)^2 = k'x^2$, whence the ratio $k/k' = [x/(1 - x)]^2$. Therefore in the case of the action of alcohol on an acid, when $x = \frac{2}{3}$, the magnitude $k/k' = 4$, that is, the reaction of the alcohol on the acid is four times as fast as that of the ethereal salt on water. If the ratio k/k' be known, then *the influence of mass may be easily determined* from it. Thus if instead of one molecule of alcohol two be taken, then the equation will be $k(2 - x)(1 - x) = k'xx$, whence $x = 0.85$ or 85 per cent., which agrees closely with the result of experiment. If 300 molecules of alcohol be taken, then x proves to be approximately 100 per cent., which is also found to be the case by experiment.^{26a}

But it is impossible to subject the formation of salts to any process directly analogous to that which is so conveniently effected in etherification. Many efforts have, however, been made to solve the problem of the measure of reaction in this case also. Thus, for example,

²⁶ With respect to double saline decompositions, it is also necessary to mention the researches of Wiedemann on the decomposing action of a mass of water on the ferric salts, which could be determined by measuring the magnetism of the solutions, because the ferric oxide (soluble colloid) set free by the water is less magnetic than the ferric salts.

^{26a} From the above it follows that an excess of acid should influence the reaction like an excess of alcohol. It is in fact shown by experiment that if two molecules of acetic acid be taken to one molecule of alcohol, 84 per cent. of alcohol is etherified. If with a large preponderance of acid or of alcohol certain discrepancies are observed, their cause must be looked for in the incomplete correspondence of the conditions and external influences.

Khichinsky (1866), Petrieff (1885), and many others investigated the distribution of metals and haloid groups in the case of one metal and several haloids, taken in excess, as acids ; or conversely with an excess of bases, the distribution of these bases with relation to an acid ; in cases where a portion of the substances forms a precipitate and a portion remains in solution. But such complex cases, although they in general confirm Berthollet's teaching (for instance, a solution of silver nitrate gives some silver oxide with lead oxide, and a solution of nitrate of lead precipitates some lead oxide under the action of silver oxide, as Petrieff demonstrated), still, owing to the complexity of the phenomena (for instance, the formation of basic and double salts), they cannot give simple results. But much more instructive and complete are researches like those made by Pattison Muir (1876), who took the simple case of the precipitation of calcium carbonate, CaCO_3 , from the mixture of solutions of calcium chloride and sodium or potassium carbonate, and found in this case that not only was the rate of action (for example, in the case of $\text{CaCl}_2 + \text{Na}_2\text{CO}_3$, 75 per cent. of CaCO_3 was precipitated in five minutes, 85 per cent. in thirty minutes, and 94 per cent. in two days) determined by the temperature, the relative masses, and the amount of water (a large mass of water decreases the rate), but that the limit of decomposition was also dependent on these influences. However, even in researches of this kind the conditions of reaction are complicated by the non-uniformity of the media, inasmuch as a portion of the substance is obtained or remains in the form of a precipitate, so that the system is heterogeneous. The investigation of double saline decompositions offers many difficulties which cannot be considered as yet entirely overcome. Although many efforts have long since been made, the majority of the researches were carried on in aqueous solutions, and as water is itself a saline compound and able to combine with salts and enter into double decomposition with them, such reactions taking place in solutions in reality present very complex cases.²⁷ In

²⁷ As an example two methods may be mentioned, Thomsen's and Ostwald's. Thomsen (1869) applied a thermo-chemical method to exceedingly dilute solutions without taking the water into further consideration. He took solutions of caustic soda containing $100\text{H}_2\text{O}$ per NaHO , and sulphuric acid containing $\frac{1}{2}\text{H}_2\text{SO}_4 + 100\text{H}_2\text{O}$. In order that these solutions may be mixed in such quantities that atomic proportions of acid and alkali would act, for forty grams of caustic soda (which answers to its equivalent) there should be employed 49 grams of sulphuric acid, and then +15,689 heat units would be evolved. If the normal sodium sulphate so formed be mixed with n equivalents of sulphuric acid, a certain amount of heat is absorbed, namely, a quantity equal to $\frac{n \cdot 1650}{n + 0.8}$ heat units. An equivalent of caustic soda, in combining with an equivalent of nitric acid, evolves +13,617 units of heat, and the augmentation of the amount of nitric acid entails an absorption of heat for each equivalent equal to -27 units ; so also in combining with hydrochloric acid +13,740 heat units are evolved, and for each equivalent of

this sense the reaction between alcohols and acids is much more simple, and therefore its significance in confirmation of Berthollet's doctrine is of particular importance. The only cases which can be compared with

hydrochloric acid beyond this amount there are absorbed -32 heat units. Thomsen mixed each one of three neutral salts, sodium sulphate, sodium chloride, and sodium nitrate, with an acid which is not contained in it; for instance, he mixed a solution of sodium sulphate with one of nitric acid and determined the number of heat units then absorbed. An absorption of heat ensued because a normal salt was taken in the first instance, and the mixture of all the above normal salts with acid produces an absorption of heat. The amount of heat absorbed enabled him to obtain an insight into the process taking place in this mixture, for sulphuric acid added to sodium sulphate absorbs a considerable quantity of heat, whilst hydrochloric and nitric acids absorb a very small amount of heat in this case. By mixing an equivalent of sodium sulphate with various numbers of equivalents of nitric acid, Thomsen observed that the amount of heat absorbed increased more and more as the amount of nitric acid was increased; thus when HNO_3 was taken per $\frac{1}{2}\text{Na}_2\text{SO}_4$, 1,752 heat units were absorbed per equivalent of soda contained in the sodium sulphate. When twice as much nitric acid was taken, 2,026 heat units, and when three times as much, 2,050 heat units were absorbed. Had the double decomposition been complete in the case where one equivalent of nitric acid was taken per equivalent of Na_2SO_4 , then according to calculation from similar data there should have been absorbed $-2,989$ units of heat, while in reality only $-1,752$ units were absorbed. Hence Thomsen concluded that a displacement of only about two-thirds of the sulphuric acid had taken place—that is, the ratio $k:k'$ for the reactions $\frac{1}{2}\text{Na}_2\text{SO}_4 + \text{HNO}_3$ and $\text{NaNO}_3 + \frac{1}{2}\text{H}_2\text{SO}_4$ is equal, as for ethereal salts, to 4. By taking this figure and admitting the above supposition, Thomsen found that for all mixtures of soda with nitric acid, and of sodium nitrate with sulphuric acid, the amounts of heat followed Guldberg and Waage's law; that is, the limit of decomposition reached was greater, the greater the mass of acid added. The relation of hydrochloric to sulphuric acid gave the same results. Therefore the researches of Thomsen fully confirm the hypotheses of Guldberg and Waage and the doctrine of Berthollet.

Whilst retaining essentially the methods of Thomsen, Ostwald (1876) determined the variation of the sp. gr. (and afterwards of volume), proceeding in the same dilute solutions, on the saturation of acids by bases, and in the decomposition of the salts of one acid by the other, and arrived at conclusions of just the same nature as Thomsen's. Ostwald's method will be clearly understood from an example. A solution of caustic soda containing an almost molecular (40 grams) weight per litre had a specific gravity of 1.04051. The specific gravities of solutions of equal volume and equivalent composition of sulphuric and nitric acids were 1.02970 and 1.03084 respectively. On mixing the solutions of NaHO and H_2SO_4 there was formed a solution of Na_2SO_4 of sp. gr. 1.02959; hence there ensued a decrease of specific gravity which we will term Q , equal to $1.04051 + 1.02970 - 2(1.02959) = 0.01103$. So also the specific gravity after mixture of the solutions of NaHO and HNO_3 was 1.02633, and therefore $Q = 0.01869$. When one volume of the solution of nitric acid was added to two volumes of the solution of sodium sulphate, a solution of sp. gr. 1.02781 was obtained, and therefore the resultant decrease of sp. gr.,

$$Q_1 = 2(1.02959) + 1.03084 - 3(1.02781) = 0.00659.$$

Had there been no chemical reaction between the salts, then, according to Ostwald's reasoning, the specific gravity of the solutions would not have changed, and if the nitric acid had entirely displaced the sulphuric acid Q_2 would be $= 0.01869 - 0.01103 = 0.00766$. It is evident that a portion of the sulphuric acid was displaced by the nitric acid. But the measure of displacement is not equal to the ratio between Q_1 and Q_2 , because a decrease of sp. gr. also occurs on mixing the solution of sodium sulphate with sulphuric acid, whilst the mixing of the solutions of sodium nitrate and nitric acid only produces a slight variation of sp. gr. which falls within the limits of experimental error. Ostwald

these reactions for simplicity are those double decompositions, investigated by G. G. Gustavson, which take place between CCl_4 and RBr_n on the one hand, and CBr_4 and RCl_n on the other. This case is convenient for investigation inasmuch as the RCl_n and RBr_n taken (such as BCl_3 , SiCl_4 , TiCl_4 , POCl_3 , and SnCl_4) belong to those substances which are decomposed by water, whilst CCl_4 and CBr_4 are not decomposed by water; and therefore, by heating, for instance, a mixture of CCl_4 + SiBr_4 it is possible to arrive at a conclusion as to the amount of interchange by treating the product with water, which decomposes the SiBr_4 left unchanged and the SiCl_4 formed by the exchange, and therefore by determining the composition of the product acted on by the water it is possible to form a conclusion as to the amount of decomposition. The mixture was always formed with equivalent quantities—for instance, $4\text{BCl}_3 + 3\text{CBr}_4$. It appeared that there was no exchange whatever on simple intermixture, but that it proceeded slowly, when the mixture was heated (for example, with the mixture above mentioned, at 123° 4.86 per cent. of Cl was replaced by Br after 14 days' heating, and 6.83 per cent. after 28 days, and 10.12 per cent. when heated at

deduces from similar data the same conclusions as Thomsen, and thus reconfirms the formula deduced by Guldberg and Waage, and the teaching of Berthollet.

The participation of water is seen still more clearly in the methods adopted by Ostwald than in those of Thomsen, because in the saturation of solutions of acids by alkalies (which Kremers, Reinhold, and others had previously studied) there is observed, not a contraction, as might have been expected from the quantity of heat which is then evolved, but an expansion, of volume (a decrease of specific gravity, if we calculate as Ostwald did in his first investigations). Thus by mixing 1,880 grams of a solution of sulphuric acid of the composition $\text{SO}_3 + 100\text{H}_2\text{O}$, occupying a volume of 1,815 c.c., with a corresponding quantity of a solution $2(\text{NaHO} + 5\text{H}_2\text{O})$, whose volume is 1,793 c.c., we obtain not 3,608 but 3,633 c.c., an expansion of 25 c.c. per gram molecule of the resulting salt, Na_2SO_4 . It is the same in other cases. Nitric and hydrochloric acids give a still greater expansion than sulphuric acid, and potassium hydroxide than sodium hydroxide, whilst a solution of ammonia gives a contraction. The relation to water must be considered as the cause of these phenomena. When sodium hydroxide and sulphuric acid dissolve in water they develop heat and give a vigorous contraction. After mutual saturation they form the salt Na_2SO_4 , which retains the water but feebly and evolves but little heat with it, i.e., in other words, has little affinity for water. In the saturation of sulphuric acid by soda the water is, as it were, displaced from a stable combination and passes into an unstable combination; hence an expansion (decrease of sp. gr.) takes place. It is not the reaction of the acid on the alkali, but the reaction of water, that produces the phenomenon by which Ostwald desires to measure the degree of salt formation. The volume of $\text{H}_2\text{SO}_4 = 53.3$, that of $2\text{NaHO} = 37.4$; there is produced $2\text{H}_2\text{O}$, volume = 36, + Na_2SO_4 , volume = 53.6. There react 90.7 c.c., and on saturation there result 89.6 c.c.; consequently contraction again ensues. Hence the phenomena studied by Ostwald depend but little on the measure of the reaction of the salts, and more on the relations of the dissolved substances to water. It may be concluded, therefore, on the basis of what has been said, that on taking water into consideration the phenomena studied by Thomsen and Ostwald are much more complex than they at first appear, and that this method can scarcely lead to a correct interpretation as to the distribution of acids between bases.

150° for 60 days). A limit was always reached which corresponded with that of the reverse system, that is, in the given instance, of the system $4\text{BBr}_3 + 3\text{CCl}_4$. In this last 89.97 per cent. of bromine in the BBr_3 was replaced by chlorine; that is, there were obtained 89.97 molecules of BCl_3 and there remained 10.02 molecules of BBr_3 , and therefore the same state of equilibrium was reached as that given by the system $4\text{BCl}_3 + 3\text{CBr}_4$. Both systems gave one and the same state of equilibrium at the limit, which is in agreement with the essence of Berthollet's doctrine.²⁸

Thus we now find ample confirmation from various quarters for the

²⁸ G. G. Gustavson's researches, which were conducted in the laboratory of the St. Petersburg University in 1871-72, are among the first in which the measure of the affinity of the elements for the halogens is recognised with perfect clearness in the limit of substitution and in the rate of reaction. The researches conducted by Prof. A. L. Potilitzin (of which mention will be made in Chap. XI., note 66), in the same laboratory, touch on another aspect of the same problem which has not yet made much progress, notwithstanding its importance and the fact that the theoretical side of the subject (thanks especially to Guldberg and van't Hoff) has since been rapidly pushed forward. If the researches of Gustavson took account of the influence of mass, and were more fully supplied with data concerning velocities and temperatures, they would be very important, because of the great significance which the case considered has for the understanding of double saline decompositions 'in the absence of water.'

Furthermore, Gustavson showed that the greater the atomic weight of the element (B, Si, Ti, As, Sn) combined *with chlorine* the greater the amount of chlorine replaced by bromine by the action of CBr_4 , and consequently the less the amount of bromine replaced by chlorine by the action of CCl_4 on bromine compounds. For instance, for chlorine compounds the percentage of substitution (at the limit) is—

BCl_3	SiCl_4	TiCl_4	AsCl_3	SnCl_4
10.1	12.5	43.6	71.8	77.5

It should be observed, however, that Thorpe, on the basis of his experiments, denies the universality of this conclusion. I may mention one conclusion which it appears to me may be drawn from the above-cited figures of Gustavson, if they are subsequently verified even within narrow limits. If CBr_4 be heated with RCl_4 , then an exchange of the bromine for chlorine takes place. But what would be the result if it were mixed with CCl_4 ? Judging by the magnitude of the atomic weights, $\text{B} = 11$, $\text{C} = 12$, $\text{Si} = 28$, about 11 per cent. of the chlorine would be replaced by bromine. But to what does this point? I think that it shows the existence of a motion of the atoms in the molecule. The mixture of CCl_4 and CBr_4 does not remain in a condition of static equilibrium; not only are the molecules contained in it in a state of motion, but so also are the atoms in the molecules, and the above figures show the measure of their translation under these conditions. The bromine in the CBr_4 is, *within the limit*, substituted by the chlorine of the CCl_4 in a quantity of about 11 out of 100: that is, some of the atoms of bromine previously to this moment in combination with one atom of carbon pass over to the other atom of carbon, and the chlorine passes over from this second atom of carbon to replace it. Therefore, also, in the homogeneous mass CCl_4 all the atoms of Cl do not remain constantly combined with the same atoms of carbon, and *there is an exchange of atoms between different molecules in a homogeneous medium also*. This hypothesis may in my opinion explain certain phenomena of dissociation, but though mentioning it I do not consider it worth while to dwell upon it. I will only observe that a similar hypothesis of dynamic or mobile equilibrium may be brought into agreement with the doctrine of a store of internal chemical energy.

following rules of Berthollet, applying them to double saline decompositions in a uniform (homogeneous) medium. 1. From two salts MX and NY containing different haloids and metals there result from their reaction two others, MY and NX, but such a substitution will not proceed to the end unless one product passes from the sphere of action. 2. This reaction is limited by the existence of an equilibrium between MX, NY, MY, and NX, because a reverse reaction ($MY + NX = MX + NY$) is quite as possible as the direct reaction $MX + NY = MY + NX$. 3. This limit is determined both by the measure of the active affinities and by the relative masses of the substances as measured most simply by the relative number of the reacting molecules. 4. Other conditions being constant, the chemical action is proportional to the product of the chemical masses in action.²⁹

Thus if the salts MX and NY after reaction partly form salts MY and NX, a state of equilibrium is reached and the reaction ceases; but if one of the resultant compounds, in virtue of its physical properties, passes from the sphere of action of the remaining substances, then the reaction will continue, because the relation between the masses is altered. This exit from the sphere of action depends on the physical properties of the substance and on the conditions under which the reaction takes place. Thus, for instance, the salt NX may, in the case of reaction between solutions, separate as a precipitate—an insoluble substance—while the other three substances remain in solution, or it may pass into vapour, and in this manner also pass away from the sphere of action of the remaining substances. Let us now suppose that it passes away in some form or other from the sphere of action of the remaining substances—for instance, that it is transformed into a precipitate or vapour—then a fresh reaction and a re-formation of the salt NX will set in, and so on. In consequence of the physical properties of the resultant substances, the reaction is then able to proceed to completion notwithstanding the possible weakness of the attraction existing between the elements entering into the composition of the resultant substance NX. Naturally, if it is formed of elements having a considerable degree of affinity, the complete position is considerably facilitated.

Such a representation of the *modus operandi* of chemical

²⁹ Berthollet's doctrine is hardly at all affected in principle by showing that there are cases in which there is no decomposition between salts, because the affinity may be so small that even a large mass would still give no observable displacements. The fundamental condition for the application of Berthollet's doctrine, as well as Deville's doctrine of dissociation, lies in the reversibility of reactions. Just as there are practically non-volatile and non-decomposable bodies, so also we must admit the existence of practically irreversible reactions (for instance, $CCl_4 + 2H_2O = CO_2 + 4HCl$).

transformations is applicable with great clearness to a number of reactions studied in chemistry, and, what is especially important, the application of this aspect of Berthollet's teaching does not in any way require the determination of the measure of affinity acting between the substances present. For instance, the action of ammonia on solutions of salts; the displacement, by its means, of basic hydrates insoluble in water; the separation of volatile nitric acid by the aid of non-volatile sulphuric acid, as well as the decomposition of common salt by means of sulphuric acid, when gaseous hydrochloric acid is formed—may be taken as examples of reactions which proceed to the end, inasmuch as one of the resultant substances is entirely removed from the sphere of action, but they in no way indicate the measure of affinity.

Returning to the displacement of hydrochloric acid from common salt by sulphuric acid as further illustrating Berthollet's doctrine,³⁰ the fact may be cited that common salt may be entirely decomposed by nitric acid, with the formation of NaNO_3 and HCl , and conversely nitre may be completely decomposed by hydrochloric acid, just as they are decomposed by sulphuric acid. This only takes place, however, when, in the first instance, a large excess of nitric acid is taken, and in the second instance, an excess of hydrochloric acid, and when the resultant acid passes off. If sodium chloride is put into a porcelain evaporating basin, nitric acid added to it, and the mixture heated, a certain amount of both hydrochloric and nitric acids are expelled by the heat. Thus the nitric acid partially acts on the

³⁰ If a solution of common salt be mixed with a solution of magnesium sulphate, double decomposition may result in the formation of sodium sulphate and magnesium chloride, substances which are soluble in water; nothing is disengaged, and therefore the decomposition $2\text{NaCl} + \text{MgSO}_4 = \text{MgCl}_2 + \text{Na}_2\text{SO}_4$ cannot proceed to the end. However the sodium sulphate formed in this manner may be separated by freezing strong solutions. Complete separation of the sodium sulphate will naturally not take place, owing to a portion of the salt remaining in the solution, but Na_2SO_4 separates out in crystals. This kind of decomposition is made use of for the preparation of sodium sulphate from the residues left after the evaporation of sea-water, which contain a mixture of magnesium sulphate and common salt. A solution of copper sulphate is of a blue colour, while a solution of copper chloride is green. If we mix the two salts together the green tint is distinctly visible, so that by this means the presence of the copper chloride in the solution of copper sulphate is clearly seen. If now we add a solution of common salt to a solution of copper sulphate, a green coloration is obtained, which indicates the formation of copper chloride. In this instance it is not separated, but it is immediately formed on the addition of common salt, as it should be according to Berthollet's doctrine.

The complete formation of a metallic chloride from common salt can only occur, judging from the above, when it separates from the sphere of action. The salts of silver are instances in point, because silver chloride is insoluble in water; and therefore if we add a solution of sodium chloride to a solution of a silver salt, a precipitate of silver chloride and a solution of the sodium salt of that acid which was in the silver salt are formed.

sodium chloride, but on heating, as both acids are volatile, they are both converted into vapour; and therefore the residue will contain a mixture of certain quantities of NaCl and NaNO_3 . If a fresh quantity of nitric acid be then added, reaction will again set in, a certain portion of hydrochloric acid is again evolved, and on heating is expelled together with nitric acid. If this be repeated several times, it is possible to expel all the hydrochloric acid, and to obtain only sodium nitrate in the residue. If, on the contrary, sodium nitrate is treated with hydrochloric acid and heated, a portion of the nitric acid is displaced, and on heating, the excess of hydrochloric acid passes away together with the nitric acid formed. On repeating this process, it is possible to displace the nitric acid by an excess of hydrochloric acid, just as it was possible to displace the hydrochloric acid by an excess of nitric acid. The influence of the mass of the substance in action and the influence of volatility are here very distinctly seen. As in these instances HCl is displaced by HNO_3 , and conversely, it may be affirmed that sulphuric acid does not displace hydrochloric acid because of an especially high degree of affinity, but that this reaction only takes place because the sulphuric acid is not volatile, whilst the hydrochloric acid which is formed is volatile.

The preparation of hydrochloric acid in the laboratory and on a large scale is based upon these data. In the first instance an excess of sulphuric acid is employed³¹ in order that the reaction may proceed easily at a low temperature, whilst on a large scale, when it is necessary to economise every material, equivalent quantities are taken in order to obtain the normal salt Na_2SO_4 and not the acid salt, which would require twice as much acid.

In chemical works the decomposition of sodium chloride by means of sulphuric acid is carried out on a very large scale, chiefly with a view

³¹ The apparatus shown in fig. 52 (Chap. VI., note 12) is generally employed for the preparation of small quantities of hydrochloric acid. Common salt is placed in the retort; the salt is generally previously fused, as it otherwise froths and boils over in the apparatus. When the apparatus is arranged, sulphuric acid mixed with water is poured down the thistle funnel into the retort. Strong sulphuric acid (about half as much again as the weight of the salt) is usually taken, and is diluted with a small quantity of water (half) if it is desired to retard the action, as in using strong sulphuric acid the action immediately begins with great vigour. The mixture, at first without the aid of heat and then at a moderate temperature (in a water-bath), evolves hydrochloric acid. Commercial hydrochloric acid contains many impurities; it is usually purified by distillation, the middle portions being collected. It is purified from arsenic by adding FeCl_3 , distilling, and rejecting the first third of the distillate. If free hydrochloric acid gas is required, it is passed through a vessel containing strong sulphuric acid to dry it, and is collected over a mercury bath.

Phosphoric anhydride absorbs hydrogen chloride (Bailey and Fowler, 1888; $2\text{P}_2\text{O}_5 + 3\text{HCl} = \text{POCl}_3 + 3\text{HPO}_3$) at the ordinary temperature, so that the gas cannot be dried by this substance.

to the preparation of normal sodium sulphate, the hydrochloric acid being a by-product.^{31a} The furnace employed is termed a **salt-cake furnace**. It is represented in fig. 74, and consists of the following two parts: the pan B and the roaster C—an enclosed space built up of large bricks *a* and enveloped on all sides by the smoke and flames from the fire grate, F. The ultimate decomposition of the salt by the sulphuric acid is accomplished in the roaster. But the first decomposition of sodium chloride by sulphuric acid does not require so high a temperature as the ultimate decomposition, and is therefore carried on in the front and cooler portion, B, the bottom of which is heated by gas flues. When the reaction in this portion ceases and the evolution of hydro-

FIG. 74.—Section of a salt-cake furnace. B, pan in which the sodium chloride and sulphuric acid are first mixed and heated. C, muffle for the ultimate decomposition.

chloric acid stops, the mass of acid sodium sulphate is removed from B and thrown into the roaster C, where the reaction is completed. Normal sodium sulphate, which we shall afterwards describe, remains in the roaster. For the present we will only turn our attention to the hydrochloric acid evolved in B and C.

The hydrochloric acid gas evolved is subjected to condensation by dissolving it in water.³² If the apparatus in which the decomposition

^{31a} In chemical works where sulphuric acid of 60° Baumé (22 per cent. of water) is employed, 117 parts of sodium chloride are taken to about 125 parts of sulphuric acid.

³² As, in works which treat common salt in order to obtain sodium sulphate, the hydrochloric acid is sometimes held to be of no value (has no sale), it might be allowed

is accomplished were hermetically closed, and only presented one outlet, the escape of the hydrochloric acid would only proceed through the escape pipe intended for this purpose. But as it is impossible to construct a perfectly hermetically closed furnace it is necessary to increase

FIG. 75.—Apparatus used in works for the condensation of hydrogen chloride, evolved in furnaces. The gas is drawn through the tubes B, B, . . . up the coke tower, down the tube M N and into the furnace shaft, while the water passes from E, down the coke tower, and then through the vessels H, H, . . ., dissolving the hydrogen chloride.

the draught by artificial means, or to compel the hydrochloric acid gas to pass through those arrangements in which it is to be condensed.

to escape with the waste furnace gases into the atmosphere, which would greatly injure the air of the neighbourhood and destroy all vegetation. In all countries, therefore, there are laws forbidding the manufacture from being carried on in this manner, and requiring the absorption of the hydrochloric acid by water at the works themselves, and not permitting the solution to be run into rivers and streams, in which it would spoil the water. It may be remarked that the absorption of hydrochloric acid presents no particular difficulties (the absorption of sulphurous acid is much more difficult) because hydrochloric acid has a great affinity for water and gives a hydrate which boils at above 100° . Hence, even steam and hot water, as well as weaker solutions, can be used for absorbing the acid. However, Warder (1888) showed that weak solutions of composition $\text{H}_2\text{O} + n\text{HCl}$ when boiled (the residue will be almost $\text{HCl}, 8\text{H}_2\text{O}$) evolve (not water but) a solution containing $\text{H}_2\text{O} + 445n\text{HCl}$; for example, on distilling $\text{HCl}, 10\text{H}_2\text{O}$, a distillate of the composition $\text{HCl}, 23\text{H}_2\text{O}$ is first obtained. As the strength of the residue becomes greater, so also does that of the distillate, and therefore in order to completely absorb hydrochloric acid it is necessary in the end to have recourse to water.

This is done by connecting the ends of the tubes through which the hydrochloric acid gas escapes from the furnace with high chimneys, where a strong draught is set up by the combustion of the fuel. This causes a current of hydrochloric acid gas to pass through the absorbing apparatus in a definite direction. Here it encounters a current of water flowing in the opposite direction, by which it is absorbed. It is not customary to cause the acid to pass through the water, but only to bring it into contact with the surface of the water (to avoid increasing the resistance). The absorption apparatus consists of large earthenware vessels having four orifices, two above and two lateral ones in the wide central portion of each vessel. The upper orifices serve for connecting the vessels together by tubes, and the hydrochloric acid gas escaping from the furnace passes through these tubes. The water for absorbing the acid enters at the upper, and flows out from the lower, vessel, passing through the lateral orifices in the vessels. The water flows from the chimney towards the furnace, and it is therefore evident that the out-flowing water will be the most nearly saturated with acid, of which it actually contains about 20 per cent. The absorption in these vessels is not complete. The ultimate absorption of the hydrochloric acid is carried on in so-called **coke towers**, which usually consist of two adjacent chimneys. A lattice-work of bricks is laid on the bottom of these towers, in which coke is piled up to the top. Water, distributing itself over the coke, trickles down to the bottom of the tower, and in so doing absorbs the hydrochloric acid gas passing upwards.

It will be readily understood that hydrochloric acid may be obtained from all other metallic chlorides.³³ It is frequently formed in other reactions, many of which we shall meet with in the further course of this work. It is, for instance, formed by the direct action of water on sulphur chloride, phosphorus chloride, antimony chloride, &c.

Hydrochloric acid, HCl , is a colourless gas having a pungent, suffocating odour and an acid taste. This gas fumes in air and attracts moisture, because it forms vapour containing a compound of

³³ Those metallic chlorides which are decomposed to a greater or less degree by water correspond with feeble bases. Such are, for example, MgCl_2 , AlCl_3 , SbCl_3 , BiCl_3 . The decomposition of magnesium chloride (and also carnallite) by sulphuric acid proceeds at the ordinary temperature; water decomposes MgCl_2 to the extent of 50 per cent. when aided by heat, and *may be employed as a convenient method for the production of hydrochloric acid*. Hydrochloric acid is also produced by the ignition in a stream of hydrogen of certain metallic chlorides, especially of those metals which are easily reduced—for instance, silver chloride. Lead chloride, when heated to redness in a current of steam, gives hydrochloric acid and lead oxide. The frequency of the formation of hydrochloric acid is understood from the fact that it is a substance which is comparatively very stable, resembling water in this respect, and most probably even more stable than water, because, at a high temperature and even under the action of light, chlorine decomposes water, with the formation of hydrochloric acid.

hydrochloric acid and water. Hydrochloric acid is liquefied by cold, and, under a pressure of 40 atmospheres, into a colourless liquid of sp. gr. about 1.26,³⁴ boiling-point about -84° , freezing-point about -110° , and absolute boiling-point $+50^{\circ}$. We have already seen (Chap. I.) that hydrochloric acid combines very energetically **with water**, and in so doing evolves a considerable amount of heat. The solution saturated in the cold attains a density 1.23. On heating such a solution—containing about 45 per cent. of acid—the hydrochloric acid gas is expelled with only a slight admixture of aqueous vapour. But it is impossible to separate the whole of the hydrochloric acid from the water by this means, as could be done in the case of an ammoniacal solution. The temperature required for the evolution of the gas rises and reaches 110° – 111° , and after this remains constant—that is, a solution having a constant boiling-point is obtained (as with HNO_3), which, however, does not (Roscoe and Dittmar) present a constant composition under different pressures, because the hydrate is decomposed in distillation, as is seen from the determinations of its vapour density (Bineau). Judging from the facts (1) that with decrease of the pressure under which the distillation proceeds the solution of constant boiling-point approaches to a composition of 25 per cent. of hydrochloric acid,³⁵ (2) that by passing a stream of dry air through a solution of hydrochloric acid there is obtained in the residue a solution which also approaches to 25 per cent. of acid, and the more nearly as the temperature falls,³⁶ (3) that many of the properties of solutions of hydrochloric acid vary distinctly according as they contain more or less than 25 per cent. of hydrochloric acid (for instance, antimonious sulphide gives hydrogen sulphide with a stronger acid, but is not acted on by a weaker solution), also a stronger solution fumes in the air, &c., and (4) that the composition $\text{HCl}, 6\text{H}_2\text{O}$ corresponds with 25.26 per cent. HCl —judging from all these data, and also from the loss of pressure which occurs in the combination of hydrochloric acid with water, it may be said that they form a **definite hydrate** of the composition $\text{HCl}, 6\text{H}_2\text{O}$. Besides this not clearly defined hydrate there exists also a crystallo-hydrate, $\text{HCl}, 2\text{H}_2\text{O}$,³⁷ which is formed by the

³⁴ According to Ansdell (1880) the sp. gr. of liquid hydrochloric acid at 0° is 0.908; at 11.67° , 0.854; at 22.7° , 0.808; and at 33° , 0.748. Hence it is seen that the expansion of this liquid is greater than that of gases (Chap. II., note 34).

³⁵ According to Roscoe and Dittmar, at a pressure of three atmospheres the solution of constant boiling-point contains 18 per cent. of hydrogen chloride, and at a pressure of one-tenth of an atmosphere, 23 per cent. The percentages are intermediate at pressures between these two.

³⁶ At 0° , 25 per cent., at 100° , 20.7 per cent.; Roscoe and Dittmar.

³⁷ This crystallo-hydrate (obtained by Pierre and Puchot, and investigated by Roozeboom) is analogous to $\text{NaCl}, 2\text{H}_2\text{O}$. The crystals $\text{HCl}, 2\text{H}_2\text{O}$ at -22° have a specific

absorption of hydrochloric acid by the fuming acid at a temperature of -23° . It crystallises and melts at -18° .³⁸

gravity 1.46; the vapour pressure (under dissociation) of the solution having a composition $\text{HCl}, 2\text{H}_2\text{O}$ at -24° is 760, at -19° , 1,010, at -18° , 1,057, and at -17° , 1,112 mm. of mercury. In a solid state the crystallo-hydrate at -17.7° has the same pressure, whilst at lower temperatures it is much less: at -24° about 150, at -19° about 580 mm. A mixture of fuming hydrochloric acid with snow reduces the temperature to -38° . If another equivalent of water is added to the hydrate $\text{HCl}, 2\text{H}_2\text{O}$ at -18° , the temperature of solidification falls to -25° , and the hydrate $\text{HCl}, 3\text{H}_2\text{O}$ is formed (Pickering, 1893).

³⁸ According to Roscoe, at 0° one *hundred* grams of water at a pressure p (in millimetres of mercury) dissolve—

$p =$	100	200	300	500	700	1,000
Grams HCl	65.7	70.7	73.8	78.2	81.7	85.6

At a pressure of 760 millimetres and temperature t , one *hundred* grams of water dissolve—

$t =$	0	8°	16°	24°	40°	60°
Grams HCl	82.5	78.3	74.2	70.0	63.3	56.1

Bakhius Roozeboom (1886) showed that at t° solutions containing c grams of hydrogen chloride per 100 grams of water may (with the variation of the pressure p) be formed together with the crystallo-hydrate $\text{HCl}, 2\text{H}_2\text{O}$;

$t =$	-23.8°	-21°	-19°	-18°	-17.7°
$c =$	84.2	86.8	92.6	98.4	101.4
$p =$	—	334	580	900	1,073 mm.

The last combination answers to the melted crystallo-hydrate $\text{HCl}, 2\text{H}_2\text{O}$, which splits up at temperatures above -17.7° . At a constant atmospheric pressure when there are no crystals—

$t =$	-24°	-21°	-18°	-10°	0°
$c =$	101.2	98.3	95.7	89.8	84.2

From these data it is seen that the hydrate $\text{HCl}, 2\text{H}_2\text{O}$ can exist in a liquid state, which is not the case with the hydrates of carbonic and sulphurous anhydrides, chlorine, &c.

According to Marignac, the specific heat c of a solution $\text{HCl} + m\text{H}_2\text{O}$ (at about 30° , taking the specific heat of water as 1) is given by the expression—

$$c(36.5 + m18) = 18m - 28.39 + 140/m - 268/m^2,$$

if m be not less than 6.25. For example, for $\text{HCl} + 25\text{H}_2\text{O}$, $c = 0.877$.

According to Thomsen's data, the amount of heat Q , expressed in thousands of calories, evolved in the solution of 36.5 grams of gaseous hydrochloric acid in $m\text{H}_2\text{O}$ or $18m$ grams of water is equal to—

$m =$	2	4	10	50	400
$Q =$	11.4	14.3	16.2	17.1	17.3

In these quantities is included the latent heat of liquefaction, which must be taken as from 5 to 9 thousand calories per molecular quantity of hydrogen chloride.

The researches of Scheffer (1888) on the rate of diffusion (in water) of solutions of hydrochloric acid show that the coefficient of diffusion k decreases with the amount of water n , if the composition of the solution is $\text{HCl}, n\text{H}_2\text{O}$ at 0° :

$n =$	5	6.9	9.8	14	27.1	129.5
$k =$	2.31	2.08	1.86	1.67	1.52	1.39

It also appears that strong solutions diffuse more rapidly into dilute solutions than into water.

The specific gravities S at 15° , taking water at its maximum density (4°) as 10,000, for solutions containing p per cent. of hydrogen chloride are—

p	S	p	S
5	10,242	25	11,266 ³⁹
10	10,490	30	11,522
15	10,744	35	11,773
20	11,001	40	11,997

Solutions of hydrochloric acid present all the **properties of an energetic acid**. They not only transform blue vegetable colouring matter into red, and disengage carbonic acid gas from carbonates, &c., but they also completely saturate bases, even such energetic ones as potash, lime, &c. In a dry state, however, hydrochloric acid does not alter vegetable dyes, and does not effect many double decompositions which take place easily in the presence of water.⁴⁰ This is explained by the fact that the gaseous elastic state of the hydrochloric acid prevents its entering into reaction. However, incandescent iron, zinc, sodium, &c., act on gaseous hydrochloric acid, displacing the hydrogen and leaving half a volume of hydrogen for each volume of hydrochloric acid gas; this reaction may serve for determining the composition of hydrochloric

³⁹ The formula $S = 9,991.6 + 49.43p + 0.0571p^2$, up to $p = 25.26$, which answers to the hydrate $\text{HCl}, 6\text{H}_2\text{O}$ mentioned above, gives the specific gravity. Above this percentage $S = 9,785.1 + 65.10p - 0.240p^2$. The rise of specific gravity with an increase of percentage (or the differential $\frac{ds}{dp}$) reaches a maximum at about 25 per cent. The intermediate solution, $\text{HCl}, 6\text{H}_2\text{O}$, is further distinguished by the fact that the variation of the specific gravity with variation of temperature is a constant quantity, so that the specific gravity of this solution is equal to 11,352.7 ($1 - 0.000447t$), where 0.000447 is the coefficient of expansion of the solution. In the case of more dilute solutions, as with water, the specific gravity per 1° (or the differential $\frac{ds}{dt}$) rises with the temperature.

$p = 0$	5	10	15	20
$S_0 - S_{15} = 7.2$	23	38	52	64
$S_{15} - S_{30} = 34.1$	42	50	59	67

Whilst for solutions which contain a greater proportion of hydrogen chloride than $\text{HCl}, 6\text{H}_2\text{O}$, these coefficients *decrease* with a rise of temperature; for instance, for 30 per cent. of hydrogen chloride, $S_0 - S_{15} = 88$ and $S_{15} - S_{30} = 87$ (according to Marignac's data). In the case of $\text{HCl}, 6\text{H}_2\text{O}$ these differences are constant, and equal 76.

Thus the formation of two definite hydrates, $\text{HCl}, 2\text{H}_2\text{O}$ and $\text{HCl}, 6\text{H}_2\text{O}$, of hydrochloric acid may be accepted upon the basis of many facts. But both of them, if they occur in a liquid state, dissociate with great facility into hydrogen chloride and water, and are completely decomposed when distilled.

⁴⁰ Even a solution of perfectly dry HCl (dried by phosphoric anhydride) in dry benzene does not act upon dry carbonates (Kahlenberg, 1902), naturally because these salts are insoluble in benzene. But dry HCl acts upon dry oleate of copper, because this is soluble in benzene (Chap. I., note 49).

acid. Combined with water, hydrochloric acid acts as an acid much resembling nitric acid⁴¹ in its energy and in many of its reactions; however, the latter contains oxygen, which is disengaged with great ease, and so very frequently acts as an oxidiser, which hydrochloric acid is not capable of doing. The majority of metals (even those which do not displace the H from H_2SO_4 , but which, like copper, decompose it to the limit of SO_2) displace the hydrogen from hydrochloric acid. Thus hydrogen is disengaged by the action of zinc, and even of copper and tin.⁴² Only a few metals withstand its action: for example, gold and platinum. Lead in compact masses is only feebly acted upon, because the lead chloride formed is insoluble and prevents the further action of the acid on the metal. The same is to be remarked with respect to the feeble action of hydrochloric acid on mercury and silver, because the compounds of these metals, AgCl and HgCl , are insoluble in water. **Metallic chlorides** are not only formed by the action of hydrochloric acid on the metals, but also by many other methods; for instance, by the action of hydrochloric acid on the carbonates, oxides, and hydroxides, and also by the action of chlorine on metals and certain of their compounds. Metallic chlorides have a composition MCl (for example, NaCl , KCl , AgCl , HgCl) if the metal replaces hydrogen, equivalent for equivalent, or, as it is said, if it is monatomic or univalent. In the case of bivalent metals, they have a composition MCl_2 ; for example, CaCl_2 , CuCl_2 , PbCl_2 , HgCl_2 , FeCl_2 , MnCl_2 . The composition of the haloid salts of other metals determines their atomicity; for example, AlCl_3 , PtCl_4 , &c. Many metals, for instance, Fe, give several degrees of combination with chlorine (FeCl_2 , FeCl_3), as with hydrogen. In their composition the metallic chlorides differ from the corresponding oxides, in that the O is replaced by Cl_2 , as should follow from the law of substitution, because oxygen gives OH_2 , and is consequently di-atomic, whilst chlorine forms HCl , and is therefore univalent. So, for instance, ferrous oxide, FeO , corresponds with ferrous chloride, FeCl_2 , and the oxide Fe_2O_3 with ferric chloride, Fe_2Cl_6 or FeCl_3 , as is also seen from the origin of these compounds, for FeCl_2 is obtained by the action of hydrochloric acid on ferrous oxide or carbonate and FeCl_3 by its action on ferric oxide. In a word, all the typical properties of acids are shown by hydrochloric acid.

⁴¹ Thus, for instance, with feeble bases they evolve in dilute solutions (Chap. III., note 53) almost equal amounts of heat; their relation to sulphuric acid is quite identical. They both form fuming solutions as well as hydrates; they both form solutions of constant boiling-point.

⁴² Ribalkin (1891) found that copper begins to disengage hydrogen at 100° , and that chloride of copper begins to give up its chlorine to hydrogen gas at 230° ; for silver these temperatures are 117° and 200° —that is, there is less difference between them.

and all the typical properties of salts by the metallic chlorides derived from it. Acids and salts without any oxygen bear the name of **haloid salts**; for instance, HCl is a haloid acid, NaCl a haloid salt, chlorine a halogen. The capacity of hydrochloric acid to give, by its action on bases, MO, a metallic chloride, MCl_2 , and water, is limited at high temperatures by the reverse reaction, $MCl_2 + H_2O = MO + 2HCl$, and the more pronounced the basic properties of MO the feebler is the reverse action, while for feeble bases such as Al_2O_3 , MgO, &c., this reverse reaction proceeds with ease. Metallic chlorides corresponding with the peroxides either do not exist, or are easily decomposed with the disengagement of chlorine. Thus there is no compound $BaCl_4$ corresponding with the peroxide BaO_2 . Metallic chlorides having the general aspect of salts, like their representative sodium chloride, are, as a rule, easily fusible, more so than the oxides (for instance, CaO is fusible at a furnace heat, whilst $CaCl_2$ is easily fused) and many other salts. Under the action of heat many chlorides are more stable than the oxides, and some can even be converted into vapour; thus corrosive sublimate, $HgCl_2$, is particularly volatile, whilst the oxide HgO decomposes at a red heat. Silver chloride, AgCl, is fusible and is decomposed with difficulty, whilst Ag_2O is easily decomposed. The majority of the metallic chlorides are soluble in water, but silver chloride, cuprous chloride, mercurous chloride, and lead chloride are sparingly soluble in water, and are therefore easily obtained as precipitates when solutions of the salts of these metals are mixed with a solution of any chloride or even with hydrochloric acid. The metal contained in a haloid salt may often be replaced by another metal, or even by hydrogen, just as is the case with a metal in an oxide. Thus, copper displaces mercury from a solution of mercuric chloride, $HgCl_2 + Cu = CuCl_2 + Hg$, and hydrogen at a red heat displaces silver from silver chloride, $2AgCl + H_2 = Ag_2 + 2HCl$. These, and a whole series of similar reactions, form the typical methods of double saline decompositions. The measure of decomposition and the conditions under which reactions of double saline decomposition proceed in one or the other direction are determined by the properties of the compounds which take part in the reaction, and of those capable of formation at the particular temperature, &c., employed, as was shown in the preceding portions of this chapter, and as will be frequently found hereafter.

If hydrochloric acid enters into double decomposition with basic oxides and their hydrates, this is only due to its acid properties; and for the same reason it rarely enters into double decomposition with acids and acid anhydrides. Sometimes, however, it combines with the

latter, as, for instance, with the anhydride of sulphuric acid, forming the compound SO_3HCl ; and in other cases it acts on acids, giving up its hydrogen to their oxygen and forming chlorine, as will be seen in the following chapter.

Hydrochloric acid, as may already be concluded from the composition of its molecule, belongs to the monobasic acids, and does not, therefore, give true acid salts (like HNaSO_4 or HNaCO_3); nevertheless many metallic chlorides, formed from powerful bases, are capable of **combining with hydrochloric acid**, just as they combine with water, or with ammonia, or give double salts. Compounds have long been known of hydrochloric acid with auric, platinic, and antimonious chlorides, and other similar metallic chlorides corresponding with very feeble bases. But Berthelot, Engel, and others have shown that the capacity of HCl for combining with M_nCl_n is much more frequently encountered than was previously supposed. Thus, for instance, dry hydrochloric acid when passed into a solution of zinc chloride (containing an excess of the salt) gives in the cold (0°) a compound, $\text{HCl}, \text{ZnCl}_2, 2\text{H}_2\text{O}$, and at the ordinary temperature, $\text{HCl}, 2\text{ZnCl}_2, 2\text{H}_2\text{O}$, just as it is able at low temperatures to form the crystallo-hydrate, $\text{ZnCl}_2, 2\text{H}_2\text{O}$ (Engel, 1886). Similar compounds are obtained with $\text{CdCl}_2, \text{CuCl}_2, \text{HgCl}_2, \text{Fe}_2\text{Cl}_6$, &c. (Berthelot, Ditte, Cheltzoff, Lachinoff, and others). These compounds with hydrochloric acid are generally more soluble in water than the metallic chlorides themselves, so that whilst hydrochloric acid decreases the solubility of M_nCl_n , corresponding with energetic bases (for instance, sodium or barium chlorides), it increases the solubility of the metallic chlorides corresponding with feeble bases (cadmium chloride, ferric chloride, &c.). Silver chloride, which is insoluble in water, is soluble in hydrochloric acid. Hydrochloric acid also combines with certain unsaturated hydrocarbons (for instance, with turpentine, $\text{C}_{10}\text{H}_{16}, 2\text{HCl}$) and their derivatives.⁴³ **Sal-ammoniac**, or **ammonia hydrochloride**, $\text{NH}_4\text{Cl} = \text{NH}_3, \text{HCl}$, also belongs to this class of compounds. If hydrogen chloride gas is mixed with ammonia gas a solid compound consisting of equal volumes of each is immediately formed. The same

⁴³ When an unsaturated hydrocarbon, or, in general, an unsaturated compound, assimilates to itself the molecules $\text{Cl}_2, \text{HCl}, \text{SO}_3, \text{H}_2\text{SO}_4$, &c., the cause of the reaction is best conceived as the attainment of the limit. As nitrogen, besides the type NX_3 to which NH_3 belongs, gives compounds of the type NX_5 —for example, $\text{NO}_2(\text{OH})$ —the formation of the salts of ammonium should be understood in this way. NH_3 gives NH_4Cl because NX_3 is capable of giving NX_5 . But as saturated limiting compounds—for instance, $\text{SO}_3, \text{H}_2\text{O}, \text{NaCl}$, &c.—are also capable of combination even between themselves, it is impossible to deny the capacity of HCl also for combination. SO_3 combines with H_2O and also with HCl and the unsaturated hydrocarbons. It is impossible to recognise the distinction between atomic and molecular compounds, and to regard, for instance, PCl_3 as an atomic compound and PCl_5 as a molecular one.

compound is obtained on mixing solutions of the two gases. It is also produced by the action of hydrochloric acid on ammonium carbonate. Sal-ammoniac is usually prepared, in practice, by the last method.⁴⁴ The specific gravity of sal-ammoniac is 1.55. We have already seen (Chap. VI.) that sal-ammoniac, like all other ammonium salts, easily decomposes; for instance, by distillation with alkalies, and even partially when its solution is boiled. The other properties and reactions of sal-ammoniac, especially in solution, fully recall those already mentioned in speaking of sodium chloride. Thus, for instance, with silver nitrate it gives a precipitate of silver chloride; with sulphuric acid it gives hydrochloric acid and ammonium sulphate, and it forms double salts with certain metallic chlorides and other salts.⁴⁵ The aqueous solutions of the chlorides and of HCl are electrolytes, and give chlorine at the anode.

⁴⁴ Sal-ammoniac is prepared from ammonium carbonate, obtained in the dry distillation of nitrogenous substances (Chapter VI.), by saturating the resultant solution with hydrochloric acid. A solution of sal-ammoniac is thus produced, which is evaporated, and in the residue a mass is obtained containing also a mixture of various other, especially tarry, products of dry distillation. The sal-ammoniac is generally purified by sublimation. For this purpose iron vessels covered with hemispherical metallic covers are employed, or else simply clay crucibles covered by other crucibles. The upper portion, or head, of the apparatus of this kind will have a lower temperature than the lower portion, which is under the direct action of the flame. The sal-ammoniac volatilises when heated, and settles on the cooler portion of the apparatus. It is thus freed from many impurities, and is obtained as a crystalline crust, generally several centimetres thick, in which form it is commonly sold. The solubility of sal-ammoniac rises rapidly with the temperature: at 0°, 100 parts of water dissolve about 28 parts of NH_4Cl , at 50° about 50 parts, and at the ordinary temperature about 35 parts. This is sometimes taken advantage of for separating NH_4Cl from solutions of other salts.

⁴⁵ The solubility of sal-ammoniac in 100 parts of water (according to Alluard) is—

0°	10°	20°	30°	40°	60°	80°	100°	110°
28.40	32.48	37.28	41.72	46	55	64	73	77

A saturated solution boils at 115.8°. The specific gravity at 15°/4° of solutions of sal-ammoniac (water at 4° = 10,000) is given by $9,991.6 + 31.26p - 0.085p^2$, where p is the amount by weight of ammonium chloride in 100 parts by weight of solution. With the majority of salts the differential ds/dp increases, but here it decreases, with increase of p . For (unlike the sodium and potassium salts) a solution of the alkali *plus* a solution of acid occupy a greater volume than that of the resultant ammonium salt. In the solution of *solid* ammonium chloride a contraction, and not an expansion, generally takes place. It may further be remarked that solutions of sal-ammoniac have an acid reaction even when prepared from the salt remaining after prolonged washing of the sublimed salt with water (A. Stecherbakoff).

CHAPTER XI

THE HALOGENS: CHLORINE, BROMINE, IODINE, AND FLUORINE

ALTHOUGH hydrochloric acid, like water, is one of the most stable substances, it is nevertheless decomposed not only by the action of a galvanic current, but also by a high temperature.¹ Sainte-Claire Deville showed that decomposition occurs even at 1300°, because a cold tube (as with CO, Chap. IX.) covered with an amalgam of silver absorbs chlorine from hydrochloric acid in a red-hot tube, and the escaping gas contains hydrogen. V. Meyer and Langer (1885) demonstrated the decomposition of hydrochloric acid when mixed with nitrogen at 1690° in a platinum vessel, not only from the fact that the hydrogen diffuses through the platinum, but also from chlorine being obtained which liberated iodine from potassium iodide.² The usual method for

¹ The decomposition of fused sodium chloride by an electric current is employed as a means for the preparation of chlorine and sodium. A strong solution of hydrochloric acid is decomposed into equal volumes of chlorine and hydrogen by the action of an electric current. If sodium chloride and lead are melted in a crucible, the former being connected with the cathode and a carbon anode immersed in the lead, the lead dissolves the sodium, and chlorine is disengaged as gas. This electrolytic method is practised on a large scale.

At the close of the nineteenth century the evolution of chlorine at the anode in the electrolysis of solutions of the chlorides became of practical importance, especially in Germany, the United States, and England, the metals deposited at the cathode being, however, the chief object in the treatment. The chlorine here appears as a by- (and therefore cheap) product, and finds a market, mostly in the form of bleaching salts. For instance in the separation (and refining) of copper and zinc, these metals are obtained in the form of chlorides (by means of HCl or NaCl) in solution, and the electrolysis of this solution gives the metal and at the anode chlorine. In the electrolytic decomposition of carnallite for the preparation of magnesium: $\text{KMgCl}_3 = \text{KCl} + \text{Mg} + \text{Cl}_2$, &c. Strong solutions of NaCl by electrolysis, also give chlorine, and the sodium separated at the cathode (which is made of mercury to dissolve the sodium) gives caustic soda under the action of water, so that the chlorine here again appears as a by-product. Electrolytic methods will now undoubtedly replace all the above-described methods for the preparation of chlorine (from HCl, by removing the H by oxygen or higher oxides), especially where it is possible to employ water power instead of steam as a motive power for the dynamo.

² To obtain so high a temperature (at which the best kinds of porcelain soften) Langer and Meyer employed the dense graphitoidal carbon from gas retorts, and a powerful blast.

the preparation of chlorine consists in the abstraction of the hydrogen by oxidising agents.^{2a}

The hydrogen has to be abstracted from the hydrochloric acid. This is accomplished by nearly all oxidising substances, and especially by those which are able to evolve oxygen at a red heat (besides bases, such as mercury and silver oxides, which are able to give salts with hydrogen chloride), for example, manganese dioxide, potassium chlorate, chromic acid, &c. The decomposition essentially consists in the oxygen of the oxidising substance displacing the chlorine from 2HCl , forming water, H_2O , and setting the chlorine free, $2\text{HCl} + \text{O}$ (disengaged by the oxidising substances) $= \text{H}_2\text{O} + \text{Cl}_2$. Even nitric acid partially produces a like reaction; but its action is more complicated, and is accompanied by the formation of oxides of nitrogen, and it is therefore not suitable for the preparation of pure chlorine.³ But other oxidising substances which do not give volatile products with hydrochloric acid may be employed for the preparation of chlorine. Among these may be mentioned: potassium chlorate, acid potassium chromate, sodium manganate, manganese dioxide, &c. Since Scheele's time (1774) manganese dioxide has been commonly employed in the laboratory, and on a large scale, for the preparation of chlorine. The chemical process in this case may be represented as follows: an exchange takes place between 4HCl and MnO_2 , in which the manganese takes the place of the four atoms of hydrogen, or the chlorine and oxygen exchange

^{2a} The acid properties of hydrochloric acid were known when Lavoisier pointed out the formation of acids by the combination of water with the oxides of the non-metals, and there was therefore reason for thinking that hydrochloric acid was also an oxygen acid. When Scheele obtained chlorine by the action of hydrochloric acid on manganese peroxide he considered it as the acid contained in common salt. When it became known that chlorine gives hydrochloric acid with hydrogen, Lavoisier and Berthollet supposed it to be a compound with oxygen of an anhydride contained in hydrochloric acid. They supposed that hydrochloric acid contained water and the oxide of a particular radicle, and that chlorine was a higher degree of oxidation of this radicle *urias* (from the Latin name of hydrochloric acid, *acidum muriaticum*). It was only in 1811 that Gay-Lussac and Thénard in France, and Davy in England, arrived at the conclusion that the substance obtained by Scheele does not contain oxygen, nor give water with hydrogen under any conditions, and that there is no water in hydrochloric acid gas, and that chlorine is an elementary substance. They named it 'chlorine' from the Greek word *χλωρός*, signifying a green colour, because of the peculiar colour by which this gas is characterised.

³ However, nitric acid has been proposed as a means for obtaining chlorine, but by methods which have the drawback of being very complicated. As nitric acid is able to take up the hydrogen from HCl , chlorine is sometimes prepared by heating a mixture of nitric and hydrochloric acids. The resultant mixture of chlorine and lower oxides of nitrogen is subjected to the action of air and steam, which give HNO_3 again, and the chlorine remains as a gas together with nitrogen, in which form it is quite suitable for bleaching or for the preparation of bleaching powder, &c.

places—that is, MnCl_4 and $2\text{H}_2\text{O}$ are produced. The chlorine compound, MnCl_4 , obtained is very unstable; it splits up into chlorine, which as a gas passes from the sphere of action, and a salt, MnCl_2 , containing less chlorine, $\text{MnCl}_4 = \text{MnCl}_2 + \text{Cl}_2$.^{3a} The action of hydrochloric acid requires a temperature of about 100° . In the laboratory the **preparation of chlorine** is carried on in flasks, heated over a water-bath, by acting on manganese peroxide with hydrochloric acid or a

^{3a} This representation of the process of the reaction is the most natural. However, this decomposition is generally represented as if chlorine gave only one degree of combination with manganese, MnCl_2 , and therefore directly reacts in the following manner— $\text{MnO}_2 + 4\text{HCl} = \text{MnCl}_2 + 2\text{H}_2\text{O} + \text{Cl}_2$, in which case it is supposed that manganese peroxide, MnO_2 , breaks up, as it were, into manganous oxide, MnO , and oxygen, both of which react with hydrochloric acid, the manganous oxide acting upon HCl as a base, giving MnCl_2 and at the same time, $2\text{HCl} + \text{O} = \text{H}_2\text{O} + \text{Cl}_2$. In reality, a mixture of oxygen and hydrochloric acid does give chlorine at a red heat, and this reaction may also take place at the moment of its evolution in this case.

All the oxides of manganese (Mn_2O_3 , MnO_2 , MnO_3 , Mn_2O_7), with the exception of manganous oxide, MnO , disengage chlorine from hydrochloric acid, because manganous chloride, MnCl_2 , is the only compound of chlorine and manganese which exists as a stable compound, all the higher chlorides of manganese being unstable and evolving chlorine. MnCl_4 is unknown, but MnCl_3 has been obtained, but it readily (even in double salts) evolves chlorine. In general many of the higher compounds of chlorine with the metals are able to part with a portion of their chlorine. Amongst them may be mentioned antimony pentachloride, SbCl_5 , which splits up into chlorine and antimony trichloride when heated. **Cupric chloride**, corresponding with copper oxide, and having a composition CuCl_2 , similar to CuO , when heated parts with half its chlorine, just as barium peroxide evolves half its oxygen. This method may even be taken advantage of for the preparation of chlorine and cuprous chloride, CuCl . The latter attracts oxygen from the atmosphere, and in so doing is converted from a colourless substance into a green compound whose composition is $\text{Cu}_2\text{Cl}_2\text{O}$. With hydrochloric acid this substance gives cupric chloride ($\text{Cu}_2\text{Cl}_2\text{O} + 2\text{HCl} = \text{H}_2\text{O} + 2\text{CuCl}_2$), which has only to be dried and heated in order again to obtain chlorine. On this property is founded Deacon's process for the preparation of chlorine from hydrochloric acid with the aid of air and copper salts, by passing a mixture of air and hydrochloric acid at about 440° over bricks saturated with a solution of a copper salt (a mixture of solutions of CuSO_4 and Na_2SO_4). CuCl_2 is then formed by the double decomposition of the salt of copper and the hydrochloric acid; the CuCl_2 liberates chlorine and the CuCl forms $\text{Cu}_2\text{Cl}_2\text{O}$ with the oxygen of the air, which again gives CuCl_2 with 2HCl , and so on. However, all the HCl cannot be converted into chlorine by this process, but only about one half of it.

Magnesium chloride, which is obtained from sea-water, carnallite, &c., may serve not only as a means for the preparation of hydrochloric acid, but also of chlorine, because its basic salt (Mg_2OCl_2) when heated in the air gives magnesium oxide and chlorine (Weldon-Pechiney's process, 1884). Chlorine is now prepared on a large scale by this method. Besides these, Solvay and Mond's methods of preparing chlorine must be mentioned. The first is based upon the reaction, $\text{CaCl}_2 + \text{SiO}_2 + \text{O}(\text{air}) = \text{CaOSiO}_2 + \text{Cl}_2$, and the second on the action of the oxygen of the air (heated) upon MgCl_2 (and certain similar chlorides) $\text{MgCl}_2 + \text{O} = \text{MgO} + \text{Cl}_2$. The remaining MgO is treated with sal-ammoniac to re-form MgCl_2 ($\text{MgO} + 2\text{NH}_4\text{Cl} = \text{MgCl}_2 + \text{H}_2\text{O} + 2\text{NH}_3$) and the resultant NH_3 again converted into sal-ammoniac, so that hydrochloric acid is the only substance consumed. The latter processes have not found much application, having been ousted by electrolysis.

mixture of common salt and sulphuric acid ⁴ and washing the gas with water to remove hydrochloric acid.⁵ Chlorine cannot be collected over mercury, because it combines with it as with many other metals, and it is soluble in water; however, it is but slightly soluble in hot water or brine. Owing to its great weight (its density referred to hydrogen is about 36 and to air about 2.5) chlorine may be directly collected in a dry vessel by carrying the gas-conducting tube down to the bottom of the vessel. The chlorine will lie in a heavy layer at the bottom of the vessel, displace the air, and the extent to which it fills the vessel may be followed by its colour.⁶

⁴ The following proportions are accordingly taken by weight: 5 parts of powdered manganese peroxide, 11 parts of salt (best fused, to prevent its frothing), and 14 parts of sulphuric acid previously mixed with an equal volume of water. The mixture is heated in a salt bath, so as to obtain a temperature above 100°. The corks in the apparatus must be soaked in paraffin (otherwise they are corroded by the chlorine), and black india-rubber tubing smeared with vaseline must be used, not vulcanised rubber (which contains sulphur, and becomes brittle under the action of the chlorine).

The reaction which proceeds may be expressed thus: $\text{MnO}_2 + 2\text{NaCl} + 2\text{H}_2\text{SO}_4 = \text{MnSO}_4 + \text{Na}_2\text{SO}_4 + 2\text{H}_2\text{O} + \text{Cl}_2$. The method of preparation of Cl_2 from manganese peroxide and hydrochloric acid was discovered by Scheele, and from sodium chloride by Berthollet.

⁵ The reaction of hydrochloric acid upon bleaching powder gives chlorine without the aid of heat, $\text{CaCl}_2\text{O}_2 + 4\text{HCl} = \text{CaCl}_2 + 2\text{H}_2\text{O} + 2\text{Cl}_2$, and is therefore also used for the preparation of chlorine. This reaction is very violent if all the acid is added at once; it should be poured in drop by drop. C. Winkler proposed to mix bleaching powder with one quarter of its weight of burnt and powdered gypsum, and having damped the mixture with water, to press and cut it up into cubes and dry at the ordinary temperature. These cubes can be used for the preparation of chlorine in the same apparatus as that used for the evolution of hydrogen and carbonic anhydride—the disengagement of the chlorine proceeds uniformly.

A mixture of potassium dichromate and hydrochloric acid evolves chlorine perfectly free from oxygen (V. Meyer and Langer). Graebe (1902) showed that the gradual addition of hydrochloric acid (360 grms. of sp. gr. 1.17) to permanganate of potassium (50 grms.) gives a uniform stream of chlorine, exactly according to the equation, $\text{KMnO}_4 + 8\text{HCl} = \text{KCl} + \text{MnCl}_2 + 4\text{H}_2\text{O} + 5\text{Cl}$.

⁶ Chlorine is manufactured on a **large scale** from manganese peroxide and hydrochloric acid. It is most conveniently prepared in the apparatus shown in fig. 76, which consists of a three-necked earthenware vessel, the central orifice of which is the largest. A clay or lead funnel, furnished with a number of orifices, is placed in the central wide neck of the vessel. Roughly ground lumps of natural manganese peroxide are placed in the funnel, which is then closed by the cover N, and luted with clay. One orifice is closed by a clay stopper, and is used for the introduction of the hydrochloric acid and the withdrawal of the residues. The chlorine disengaged passes along a leaden gas-conducting tube fixed in the other orifice. A row of these vessels is surrounded by a water-bath to ensure their being uniformly heated. Manganese chloride is found in the residue. In Weldon's process lime is added to the acid solution of manganese chloride. A double decomposition takes place, resulting in the formation of manganous hydroxide and calcium chloride. When the insoluble manganous hydroxide has settled, a further excess of milk of lime is added (to make a

FIG. 76.—Clay retort for the preparation of chlorine on a large scale.

Chlorine is a **gas** of a yellowish-green colour, and has a very suffocating and characteristic odour. On lowering the temperature to -50° or increasing the pressure to six atmospheres (at 0°) chlorine condenses⁷ into a liquid which has a yellowish-green colour, a density of 1.4, and boils at -34° and solidifies about -100° . The density and atomic weight of chlorine are 35.5 times greater than those of hydrogen, hence the molecule contains Cl_2 .⁸ At 0° one volume of water dissolves about $1\frac{1}{2}$ volume of chlorine, at 10° about 3 volumes, at 50° again $1\frac{1}{2}$ volume.⁹ Such a solution of chlorine is termed chlorine water, and is employed in a diluted form in medicine and as a laboratory reagent. It is prepared by passing chlorine through a series of Woulfe's bottles or into an inverted retort filled with water. Under the action of light, chlorine water gives oxygen and hydrochloric acid. At 0° a saturated solution of chlorine yields a crystallo-hydrate, $\text{Cl}_2, 8\text{H}_2\text{O}$, which readily splits up into chlorine and water when heated, so that if

mixture $2\text{Mn}(\text{OH})_2 + \text{CaO} + x\text{CaCl}_2$, which are found by experiment to be the best proportions), and then air is forced through the mixture. The hydroxide is thus converted from a colourless to a brown substance, containing peroxide, MnO_2 , and oxide of manganese, Mn_2O_3 . This is due to the manganous oxide absorbing oxygen from the air. Under the action of hydrochloric acid this mixture evolves chlorine, because, of all the compounds of chlorine and manganese, the chloride MnCl_2 is the only one which is stable (see note 3). Thus one and the same mass of manganese may be repeatedly used for the preparation of chlorine. The same result is attained in other ways. If manganous oxide is subjected to the action of oxides of nitrogen and air (Coleman's process), manganese nitrate is formed, which at a red heat gives oxides of nitrogen (which are again used in the process) and manganese peroxide, which is thus renewed for the fresh evolution of chlorine.

⁷ Davy and Faraday liquefied chlorine in 1823 by heating the crystallo-hydrate, $\text{Cl}_2, 8\text{H}_2\text{O}$, in a bent tube (as with NH_3), surrounded by warm water, while the other end of the tube was immersed in a freezing mixture. Melsens condensed chlorine in freshly burnt charcoal (placed in a glass tube), which when cold absorbs an equal weight of chlorine. The tube was then fused up, the bent end cooled, and the charcoal heated, by which means the chlorine was expelled from the charcoal, and the pressure increased, as must be done in order to liquefy the gas.

⁸ V. Meyer and Langer (1885) having remarked that at 1400° the density of chlorine (taking its expansion as equal to that of nitrogen) is 29, consider that the molecules of chlorine partially split up and give molecules Cl , but it might be maintained that the decrease in density observed only depends on the increase of the coefficient of expansion.

⁹ The equilibrium between chlorine and steam as gases and between water, liquid chlorine, ice, and the solid crystallo-hydrate of chlorine, is evidently very complex. Gibbs, Guldberg (1870), and others gave a theory for similar states of equilibrium (strictly speaking phases), which was afterwards developed by Roozeboom (1887); but it would be inopportune here to enter into its details, which belong to the province of physical and theoretical chemistry. It will be sufficient in the first place to mention that there is now no doubt (according to the theory of heat, and the direct observations of Ramsay and Young) that the vapour pressures at one and the same temperature are different for the liquid and solid states of substances; secondly, to call attention to the following note; and, thirdly, to state that, in the presence of the crystallo-hydrate, water between 0.24° and $+28.7^{\circ}$ (when the hydrate and a solution may occur simultaneously) dissolves an amount of chlorine different from that dissolved in the absence of the crystallo-hydrate.

it be sealed up in a tube and heated to 35° , two layers of liquid are formed—a lower stratum of chlorine containing a small quantity of water, and an upper stratum of water containing a small quantity of chlorine.¹⁰

Chlorine explodes **with hydrogen**, if a mixture of equal volumes be exposed to the direct action of the sun's rays¹¹ or brought into contact with spongy platinum or a strongly heated substance, or subjected to the action of an electric spark. The explosion in this case takes place for exactly the same reasons—i.e., the evolution of heat and expansion of the resultant product—as in the case of detonating gas (Chap. III.). Diffused light acts in the same way, but slowly, whilst direct sunlight causes an explosion.¹² The hydrochloric acid gas produced by the

¹⁰ According to Faraday's data the hydrate of chlorine contains $\text{Cl}_2, 10\text{H}_2\text{O}$, but Roozeboom (1885) showed that it is poorer in water and has the composition $\text{Cl}_2, 8\text{H}_2\text{O}$. At first small, almost colourless, crystals are obtained, but they gradually form (if the temperature be below their critical point 28.7° , above which they do not exist) large yellow crystals, like those of potassium chromate. The specific gravity is 1.23. The hydrate is formed if there is more chlorine in a solution than it is able to dissolve under the dissociation pressure corresponding with a given temperature. *In the presence of the hydrate* the percentage amount of chlorine is 0.5 at 0° , 0.9 at 9° , and 1.82 at 20° . At temperatures below 9° the solubility is dependent on the formation of the hydrate; whilst at higher temperatures under the ordinary pressure the hydrate cannot be formed, and the solubility of chlorine falls, as it does for all gases (Chap. I.). If the crystallo-hydrate is not formed, then below 9° the solubility follows the same rule (at 6° , 1.07 per cent. Cl_2 , and at 9° , 0.95 per cent.). According to Roozeboom, the chlorine evolved by the hydrate presents the following dissociation pressures: 249 mm. at 0° , 398 at 4° , 620 at 8° , 797 at 10° , and 1,400 mm. at 14° . In this case a portion of the crystallo-hydrate remains solid. At 9.6° the pressure of dissociation is equal to the atmospheric pressure. At a higher pressure the crystallo-hydrate may form at temperatures above 9° and up to 28.7° , when the vapour pressure of the hydrate equals the pressure of the chlorine. It is evident that the equilibrium which is established is on the one hand a case of a complex heterogeneous system, and on the other hand a case of the solution of solid and gaseous substances in water.

The crystallo-hydrate or chlorine water must be kept in the dark, or the access of light prevented by coloured glass, otherwise oxygen is evolved and hydrochloric acid formed.

¹¹ The chemical action of light on a mixture of chlorine and hydrogen was discovered by Gay-Lussac and Thénard (1809). It has been investigated by many savants, and especially by Draper, Bunsen, and Roscoe. Electric or magnesium light, or the light emitted by the combustion of carbon bisulphide in nitric oxide, and actinic light in general, acts in proportion to its intensity, in the same manner as sunlight. At temperatures below -12° , light no longer brings about reaction, or at all events does not give an explosion. It was long supposed that chlorine that had been subjected to the action of light was afterwards able to act on hydrogen in the dark, but it was shown that this only takes place with moist chlorine, and depends on the formation of oxides of chlorine. The presence of foreign gases, and even of excess of chlorine or of hydrogen, very much enfeebles the explosion, and the experiment is therefore conducted with a detonating mixture prepared by the action of an electric current on a strong solution (sp. gr. 1.15) of hydrochloric acid, in which case the water is not decomposed—that is, no oxygen becomes mixed with the chlorine.

¹² The quantity of chlorine and hydrogen which combine is proportional to the intensity of the light—not of all the rays, but only of those so-called chemical (actinic) rays which

reaction of chlorine on hydrogen occupies (at the original temperature and pressure) a volume equal to the sum of the original volumes; that is, a reaction of substitution here takes place: $\text{H}_2 + \text{Cl}_2 = 2\text{HCl}$. In this reaction twenty-two thousand heat units are evolved for one part by weight (1 gram) of hydrogen.¹³

These relations show that the affinity of chlorine for hydrogen is very great and analogous to that between hydrogen and oxygen. Thus,¹⁴ on the one hand by passing a mixture of steam and chlorine through a red-hot tube, or by exposing water and chlorine to the sunlight, oxygen is disengaged, while on the other hand, as we saw above, oxygen in many cases displaces chlorine from its compound with

produce chemical action. Hence a mixture of chlorine and hydrogen, when exposed to the action of light in vessels of given capacity and surface, may be employed as an actinometer. Investigations of this kind (photo-chemical) showed that chemical action is chiefly limited to the violet end of the spectrum, and that even the invisible ultra-violet rays produce this action. A colourless gas flame contains no chemically active rays; the flame coloured green by a salt of copper evinces more chemical action than the colourless flame, but the flame coloured bright yellow by salts of sodium has no more chemical action than that of the colourless flame.

As the chemical action of light becomes evident in plants, photography, the bleaching of tissues, and the fading of colours in the sunlight, and as a means for studying the phenomenon is given in the reaction of chlorine on hydrogen, this subject has been the most fully investigated in **photo-chemistry**. The researches of Bunsen and Roscoe in the fifties and sixties form the basis of our knowledge of this subject. Their actinometer contains hydrogen and chlorine, and is surrounded by a solution of chlorine in water. The hydrochloric acid is absorbed as it forms, and therefore the variation in volume indicates the progress of the combination. The action of light proved, as might have been expected, to be proportional to the time of exposure and intensity of the light, so that it was possible to conduct detailed photometrical investigations respecting the time of day and season of the year, various sources of light, its absorption, &c. This subject is considered in detail in photo-chemistry.

As much heat is evolved in the reaction of chlorine on hydrogen, and as this reaction, being exothermal, may proceed by itself, the action of light is essentially the same as that of heat—that is, it brings the chlorine and hydrogen into the condition necessary for the reaction—it, as we may say, disturbs the original equilibrium; this is the work done by the luminous energy. It seems to me that the action of light on the mixed gases should be understood in this sense, as Pringsheim (1877) pointed out.

¹³ In the formation of steam (from one part by weight [1 gram] of hydrogen) 29,000 heat units are evolved. The following are the quantities of heat (thousands of units) evolved in the formation of various other *corresponding* compounds of oxygen and of chlorine (from Thomsen's, and, for Na_2O , Beketoff's results):

{ 2NaCl, 195;	CaCl ₂ , 170;	HgCl ₂ , 63;	2AgCl, 59.
{ Na ₂ O, 100;	CaO, 131;	HgO, 42;	Ag ₂ O, 6.
{ 2AsCl ₃ , 143;	2PCl ₅ , 210;	CCl ₄ , 21;	2HCl, 44 (gas).
{ As ₂ O ₃ , 155;	P ₂ O ₅ , 370;	CO ₂ , 97;	H ₂ O, 58 (gas).

With the first four elements the formation of the chlorine compound gives the more heat, and with the four following the formation of the oxygen compound evolves the greater amount of heat. The first four chlorides are true salts formed from HCl and the oxide, whilst the remainder have other properties, as is seen from the fact that they are not formed from hydrochloric acid and the oxide, but give hydrochloric acid with water.

¹⁴ This has been already pointed out in Chap. III., note 5.

hydrogen, and therefore the reaction, $\text{H}_2\text{O} + \text{Cl}_2 \rightleftharpoons 2\text{HCl} + \text{O}$, belongs to the class of reversible reactions, and hydrogen will distribute itself between oxygen and chlorine. This determines the relation of Cl to substances containing hydrogen and its reactions in the presence of water, to which we shall turn our attention after having pointed out the relation of chlorine to other elements.

Many **metals** when brought into contact with chlorine immediately combine with it, and form metallic chlorides corresponding with hydrogen chloride and with the oxide of the metal taken. This combination may proceed rapidly with the evolution of heat and light; that is, metals are able to burn in chlorine. Thus, for example, sodium¹⁵ burns in chlorine, synthesising common salt. Metals in the form of powder burn without the aid of heat, and become highly incandescent in the process; for instance, antimony, which is a metal readily convertible into a powder.¹⁶ Even such metals as gold and platinum,¹⁷ which do not combine directly with oxygen, and give very unstable compounds with it, unite directly with chlorine to form metallic chlorides. Either chlorine water or aqua regia may be employed for this purpose instead of gaseous chlorine. These dissolve gold and platinum, converting them into metallic chlorides. **Aqua regia** is a mixture of 1 part of nitric acid with 2 to 3 parts of hydrochloric acid.^{17a} This mixture converts into soluble chlorides, not only those metals which are acted on by hydrochloric and nitric acids, but also gold and platinum, which are insoluble in either acid separately. This action of aqua regia depends on the fact that nitric acid in acting

¹⁵ Sodium remains unaltered in perfectly dry chlorine at the ordinary temperature, and even when slightly warmed; but the combination is exceedingly violent at a red heat.

¹⁶ An instructive experiment on combustion in chlorine may be conducted as follows: leaves of Dutch metal (used instead of gold for gilding) are placed in a glass globe, and a gas-conducting tube furnished with a glass cock placed in the cork closing it, the air being then pumped out of the globe. The gas-conducting tube is then connected with a vessel containing chlorine, and the cock opened; the chlorine rushes in, and the metallic leaves are consumed.

¹⁷ The behaviour of platinum to chlorine at a high temperature (1400°) is very remarkable, because platinous chloride, PtCl_2 , is then formed, whilst this substance decomposes at a much lower temperature into chlorine and platinum. Hence, when chlorine comes into contact with platinum at such high temperatures, it forms fumes of platinous chloride, and these on cooling decompose, with the liberation of platinum, so that the phenomenon appears to be dependent on the volatility of platinum. Deville proved the formation of platinous chloride by inserting a cold tube inside a red-hot one (as in the experiment on carbonic oxide). However, V. Meyer was able to observe the density of chlorine in a platinum vessel at 1690° , at which temperature chlorine does not exert this action on platinum, or at least only to an insignificant degree.

^{17a} Geber, the Arabian alchemist of the middle ages, showed that when a mixture of nitre and common salt is distilled in oil of vitriol it gives **aqua regia**, which dissolves gold. Chlorine is the active agent in aqua regia.

on hydrochloric acid evolves chlorine. If the chlorine evolved be transferred to a metal, then a fresh quantity is formed from the remaining acids and also combines with the metal.¹⁸ Thus the aqua regia acts by virtue of the chlorine which it contains and disengages.

The majority of **non-metals** also react directly on chlorine; hot sulphur and phosphorus burn in it and combine with it at the ordinary temperature. Only nitrogen, carbon, and oxygen do not combine directly with it. The chlorine compounds formed by the non-metals—for instance, phosphorus trichloride, PCl_3 , and sulphurous chloride, &c., have not the properties of salts, but correspond, as we shall afterwards see more fully, to acid anhydrides and acids; for example, PCl_3 —to phosphorous acid, $\text{P}(\text{OH})_3$:

As the above-mentioned relation in composition---i.e., substitution of Cl by the aqueous residue---exists between many chloride compounds and their corresponding hydrates, and as furthermore some (acid) hydrates are obtained from chlorine compounds by the action of water, for instance,

whilst other chlorine compounds are formed from hydroxides and hydrochloric acid, with the liberation of water, for example,

we endeavour to express this intimate connection between the hydrates and chlorine compounds by calling the latter **chloranhydrides**. In general terms, if the hydrate be basic,

and if the hydrate ROH be acid, then,

¹⁸ When left exposed to the air aqua regia disengages chlorine, and afterwards it no longer acts on gold. Gay-Lussac, in explaining the action of aqua regia, showed that when heated it evolves, besides chlorine, the vapours of two chloranhydrides—that of nitric acid, NO_2Cl (nitric acid, NO_2OH , in which HO is replaced by chlorine; see chapter on Phosphorus), and that of nitrous acid, NOCl —but these do not act on gold. The formation of aqua regia may therefore be expressed by: $4\text{NHO}_3 + 8\text{HCl} = 2\text{NO}_2\text{Cl} + 2\text{NOCl} + 6\text{H}_2\text{O} + 2\text{Cl}_2$. The formation of the chlorides NO_2Cl and NOCl is explained by the fact that the nitric acid is deoxidised, gives the oxides NO and NO_2 , and these combine directly with chlorine to form the above anhydrides.

The chloranhydrides MCl corresponding with the bases are evidently metallic chlorides or salts corresponding with HCl . In this manner a distinct equivalency is noticed between the compounds of chlorine and the so-called hydroxyl radicle (HO), which is also expressed in the analogy existing between chlorine, Cl_2 , and hydrogen peroxide $(HO)_2$; for instance, both oxidise, bleach, &c.

As regards the chloranhydrides corresponding with acids and non-metals, these bear but little resemblance to metallic salts. They are nearly all volatile, and have a powerful suffocating smell which irritates the eyes and respiratory organs. They react on water like many anhydrides of the acids, with the evolution of heat and liberation of hydrochloric acid, forming acid hydrates. There are many intermediate chlorine compounds between true saline metallic chlorides like sodium chloride and true acid chloranhydrides, like PCl_3 , just as there are all degrees of transition between bases and acids. Acid chloranhydrides are not only obtained from chlorine and non-metals, but also from many lower oxides, by the aid of chlorine. Thus, for example, CO , NO , NO_2 , SO_2 , and other lower oxides which are capable of combining with oxygen, may also combine with a corresponding quantity of chlorine, $COCl_2$, $NOCl$, NO_2Cl , SO_2Cl_2 , &c., being obtained. They correspond with the hydrates $CO(OH)_2$, $NO(OH)$, $NO_2(OH)$, $SO_2(OH)_2$, &c., and with the anhydrides CO_2 , N_2O_3 , N_2O_5 , SO_3 , &c. Here we should notice two aspects of the question: (1) chlorine combines with that with which oxygen is able to combine, because it is in many respects as energetic as, if not more so than, oxygen, and replaces it in the proportion $Cl_2 : O$; (2) that highest limit of possible combination which is proper to a given element or grouping of elements is very easily and often attained by combination with chlorine. If phosphorus gives PCl_3 and PCl_5 , it is evident that PCl_5 is the higher form of combination compared with PCl_3 . To the form PCl_5 , or in general PX_5 , correspond PH_4I , $PO(OH)_3$, $POCl_3$, &c. If chlorine does not always directly give compounds of the highest possible forms for a given element, then generally the lower forms combine with it in order to reach or approach the limit. This is particularly clear in hydrocarbons, where we see the limit, C_nH_{2n+2} , very distinctly. The unsaturated hydrocarbons are sometimes able to combine with chlorine with the greatest ease, and thus reach the limiting state. Thus ethylene, C_2H_4 , combines with Cl_2 , forming the so-called Dutch liquid or ethylene chloride, $C_2H_4Cl_2$, because it then reaches the limit C_nX_{2n+2} . In this and all similar cases the combined chlorine is able by reactions of substitution to give more or less easily a hydroxide and a whole

series of other derivatives. Thus a hydroxide called glycol, $\text{C}_2\text{H}_4(\text{OH})_2$, is obtained from $\text{C}_2\text{H}_4\text{Cl}_2$.

Chlorine in the presence of water very often acts directly as an **oxidising agent**. A substance A combines with chlorine and gives, for example, ACl_2 , and this in turn a hydroxide, $\text{A}(\text{OH})_2$, which on losing water forms AO . Here the chlorine has oxidised the substance A. This frequently happens in the simultaneous action of water and chlorine: $\text{A} + \text{H}_2\text{O} + \text{Cl}_2 = 2\text{HCl} + \text{AO}$. Examples of this oxidising action of chlorine may frequently be observed both in practical chemistry and in technical processes. Thus, for instance, chlorine in the presence of water oxidises sulphur and metallic sulphides. In this case the sulphur is converted into sulphuric acid, and the chlorine into hydrochloric acid, or a metallic chloride if a metallic sulphide be taken. A mixture of carbonic oxide and chlorine passed into water gives carbonic anhydride and hydrochloric acid: $\text{CO} + \text{Cl}_2 + \text{H}_2\text{O} = \text{CO}_2 + 2\text{HCl}$. Sulphurous anhydride is oxidised by chlorine in the presence of water into sulphuric acid, just as it is by the action of nitric acid: $\text{SO}_2 + 2\text{H}_2\text{O} + \text{Cl}_2 = \text{H}_2\text{SO}_4 + 2\text{HCl}$.

The oxidising action of chlorine in the presence of water is taken advantage of in practice for the rapid **bleaching of tissues** and fibres. The colouring matter of the fibres is altered by oxidation and converted into a colourless substance.¹⁹

The power of chlorine for combination is intimately connected with its capacity for substitution, because, according to the law of substitution, if chlorine combines with hydrogen, then it also replaces hydrogen, and, furthermore, the combination and substitution are accomplished in the same quantities. Therefore the **atom of chlorine** which combines with the atom of hydrogen is also able **to replace the atom of hydrogen**. This property of chlorine illustrates the application of the law of

¹⁹ But the chlorine afterwards acts on the tissue itself. Bleaching by means of chlorine therefore requires a certain amount of technical skill in order that the chlorine should not act on the fibres themselves, but that its action should be limited to the colouring matter only. The fibre for making writing paper, for instance, is bleached in this manner. The bleaching property of chlorine was discovered by Berthollet, and forms an important acquisition to the arts, because it has in the majority of cases replaced what was before the universal method of bleaching—namely, exposure to the sun of the fabrics damped with water—which is still employed for linens, &c. Time and great trouble, and therefore money also, have been saved by this change. Ozone and peroxide of hydrogen also bleach tissues. As the action of peroxide of hydrogen is easily controlled by taking a weak solution, and as it has hardly any action upon the tissues themselves, it is replacing chlorine more and more as a bleaching agent. The oxidising property of chlorine is apparent in destroying the majority of organic tissues, proving fatal to organisms. This action of chlorine is taken advantage of in quarantine stations. But the simple fumigation by chlorine must be carried on with great care in dwelling-places, because chlorine discharged into the atmosphere renders it injurious to health.

substitution in clear and historically important examples, and reactions of this kind explain those **indirect methods** of the formation of many substances which we have often mentioned, and to which recourse is had in many cases in chemistry. Thus chlorine does not act on carbon,²⁰ oxygen, or nitrogen, but nevertheless its compounds with these elements may be obtained by the indirect method of the substitution of hydrogen by chlorine.

As chlorine easily combines with hydrogen, and does not act on carbon, it decomposes hydrocarbons (and many of their derivatives) at a high temperature, depriving them of their hydrogen and liberating the carbon, as is clearly seen, for example, when a lighted candle is placed in a vessel containing chlorine. The flame becomes smaller, but continues for a certain time, a large amount of soot being obtained, and hydrochloric acid being formed. In this case the gaseous and incandescent substances of the flame are decomposed by the chlorine, the hydrogen combines with it, and the carbon is disengaged as soot.²¹ This action of chlorine on hydrocarbons proceeds otherwise at low temperatures, as we will now consider.

A very important epoch in the history of chemistry was inaugurated by the discovery of Dumas and Laurent that chlorine is able to displace and **replace hydrogen**. This discovery is important from the fact that chlorine proved to be an element which combines with great ease simultaneously with both the hydrogen and the element with which the hydrogen was combined. This clearly proved that there is no opposite polarity between elements forming stable compounds. Chlorine does not combine with hydrogen because it has opposite properties, as was previously stated by Dumas and Laurent, who accounted hydrogen to be electro-positive and chlorine electro-negative ; this is not the reason of their combining together, for the same chlorine which combines with hydrogen is also able to replace it without altering many of the properties of the resultant substance. This substitution of hydrogen by chlorine is termed **metalepsis**. The mechanism of this substitution follows a very uniform course. If we take a hydrogen compound, preferably a hydrocarbon, and allow chlorine to act directly on it, there is produced, on the one hand, hydrochloric acid, and, on the other,

²⁰ A tendency of carbon to attract chlorine is evidenced in the immense absorption of chlorine by charcoal (note 7), but, so far as is at present known (if I am not mistaken, no one has tried the aid of light), no combination takes place between the chlorine and carbon.

²¹ The same reaction takes place under the action of oxygen, with the difference that it burns the carbon, which chlorine is not able to do. If chlorine and oxygen compete together at a high temperature, the oxygen will unite with the carbon, and the chlorine with the hydrogen.

a compound containing chlorine in the place of the hydrogen; so that the chlorine divides itself into two equal portions: one portion is evolved as hydrochloric acid, and the other portion takes the place of the hydrogen thus liberated. **Hence this metalepsis is always accompanied by the formation of hydrochloric acid.**²² The scheme of the process is as follows:

Or, generally—

The conditions under which metalepsis takes place are also very constant. In the dark, chlorine rarely acts on hydrogen compounds, but the action commences under the influence of light. The direct action of the sun's rays is particularly favourable to metalepsis. It is also remarkable that the presence of traces of certain substances,²³ especially of iodine, aluminium chloride, antimony chloride, &c., promotes the action. A trace of iodine added to the substance subjected to metalepsis often produces the same effect as sunlight.²⁴

If marsh gas is mixed with chlorine and the mixture ignited, the hydrogen is entirely taken up from the marsh gas and hydrochloric acid and carbon are formed, but there is no metalepsis.²⁵ But if a mixture

²² This division of chlorine into two portions may at the same time be taken as a clear confirmation of the conception of the molecule Cl_2 containing two atoms.

²³ Such carriers or media for the transference of chlorine and the halogens in general were long known to exist in iodine and antimonious chloride, and have been most fully studied by Gustavson and Friedel, of the Petroffsky Academy—the former with respect to aluminium bromide, and the latter with respect to aluminium chloride. Gustavson showed that if a trace of metallic aluminium be dissolved in bromine (it floats on bromine, and when combination takes place much heat and light are evolved), the latter becomes endowed with the property of entering into metalepsis, which it is not able to do of its own accord. When pure, for instance, it acts very slowly on benzene, C_6H_6 , but in the presence of a trace of aluminium bromide the reaction proceeds violently and easily, so that each drop of the hydrocarbon gives a mass of hydrobromic acid, and of the product of metalepsis. Gustavson showed that the *modus operandi* of this instructive reaction is based on the power of aluminium bromide to enter into combination with hydrocarbons and their derivatives. The details of this and all researches concerning the metalepsis of the hydrocarbons must be looked for in works on organic chemistry.

²⁴ As small admixtures of iodine, aluminium bromide, &c., aid the metalepsis of large quantities of a substance, just as nitric oxide aids the reaction of sulphurous anhydride on oxygen and water, so the principle is essentially the same in both cases. Effects of this kind (which should also be explained by a chemical reaction proceeding at the surfaces) only differ from true contact phenomena in that the latter are produced by solid bodies and are accomplished at their surfaces, whilst in the former all is in solution. Probably the action of iodine is founded on the formation of iodine chloride, which reacts more easily than chlorine.

²⁵ Metalepsis belongs to the category of delicate reactions—if it may be so expressed—as compared with the energetic reaction of combustion. Many cases of substitution are

of equal volumes of chlorine and marsh gas be exposed to the action of diffused light, then the greenish-yellow mixture will gradually become colourless, and hydrochloric acid and the first product of metalepsis—namely, methyl chloride—will be formed :

The volume of the mixture remains unaltered. The methyl chloride which is formed is a gas. If it be separated from the hydrochloric acid (it is soluble in acetic acid, in which hydrochloric acid is but sparingly soluble) and be again mixed with chlorine, it may be subjected to a further metalepsical substitution—the second atom of hydrogen may be substituted by chlorine, and a liquid substance, CH_2Cl_2 , called methylene chloride, obtained. In the same manner the substitution may be carried on still further, and CHCl_3 , or chloroform, and lastly carbon tetrachloride, CCl_4 , produced. Of these substances the best known and most widely used is chloroform, owing to its being formed from many organic substances (by the action of bleaching powder) and to its being used in medicine as an anæsthetic ; chloroform boils at 62° and carbon tetrachloride at 78° . They are both colourless odoriferous liquids, heavier than water. The progressive substitution of hydrogen by chlorine is thus evident, and it can be clearly seen that the double decompositions are accomplished between molecular quantities of the substances—that is, between equal volumes in a gaseous state.

It is evident that by ultimate metalepsis a corresponding carbon chloride may be obtained from any hydrocarbon—indeed, the number of chlorides of carbon, C_nCl_{2m} , already known is very large.

As a rule, the fundamental chemical characters of hydrocarbons are not changed by metalepsis ; that is, if a neutral substance is taken, then the product of metalepsis is also a neutral substance, or if an acid be taken the product of metalepsis also has acid properties. Even the crystalline form not infrequently remains unaltered after metalepsis. The metalepsis of acetic acid, $\text{CH}_3\cdot\text{COOH}$, is historically the most important. This acid contains three of the atoms of the hydrogen of marsh gas, the fourth being replaced by carboxyl, and therefore by the action of chlorine it gives three products of metalepsis (according to the amount of the chlorine and conditions under which the reaction

of this kind. Reactions of metalepsis are accompanied by an evolution of heat, but in a less quantity than that evolved in the formation of the resulting quantity of the halogen acids. Thus the reaction, $\text{C}_2\text{H}_6 + \text{Cl}_2 = \text{C}_2\text{H}_5\text{Cl} + \text{HCl}$, according to the data given by Thomsen, evolves about 20,000 heat units, whilst the formation of hydrochloric acid evolves 22,000 units.

takes place), mono-, di-, and tri-chloracetic acids— $\text{CH}_2\text{Cl}\cdot\text{COOH}$, $\text{CHCl}_2\cdot\text{COOH}$, and $\text{CCl}_3\cdot\text{COOH}$; these are all, like acetic acid, mono-basic. The resulting products of metalepsis, in containing an element which so easily acts on metals as chlorine, possess the possibility of attaining a further complexity of molecules of which the original hydrocarbon is often in no way capable. Thus on treating with an alkali (or first with a salt and then with an alkali, or with a basic oxide and water, &c.), the chlorine forms a salt with its metal, and the hydroxyl radicle takes the place of the chlorine—for example, $\text{CH}_3\cdot\text{OH}$ is obtained from CH_3Cl . By the action of metallic derivatives of hydrocarbons—for example, $(\text{CH}_3)_2\text{Zn}$, CH_3Na —the chlorine also gives a salt, and the hydrocarbon radicle—for instance, CH_3 —takes the place of the chlorine. In this, or in a similar manner, $\text{CH}_3\cdot\text{CH}_3$, or C_2H_6 is obtained from CH_3Cl and $\text{C}_6\text{H}_5\cdot\text{CH}_3$ from $\text{C}_6\text{H}_5\text{Cl}$. The products of metalepsis also often react on ammonia, forming hydrochloric acid (and thence NH_4Cl) and an amide, that is, the product of metalepsis in which the ammonia radicle, NH_2 , takes the place of chlorine. Thus, by means of metalepsical substitution, methods were found in chemistry for an artificial and general means of the formation of complex carbon compounds from more simple compounds which are often totally incapable of direct reaction. Besides which, this key opened the door of that secret edifice of complex organic compounds into which man had up to then feared to enter, supposing the hydrocarbon elements to be united only under the influence of those mystic forces acting in organisms.²⁶

It is not only hydrocarbons which are subject to **metalepsis**. Certain other hydrogen compounds, under the action of chlorine, also

²⁶ With the predominance of the representation of compound radicles (this doctrine dates from the time of Lavoisier and Gay-Lussac) in organic chemistry, it was a very important moment in its history when it became possible to gain an insight into the structure of the radicles themselves. It was clear, for instance, that ethyl, C_2H_5 , or the radicle of common alcohol, $\text{C}_2\text{H}_5\cdot\text{OH}$, passes, without changing, into a number of ethyl derivatives, but its relation to the still simpler hydrocarbons was not clear, and occupied the attention of science in the 'forties' and 'fifties.' Ethyl hydride, $\text{C}_2\text{H}_5\text{H} = \text{C}_2\text{H}_6$, being obtained, it was regarded as containing the same ethyl, just as methane, $\text{CH}_4 = \text{CH}_3\text{H}$, was considered as methyl hydride. Having obtained free methyl, $\text{CH}_3\text{CH}_3 = \text{C}_2\text{H}_6$, from it, it was considered as a derivative of methyl alcohol, CH_3OH , and as only isomeric with ethyl hydride. By means of the products of metalepsis it was proved that this is a case, not of isomerism, but of strict identity, and it therefore became clear that ethyl is methylated methyl, $\text{C}_2\text{H}_5 = \text{CH}_2\text{CH}_3$. In its time a still greater impetus was given by the study of the reactions of monochloracetic acid, $\text{CH}_2\text{Cl}\cdot\text{COOH}$, or $\text{CO}(\text{CH}_2\text{Cl})(\text{OH})$. It appeared that metalepsical chlorine, like the chlorine of chloranhydrides—for instance, of methyl chloride, CH_3Cl , or ethyl chloride, $\text{C}_2\text{H}_5\text{Cl}$ —is capable of substitution; for example, glycollic acid, $\text{CH}_2(\text{OH})(\text{CO}_2\text{H})$, or $\text{CO}(\text{CH}_2\cdot\text{OH})(\text{OH})$, was obtained from it, and it appeared that the OH in the group $\text{CH}_2(\text{OH})$ reacted like that in alcohols, and it became clear, therefore, that it was necessary to examine the radicles themselves by analysing them from the point of view of the bonds connecting the constituent atoms. Whence arose the present doctrine of the structure of the carbon compounds.

give corresponding chlorine derivatives in exactly the same manner ; for instance, ammonia, caustic potash, caustic lime, and a whole series of **alkaline** substances.²⁷ In fact, just as the hydrogen in marsh gas can be replaced by chlorine, forming methyl chloride, so the hydrogen in caustic potash, KHO, ammonia, NH₃, and calcium hydroxide, CaH₂O₂ or Ca(OH)₂, may be replaced by chlorine and give potassium hypochlorite, KClO, calcium hypochlorite, CaCl₂O₂, and the so-called chloride of nitrogen, NCl₃. For not only is the correlation in composition the same as in the substitution in marsh gas, but the whole mechanism of the reaction is the same. Here also two atoms of chlorine act : one takes the place of the hydrogen whilst the other is evolved as hydrochloric acid, only in the former case the hydrochloric acid evolved remained free, and in the latter, in presence of alkaline substances, it reacts on them. Thus, in the action of chlorine on caustic potash, the hydrochloric acid formed acts on a further quantity of caustic potash and gives potassium chloride and water, and therefore not only $\text{KHO} + \text{Cl}_2 = \text{HCl} + \text{KClO}$, but also $\text{KHO} + \text{HCl} = \text{H}_2\text{O} + \text{KCl}$, and the result of the two simultaneous actions will be $2\text{KHO} + \text{Cl}_2 = \text{H}_2\text{O} + \text{KCl} + \text{KClO}$.

The action of **chlorine on ammonia** may result either in the entire breaking down of the ammonia, with the evolution of gaseous nitrogen, or in a product of metalepsis (as with CH₄). With an excess of chlorine and the aid of heat the ammonia is decomposed, with the disengagement of free nitrogen.²⁸ This reaction evidently results

²⁷ By including many instances of the action of chlorine under metalepsis we not only explain the indirect formation of CCl₄, NCl₃, and Cl₂O by one method, but we also arrive at the fact that the reactions of the metalepsis of the hydrocarbons lose that exclusiveness which was often ascribed to them. Also by subjecting the chemical representations to the law of substitution we may predict metalepsis to be a particular case of a general law. It must be remembered, however, that the chlorine in all the products of metalepsis reacts more or less differently from the chlorine in chlorides. Thus, for instance, salts of silver, AgX, immediately give AgCl + MX with solutions of soluble chlorides, MCl, but this reaction proceeds very slowly with products of metalepsis. Without entering into the consideration of the velocity of reaction (which belongs to theoretical chemistry) I will only mention that the chlorine in the so-called 'complex' compounds (see Chapters XXII. and XXIII.), which is apparently combined with the metal, either does not react or reacts slowly with AgX, and so recalls metalepsical chlorine. The relations of this latter property cannot yet be considered as satisfactorily explained, but they are being worked at by many and present a peculiar interest. Owing to the complexity and incompleteness of the subject I have only referred to it in the last chapters of this work and have limited myself as far as possible to facts and analogies.

²⁸ This may be taken advantage of in the preparation of nitrogen. If a large excess of chlorine water be poured into a beaker, and a small quantity of a solution of ammonia be added, then, after shaking, nitrogen is evolved. If ammonia gas be passed through a fine orifice into a vessel containing chlorine, the reaction of the formation of nitrogen is accompanied by the emission of light and the appearance of a cloud of sal-ammoniac. In all these instances an excess of chlorine must be present.

in the formation of sal-ammoniac, $8\text{NH}_3 + 3\text{Cl}_2 = 6\text{NH}_4\text{Cl} + \text{N}_2$. But if the ammonium salt is in excess, the reaction takes the direction of the replacement of the hydrogen in the ammonia by chlorine. The principal result is that $\text{NH}_3 + 3\text{Cl}_2$ forms $\text{NCl}_3 + 3\text{HCl}$.²⁹ The resulting product of metalepsis, or **chloride of nitrogen**, NCl_3 , discovered by Dulong, is a liquid having the property of decomposing with excessive ease, not only when heated, but even under the action of mechanical influences, such as a blow or contact with certain solid substances. The explosion which accompanies the decomposition is due to the fact that the liquid chloride of nitrogen gives gaseous products, nitrogen and chlorine.^{29a}

²⁹ The hydrochloric acid formed combines with ammonia, and therefore the final result is: $4\text{NH}_3 + 3\text{Cl}_2 = \text{NCl}_3 + 3\text{NH}_4\text{Cl}$. The metalepsical reaction only takes place with an excess of ammonia or its salt. If bubbles of chlorine are passed through a fine tube into a vessel containing ammonia gas, each bubble gives rise to an explosion. If, however, chlorine is passed into a solution of ammonia, the reaction at first brings about the formation of nitrogen, because chloride of nitrogen acts on ammonia like chlorine. But when sal-ammoniac has begun to form, the reaction then directs itself towards the formation of chloride of nitrogen. The first action of chlorine on a solution of sal-ammoniac always causes the formation of chloride of nitrogen, which then reacts on ammonia thus: $\text{NCl}_3 + 4\text{NH}_3 = \text{N}_2 + 3\text{NH}_4\text{Cl}$. Therefore, so long as the liquid is alkaline from the presence of ammonia the chief product will be nitrogen. The reaction, $\text{NH}_4\text{Cl} + 3\text{Cl}_2 = \text{NCl}_3 + 4\text{HCl}$ is reversible; with a dilute solution it proceeds in the above-described direction (perhaps owing to the affinity of the hydrochloric acid for the excess of water), but with a strong solution of hydrochloric acid it takes the opposite direction (probably by virtue of the affinity of hydrochloric acid for ammonia). Therefore there must exist a very interesting case of equilibrium between ammonia, hydrochloric acid, chlorine, water, and chloride of nitrogen. The reaction $\text{NCl}_3 + 4\text{HCl} = \text{NH}_4\text{Cl} + 3\text{Cl}_2$ enabled Deville and Hautefeuille to determine the composition of chloride of nitrogen. When slowly decomposed by water, chloride of nitrogen gives, like a chloranhydride, nitrous acid or its anhydride, $2\text{NCl}_3 + 3\text{H}_2\text{O} = \text{N}_2\text{O}_3 + 6\text{HCl}$. From these observations it is evident that chloride of nitrogen presents great chemical interest, which is strengthened by its analogy with trichloride of phosphorus. The researches of F. F. Selivanoff (1891-94) prove that NCl_3 may be regarded as an ammonium derivative of hypochlorous acid. Chloride of nitrogen is decomposed by dilute sulphuric acid in the following manner: $\text{NCl}_3 + 3\text{H}_2\text{O} + \text{H}_2\text{SO}_4 = \text{NH}_4\text{HSO}_4 + 3\text{HClO}$. This reaction is reversible and is only complete when some substance, combining with HClO (for instance, succinimide) or decomposing it, is added to the liquid. This is partly understood from the fact that hypochlorous acid itself, HClO , may, according to the view held in this book, be regarded as the product of the metalepsis of water, and consequently bears the same relation to NCl_3 as H_2O does to NH_3 , or as RHO to RNH_2 , R_2NH , and R_3N —that is to say, NCl_3 corresponds, as an ammonium derivative, with ClOH and Cl_2 in exactly the same manner as NR_3 corresponds with ROH and R_2 . Selivanoff obtained, investigated, and classified many of the compounds NR_2Cl and NRCl_2 , where R is a residue of an organic acid or alcohol, and showed their difference from the chloranhydrides, and thus supplemented the history of chloride of nitrogen, which is the simplest of the amides containing chlorine— NR_3 where R is fully substituted by chlorine.

^{29a} In preparing NCl_3 every precaution must be used to guard against an explosion, and care should be taken that the NCl_3 remains under a layer of water. Whenever an ammoniacal substance comes into contact with chlorine great care must be taken, because it may lead to the formation of such products, and a very dangerous explosion ensue. The liquid product of the metalepsis of ammonia may be most safely pre-

Chloride of nitrogen is a yellow oily liquid of sp. gr. 1.65, which boils at 71°, and breaks up into $N + Cl_3$ at 97°. The contact of phosphorus, turpentine, indiarubber, &c., causes an explosion, which is sometimes so violent that a small drop will pierce a thick board. The great ease with which chloride of nitrogen decomposes is dependent upon the fact that it is formed with an absorption of heat, which it evolves when decomposed, to the amount of about 38,000 heat units for NCl_3 , as Deville and Hautefeuille determined.

Chlorine, when absorbed by a solution of caustic soda (and also of other alkalies) at the ordinary temperature, causes the replacement of the hydrogen in the caustic soda by the chlorine, with the formation of sodium chloride by the hydrochloric acid, so that the reaction may be represented in two phases, as described above, or, taken as a whole, by the equation: $2NaHO + Cl_2 = NaCl + NaClO + H_2O$. The resultant solution contains $NaClO$ and is termed 'eau de Javelle.'^{29b} An exactly similar reaction takes place when chlorine is passed over dry hydrate of lime at the ordinary temperature: $2Ca(HO)_2 + 2Cl_2 = CaCl_2O_2 + CaCl_2 + 2H_2O$. A mixture of the product of metalepsis with calcium chloride is obtained. This mixture is employed in practice on a large scale, and is termed **bleaching powder**, owing to its acting, especially when mixed with acids, as a bleaching agent on tissues, in which respect it hence resembles chlorine. It is, however, preferable to chlorine, because the destructive action of the chlorine can be moderated in this case, and because it is much more convenient to deal with a solid substance than with gaseous chlorine. Bleaching powder is also called **chloride of lime**, because it is obtained from chlorine

pared in the form of small drops by the action of a galvanic current on a slightly warm solution of sal-ammoniac; chlorine is then evolved at the anode, and this chlorine acting on the ammonia gradually forms the product of metalepsis, which floats on the surface of the liquid (being carried up by the gas), and if a layer of turpentine be poured on to it these small drops, on coming into contact with the turpentine, give feeble explosions, which are in no way dangerous owing to the small mass of the substance formed. Drops of chloride of nitrogen may with great caution be collected for investigation in the following manner. The neck of a funnel is immersed in a basin containing mercury, and first a saturated solution of common salt is poured into the funnel, and above it a solution of sal-ammoniac in 9 parts of water. Chlorine is then slowly passed through the solutions, when drops of chloride of nitrogen fall into the salt water. Hentschel (1897) proceeded as follows in order to prepare a solution of NCl_3 in benzene. He carefully mixed a solution of bleaching powder with as much hydrochloric acid as would not lead to the formation of gas on the addition of sal-ammoniac, and then added a solution of NH_4Cl and benzene. By constant shaking the NCl_3 formed, dissolved in the benzene, and floated on the surface. Such a solution may be kept without danger in the dark.

^{29b} Solutions of hypochlorite of sodium can only be kept without change (without forming $NaClO_3$) in the presence of an excess of alkali and in the dark (Graebe).

and hydrate of lime, and contains ³⁰ both these substances. It may be prepared in the laboratory by passing a current of chlorine through a cold mixture of water and lime (milk of lime). The mixture must be kept cold, as otherwise $3\text{Ca}(\text{ClO})_2$ passes into $2\text{CaCl}_2 + \text{Ca}(\text{ClO}_3)_2$. In the manufacture of bleaching powder in large quantities at chemical works, the purest possible slaked lime is taken and laid in a thin layer in large flat chambers, M (whose walls are made of Yorkshire flags or tarred wood, on which chlorine has no action), and into which chlorine gas is introduced by lead tubes. The distribution of the plant is shown in the annexed drawing (fig. 77).

The products of the metalepsis of alkaline hydrates, NaClO and $\text{Ca}(\text{ClO})_2$, which are present in solutions of 'Javelle salt' and bleaching powder (they are not obtained free from metallic chlorides), must be counted as salts, because their metals are capable of substitution. But

³⁰ Quicklime, CaO (or calcium carbonate, CaCO_3), does not absorb chlorine when cold, but at a red heat, in a current of chlorine, it forms calcium chloride, with the evolution of oxygen. (This was confirmed in 1893 by Wells, at Oxford.) This reaction corresponds with the decomposing action of chlorine on methane, ammonia, and water. Slaked lime (calcium hydroxide, CaH_2O_2) also, when dry, does not absorb chlorine at 100° . The absorption proceeds at the ordinary temperature (below 40°). The dry mass thus obtained contains not less than three equivalents of calcium hydroxide to four of chlorine, so that its composition is $[\text{Ca}(\text{HO})_2]_3\text{Cl}_4$. In all probability a simple absorption of chlorine by the lime at first takes place in this case, as may be seen from the fact that even carbonic anhydride, when acting on the dry mass obtained as above, disengages all the chlorine from it, leaving only calcium carbonate. But if the bleaching powder be obtained by a wet method, or if it be dissolved in water (in which it is very soluble), and carbonic anhydride be passed into it, chlorine will no longer be disengaged, but its oxide, Cl_2O , into which only half of the chlorine is converted, the other half remaining in the liquid as calcium chloride. From this it may be inferred that calcium chloride is formed by the action of water on bleaching powder, and this is proved to be the case by the fact that small quantities of water extract a considerable amount of calcium chloride from bleaching powder. If a large quantity of water acts on bleaching powder an excess of calcium hydroxide remains, a portion of which is not subjected to change. The action of the water may be expressed by the following formulæ: From the dry mass, $\text{Ca}_3(\text{HO})_6\text{Cl}_4$ there is formed lime, $\text{Ca}(\text{HO})_2$, calcium chloride, CaCl_2 , and a saline substance, $\text{Ca}(\text{ClO})_2$: $\text{Ca}_3\text{H}_6\text{O}_6\text{Cl}_4 = \text{CaH}_2\text{O}_2 + \text{CaCl}_2\text{O}_2 + \text{CaCl}_2 + 2\text{H}_2\text{O}$. The resulting substances are not equally soluble; water first extracts the calcium chloride, which is the most soluble, then the compound $\text{Ca}(\text{ClO})_2$, calcium hydroxide being ultimately left. A mixture of calcium chloride and hypochlorite passes into solution. On evaporation there remains $\text{Ca}_2\text{O}_2\text{Cl}_4, 3\text{H}_2\text{O}$. The dry bleaching powder does not absorb more chlorine, but the solution is able to absorb it in considerable quantity. If the liquid be boiled, a considerable amount of chlorine monoxide is evolved. After this, calcium chloride alone remains in solution, and the decomposition may be expressed as follows: $\text{CaCl}_2 + \text{CaCl}_2\text{O}_2 + 2\text{Cl}_2 = 2\text{CaCl}_2 + 2\text{Cl}_2\text{O}$. Chlorine monoxide may be prepared in this manner. As bleaching salts in solution are used for bleaching fibres and tissues, attention should be turned to the fact that such solutions may be obtained with comparative ease by means of an electric current, for at low temperatures (up to 25°) bleaching salts are formed at the anode in the electrolysis of chlorides. Thus a 10 per cent. of NaCl can easily give solutions containing 1 per cent. of active chlorine with a sufficiently large anode surface and in suitable apparatus. This corresponds to the requirements of many bleaching establishments, where this method is frequently employed.

the hydrate, HClO , corresponding with these salts, or **hypochlorous acid**, is not obtained in a free or pure state, for two reasons: in the first place, because this hydrate, as a very feeble acid, splits up (like H_2CO_3 or HNO_3) into water and the anhydride, or **chlorine monoxide**, $\text{Cl}_2\text{O} = 2\text{HClO} - \text{H}_2\text{O}$; and, in the second place, because, in a number of instances, it evolves oxygen with great facility, forming hydrochloric acid: $\text{HClO} = \text{HCl} + \text{O}$. Both hypochlorous acid and chlorine monoxide may be regarded as products of the metalepsis of water, because HOH corresponds with ClOH and ClOCl . Hence in many instances bleaching salts (a mixture of hypochlorites and chlorides) break up, with the evolution of (1) *chlorine*, under the action of an excess of a powerful acid capable of evolving hydrochloric acid from sodium or calcium chlorides, and this takes place most simply under the action of hydrochloric acid itself, because $\text{NaCl} + \text{NaClO} + 3\text{HCl}$

FIG. 77.—Apparatus for the manufacture of bleaching powder (on a small scale) by the action of chlorine, which is generated in the vessels C, on lime, which is charged into M.

$= 2\text{NaCl} + \text{HCl} + \text{Cl}_2 + \text{H}_2\text{O}$; (2) *oxygen*, as we saw in Chapter III. The bleaching properties and, in general, **oxidising action**, of bleaching salts are based on this evolution of oxygen (or chlorine); oxygen is also disengaged on heating the dry salts—for instance, $\text{NaCl} + \text{NaClO} = 2\text{NaCl} + \text{O}$; (3) and, lastly, *chlorine monoxide* which contains both chlorine and oxygen. Thus, if a little sulphuric, nitric, or similar acid (not enough to liberate hydrochloric acid from the CaCl_2) be added to a solution of a bleaching salt (which has an alkaline reaction, owing either to an excess of alkali or to the feeble acid properties of HClO), then the hypochlorous acid set free gives water and chlorine monoxide. If carbonic anhydride (or boracic or a similar very feeble acid) acts on the solution of a bleaching salt, hydrochloric acid is not evolved from the sodium or calcium chlorides, but the hypochlorous acid is displaced and gives chlorine

monoxide,³¹ because hypochlorous acid is one of the most feeble acids. Another method for the preparation of chlorine monoxide is based on these feeble acid properties of hypochlorous acid. Zinc oxide and mercury oxide, under the action of chlorine in the presence of water, do not give a salt of hypochlorous acid, but form a chloride and hypochlorous acid, which fact shows the incapacity of this acid to combine with the bases mentioned. Therefore, if such oxides as those of zinc or mercury be shaken up in water, and chlorine be passed through the turbid liquid,³² a reaction will occur which may be expressed in the following manner: $2\text{HgO} + 2\text{Cl}_2 = \text{Hg}_2\text{OCl}_2 + \text{Cl}_2\text{O}$. Here a compound of mercury oxide with mercury chloride, or the so-called mercury oxychloride, is obtained: $\text{Hg}_2\text{OCl}_2 = \text{HgO} + \text{HgCl}_2$. This is insoluble in water, and is not affected by hypochlorous anhydride, so that the solution will contain only hypochlorous acid, splitting up into the anhydride and water.^{32a}

Chlorine monoxide, which corresponds with bleaching and hypochlorous salts, containing as it does the two elements oxygen and chlorine, forms a characteristic example of a compound of elements which, in the majority of cases, act chemically in an analogous manner. Chlorine monoxide, as prepared from an aqueous solution by the abstraction of water or by the action of dry chlorine on cooled mercuric oxide, is, at the ordinary temperature, a gas or vapour which condenses into a red liquid boiling at $+20^\circ$ and giving a vapour whose

³¹ For this reason it is necessary that in the preparation of bleaching powder the chlorine should be free from hydrochloric acid, and even the lime from calcium chloride. An excess of chlorine, in acting on a solution of bleaching powder, may also give chlorine monoxide, because calcium carbonate also gives chlorine monoxide under the action of chlorine. This reaction may be brought about by treating freshly precipitated calcium carbonate in water with a stream of chlorine: $2\text{Cl}_2 + \text{CaCO}_3 = \text{CO}_2 + \text{CaCl}_2 + \text{Cl}_2\text{O}$. From this we may conclude that, although carbonic anhydride displaces hypochlorous anhydride, it may be itself displaced by an excess of the latter.

³² Red mercuric oxide acts on chlorine, forming dry hypochlorous anhydride (chlorine monoxide) (Balard); when mixed with water, red mercuric oxide acts feebly on chlorine, and when freshly precipitated it evolves oxygen and chlorine. An oxide of mercury which easily and abundantly evolves chlorine monoxide under the action of chlorine in the presence of water may be prepared as follows: the oxide of mercury, precipitated from a mercuric salt by an alkali, is heated to 300° and cooled (Pelouze). If a salt, MClO , be added to a solution of mercuric salt, HgX_2 , mercuric oxide is liberated, because the hypochlorite is decomposed.

^{32a} A solution of hypochlorous anhydride is also obtained by the action of chlorine on many salts; for example, in the action of chlorine on a solution of sodium sulphate the following reaction takes place: $\text{Na}_2\text{SO}_4 + \text{H}_2\text{O} + \text{Cl}_2 = \text{NaCl} + \text{HClO} + \text{NaHSO}_4$. Here the hypochlorous acid is formed, together with HCl , at the expense of the chlorine and water, for $\text{Cl}_2 + \text{H}_2\text{O} = \text{HCl} + \text{HClO}$. A dilute solution of hypochlorous acid or chlorine monoxide may be concentrated by distillation, and if a substance which takes up water (without destroying the acid)—for instance, calcium nitrate—be added to the stronger solution, then the anhydride of hypochlorous acid—i.e., chlorine monoxide—will be disengaged.

density (43 referred to hydrogen) shows that 2 vols. of chlorine and 1 vol. of oxygen give 2 vols. of chlorine monoxide. In an anhydrous form the gas or liquid **easily explodes**, splitting up into chlorine and oxygen. This explosiveness is determined by the fact that heat is evolved *in the decomposition* to the amount of about 15,000 heat units for Cl_2O .³³ The explosion may even take place spontaneously, and also in the presence of many oxidisable substances (for instance, sulphur, organic compounds, &c.); but the solution, although unstable and showing a strong oxidising tendency, does not explode.³⁴ It is evident that the presence of hypochlorous acid, HClO , may be assumed in an aqueous solution of Cl_2O , since $\text{Cl}_2\text{O} + \text{H}_2\text{O} = 2\text{HClO}$.

Hypochlorous acid, its salts, and chlorine monoxide serve as a transition between hydrochloric acid, chlorides, and chlorine, and a whole series of compounds containing the same elements combined with a still greater proportion of oxygen. The higher oxides of chlorine, as their origin indicates, are closely related to hypochlorous acid and its salts:

Cl_2 ,	NaCl ,	HCl ,	hydrochloric acid.
Cl_2O ,	NaClO ,	HClO ,	hypochlorous acid.
Cl_2O_3 ,	NaClO_2 ,	HClO_2 ,	chlorous acid. ³⁵
Cl_2O_5 ,	NaClO_3 ,	HClO_3 ,	chloric acid.
Cl_2O_7 ,	NaClO_4 ,	HClO_4 ,	perchloric acid.

³³ All explosive substances are of this kind—ozone, hydrogen peroxide, chloride of nitrogen, nitro-compounds, &c. Hence they easily decompose. In a liquid state chlorine monoxide explodes even on contact with powdery substances, or when rapidly agitated—for instance, if a file be rasped over the vessel in which it is contained.

³⁴ A solution of chlorine monoxide, or hypochlorous acid, does not explode, owing to the presence of the mass of water. In dissolving, chlorine monoxide evolves about 9,000 heat units, so that its store of heat becomes less.

The capacity of hypochlorous acid (Carius and others) for entering into combination with the unsaturated hydrocarbons is very often taken advantage of in organic chemistry. Thus its solution absorbs ethylene, forming the chlorhydrin $\text{C}_2\text{H}_4\text{ClOH}$.

The oxidising action of hypochlorous acid and its salts is applied not only to bleaching, but also to many reactions of oxidation. Thus it converts the lower oxides of manganese into the peroxide.

³⁵ **Chlorous acid**, HClO_2 (according to the data given by Millon, Brandau, and others), in many respects resembles hypochlorous acid, HClO , whilst they both differ from chloric and perchloric acids in their degree of stability, evidenced, for instance, in their bleaching properties; the two higher acids do not bleach, but both the lower ones do so (oxidise at the ordinary temperature). On the other hand chlorous acid is analogous to nitrous acid, HNO_2 . The anhydride of chlorous acid, Cl_2O_3 , is not known in a pure state, but it probably occurs in admixture with the chlorine dioxide, ClO_2 , obtained by the action of nitric and sulphuric acids on a mixture of potassium chlorate with such reducing substances as nitric oxide, arsenious oxide, sugar, &c. Pure chlorine dioxide, ClO_2 (see notes 39–43) is gradually converted into a mixture of hypochlorous and chlorous acids under the action of water (and alkalies); that is, it acts like nitric peroxide, NO_2 (giving HNO_3 and HNO_2), or as a mixed anhydride, $2\text{ClO}_2 + \text{H}_2\text{O} = \text{HClO}_3 + \text{HClO}_2$. The silver salt, AgClO_2 , is sparingly soluble in water. The investigations of Garzarolli-Thurnlackh and others seem to show that the anhydride Cl_2O_3 does not exist in a free state.

When heated, solutions of hypochlorites undergo a remarkable change. Themselves so unstable, they, without any further addition, yield two fresh salts which are both much more stable; one contains more oxygen than MClO , the other contains none at all.

Part of the salt—namely, two-thirds of it—parts with its oxygen in order to oxidise the remaining third.³⁶ From an intermediate substance, two extremes are formed, just as nitrous anhydride splits up into nitric oxide and nitric anhydride (or nitric acid). The resulting salt, MClO_3 , corresponds with **chloric acid** and potassium chlorate, KClO_3 . It is evident that a similar salt may be obtained directly by the action of chlorine on an alkali if its solution be heated, because RClO will be first formed, and then RClO_3 ; for example, $6\text{KHO} + 3\text{Cl}_2 = \text{KClO}_3 + 5\text{KCl} + 3\text{H}_2\text{O}$. Chlorates are so prepared, for instance, **potassium chlorate**, which is easily separated from potassium chloride, being sparingly soluble in cold water.³⁷

³⁶ Hydrochloric acid, which is an example of compounds of this kind, is a saturated substance which does not combine directly with oxygen, but in which, nevertheless, a considerable quantity of oxygen may be inserted between the elements forming it. The same may be observed in a number of other cases. Thus oxygen may be added or inserted between the elements, sometimes in considerable quantities, in the saturated hydrocarbons; for instance, in C_3H_8 , three atoms of oxygen produce an alcohol, glycerin or glycerol, $\text{C}_3\text{H}_5(\text{OH})_3$. We shall meet with similar examples hereafter. This is generally explained by regarding oxygen as a bivalent element—that is, as capable of combining with two different elements, such as chlorine, hydrogen, &c. On the basis of this view, it may be inserted between each pair of combined elements; the oxygen will then be combined with one of the elements by one of its affinities and with the other element by its other affinity. This view does not, however, express the entire truth of the matter, even when applied to the compounds of chlorine. Hypochlorous acid, HOCl —that is, hydrochloric acid in which one atom of oxygen is inserted—is a substance of small stability; it might therefore be expected that on the addition of a fresh quantity of oxygen, a still less stable substance would be obtained, because, according to the above view, the chlorine and hydrogen, which form such a stable compound together, are then still further removed from each other. But it appears that chloric and perchloric acid, HClO_3 and HClO_4 , are much more stable substances. Furthermore, the addition of oxygen has also its limit; it can only be added to a certain extent. If the above representation were true and not merely hypothetical, there would be no limit to the combination of oxygen, and the more it entered into one continuous chain the more unstable would be the resultant compound. But not more than four atoms of oxygen can be added to hydrogen sulphide, or to hydrochloric acid, or to hydrogen phosphide. This peculiarity must lie in the properties of oxygen itself; four atoms of oxygen seem to have the power of forming a kind of radicle which retains two or several atoms of various other substances—for example, chlorine and hydrogen, hydrogen and sulphur, sodium and manganese, phosphorus and metals, &c., forming comparatively stable compounds, NaClO_4 , Na_2SO_4 , NaMnO_4 , Na_3PO_4 , &c. (see Chap. X., note 1, and Chap. XV.).

³⁷ If chlorine is passed through a *cold* solution of potash, a bleaching salt, potassium chloride and hypochlorite, $\text{KCl} + \text{KClO}$, is formed, but if it is passed through a *hot*

If dilute sulphuric acid is added to a solution of potassium chlorate, **chloric acid** is liberated, but it cannot be separated by distillation, as it is decomposed in the process. To obtain the free acid, sulphuric acid is added to a solution of barium chlorate.³⁸ The sulphuric acid

solution potassium chlorate is formed. As this is sparingly soluble in water, it chokes the gas-conducting tube, which should therefore be widened out at the end.

Potassium chlorate is usually obtained on a large scale from calcium chlorate, which is prepared by passing chlorine (as long as it is absorbed) into warm water containing lime. A mixture of calcium chlorate and chloride is thus formed in the solution. Potassium chloride is then added to the warm solution, and on cooling, a precipitate of potassium chlorate is formed as a substance which is sparingly soluble in cold water, especially in the presence of other salts. The double decomposition taking place is $\text{Ca}(\text{ClO}_3)_2 + 2\text{KCl} = \text{CaCl}_2 + 2\text{KClO}_3$. At the present time chlorate of potassium (and also KClO_4) is prepared exclusively by an electrolytic method. If a current is passed between platinum electrodes 10 mm. apart in a solution of KCl (1 part of salt to $2\frac{1}{2}$ parts of water) at 40° – 60° and containing some 1 per cent. of bichromate of potassium (this forms chromic oxide at the anode and counterbalances the reducing action of the hydrogen evolved at the cathode), the chlorine evolved at the anode (density of current should be 20 ampères per 100 sq. cm.) converts the caustic potash formed at the cathode into KClO_3 , which crystallises out as it accumulates, especially after cooling (Halenssermann and Naschold, 1894, and others). At lower temperatures KClO is formed. If the temperature of the solution is lowered, the KClO_3 gives KClO_4 under the action of the current. Both these salts are used in explosives, and are now exclusively prepared from KCl by these means.

Potassium chlorate readily crystallises in large colourless tabular crystals. Its solubility in 100 parts of water is 3 parts at 0° , 8 parts at 20° , 14 parts at 40° , 25 parts at 60° , and 40 parts at 80° . For comparison we will cite the following figures showing the solubility of potassium chloride and perchlorate in 100 parts of water: potassium chloride, 28 parts at 0° ; at 20° , 35 parts; at 40° , 40 parts; and at 100° , 57 parts; potassium perchlorate, at 0° , about 1 part; at 20° , about $1\frac{2}{3}$ part; and at 100° , about 18 parts. When heated, potassium chlorate melts (the melting-point has been given as from 335° to 376°) and decomposes with the evolution of oxygen, potassium perchlorate being at first formed, as will afterwards be described (see note 47). A mixture of potassium chlorate and nitric and hydrochloric acids effects oxidation and chlorination in solutions. It deflagrates when thrown upon incandescent carbon, and when mixed with sulphur ($\frac{1}{3}$ part by weight) it ignites it on being struck, in which case an explosion takes place. The same occurs with many metallic sulphides and organic substances. Such mixtures are also ignited by a drop of sulphuric acid. All these effects are due to the large amount of oxygen contained in potassium chlorate, and to the ease with which it is evolved. A mixture of two parts of potassium chlorate, one part of sugar, and one part of yellow prussiate of potash acts like gunpowder, but burns too rapidly, and therefore bursts the guns, and has also a very strong oxidising action on the metal. The sodium salt, NaClO_3 , is much more soluble than the potassium salt, and is therefore more difficult to free from sodium chloride, &c. The barium salt is also more soluble than the potassium salt: at 0° , 24 parts; at 20° , 37 parts; and at 80° , 98 parts of salt dissolve per 100 of water.

³⁸ Barium chlorate, $\text{Ba}(\text{ClO}_3)_2 \cdot \text{H}_2\text{O}$, is obtained by first preparing impure chloric acid and saturating it with baryta, the barium salt being purified by crystallisation. The impure free chloric acid is obtained by converting the potassium in potassium chlorate into an insoluble salt. This is done by adding tartaric or hydrofluosilicic acid to a solution of potassium chlorate, because potassium tartrate and potassium silicofluoride are very sparingly soluble in water. Chloric acid is readily soluble in water. The salts of Mg, Zn, Co, and Ni crystallise with 6 molecules of water, but above 15° – 30° they pass into $\text{R}(\text{ClO}_3)_2 \cdot 4\text{H}_2\text{O}$. Further heating gives a compound with $2\text{H}_2\text{O}$, which is

gives a precipitate of barium sulphate, and free chloric acid remains in solution. The solution may be evaporated under the receiver of an air-pump. This solution is colourless, has no smell, and acts as a powerful acid (it neutralises sodium hydroxide, decomposes sodium carbonate, gives hydrogen with zinc, &c.); when heated above 40° it decomposes, forming chlorine, oxygen, and perchloric acid: $4\text{HClO}_3 = 2\text{HClO}_4 + \text{H}_2\text{O} + \text{Cl}_2 + \text{O}_3$. In a concentrated condition the acid acts as an exceedingly energetic oxidiser, so that organic substances brought into contact with it burst into flame. Iodine, sulphurous acid, and similar oxidisable substances form higher oxidation products and reduce the chloric acid to hydrochloric acid. Hydrochloric acid gas gives chlorine with chloric acid (and consequently with KClO_3 also), acting in the same manner as it acts on the lower acids: $\text{HClO}_3 + 5\text{HCl} = 3\text{H}_2\text{O} + 3\text{Cl}_2$.

By cautiously acting on potassium chlorate with sulphuric acid, the **dioxide (chloric peroxide)**, ClO_2 ,³⁹ is obtained (Davy, Millon). This gas is easily liquefied in a freezing mixture, and boils at $+10^{\circ}$. The vapour density (about 35, taking H as 1) shows that the molecule of this substance is ClO_2 .⁴⁰ In a gaseous or liquid state it very easily explodes (for instance, at 60° , or by contact with organic compounds or finely divided substances, &c.), forming Cl and O_2 , and in many instances⁴¹ therefore it acts as an oxidising agent, although (like nitric peroxide) it may itself be further oxidised.⁴² In dissolving in water or alkalies,

also contained in the stable $\text{Cd}(\text{ClO}_3)_2 \cdot 2\text{H}_2\text{O}$. Thus in this case the amount of water of crystallisation varies by $2\text{H}_2\text{O}$, while with the nitrates it varies by $3\text{H}_2\text{O}$. The nitrates of the above metals are also less soluble than the chlorates (Meusser, 1902).

³⁹ To prepare ClO_2 , 100 grams of sulphuric acid are cooled in a mixture of ice and salt, and 15 grams of powdered potassium chlorate gradually added to the acid, which is then carefully distilled at 20° to 40° , the vapour given off being condensed in a freezing mixture: $3\text{KClO}_3 + 2\text{H}_2\text{SO}_4 = 2\text{KHSO}_4 + \text{KClO}_4 + 2\text{ClO}_2 + \text{H}_2\text{O}$. The reaction may result in an explosion. Calvert and Davies obtained chlorine peroxide without the least danger by heating a mixture of oxalic acid and potassium chlorate in a test-tube in a water-bath: $2\text{KClO}_3 + 3\text{C}_2\text{H}_2\text{O}_4 \cdot 2\text{H}_2\text{O} = 2\text{C}_2\text{HKO}_4 + 2\text{CO}_2 + 2\text{ClO}_2 + 8\text{H}_2\text{O}$. The reaction is still further facilitated by the addition of a small quantity of sulphuric acid.

⁴⁰ By analogy with nitrogen peroxide it might be expected that at low temperatures a doubling of the molecule into Cl_2O_4 would take place, as the reactions of ClO_2 point to its being a mixed anhydride of HClO_2 and HClO_3 .

⁴¹ Owing to the formation of this chlorine dioxide, a mixture of potassium chlorate and sugar is ignited by a drop of sulphuric acid. This property was formerly made use of for making matches, and is now sometimes employed for setting fire to explosive charges by means of an arrangement in which the acid is caused to fall on the mixture at the moment required. An interesting experiment on the combustion of phosphorus under water may be conducted with chlorine dioxide. Pieces of phosphorus and of potassium chlorate are placed under water, and sulphuric acid is poured on to them (through a long funnel); the phosphorus then burns at the expense of the chlorine dioxide.

⁴² Potassium permanganate oxidises chlorine dioxide into chloric acid (Fürst).

chlorine peroxide gives chlorous and hypochlorous acids— $2\text{ClO}_2 + 2\text{KHO} = \text{KClO}_3 + \text{KClO}_2 + \text{H}_2\text{O}$ —and therefore, like nitric peroxide, the dioxide may be regarded as an intermediate oxide between the (unknown) anhydrides of chlorous and chloric acids : $4\text{ClO}_2 = \text{Cl}_2\text{O}_3 + \text{Cl}_2\text{O}_5$.⁴³

As the salts of chloric acid, HClO_3 , are produced by the splitting up of those of hypochlorous acid, so in the same way the salts of perchloric acid, HClO_4 , are produced from the salts of chloric acid, HClO_3 . But this is the highest form of the oxidation of HCl . **Perchloric acid**, HClO_4 , in a free state, is the most stable of all the acids of chlorine. When fused potassium chlorate begins to swell up and solidify, after having parted with one-third of its oxygen, potassium chloride and potassium perchlorate have been formed according to the equation : $2\text{KClO}_3 = \text{KClO}_4 + \text{KCl} + \text{O}_2$.

The formation of this salt is easily observed in the preparation of oxygen from potassium chlorate, owing to the fact that the potassium perchlorate fuses with greater difficulty than the chlorate, and therefore appears in the molten salt as solid grains (see Chap. III., note 12). Under the action of an electric current and of certain acids—for instance, sulphuric and nitric—potassium chlorate also gives potassium perchlorate. This latter may be easily purified, because it is but sparingly soluble in water, although other salts of perchloric acid are very soluble and even deliquesce in the air. The perchlorates, although they contain more oxygen than the chlorates, are decomposed with greater difficulty, and even when thrown on ignited charcoal give a much feebler deflagration than the chlorates. Sulphuric acid on heating causes the evolution of volatile and to a certain extent stable perchloric acid from potassium perchlorate. Perchloric acid can be distilled.⁴⁴ The pure hydrate HClO_4 ⁴⁵ is a colourless and exceedingly caustic

⁴³ The euchlorine obtained by Davy by gently heating potassium chlorate with hydrochloric acid is (Pebal) a mixture of chlorine dioxide and free chlorine.

⁴⁴ If a solution of chloric acid, HClO_3 , be first concentrated over sulphuric acid under the receiver of an air-pump and afterwards distilled, chlorine and oxygen are evolved and perchloric acid formed : $4\text{HClO}_3 = 2\text{HClO}_4 + \text{Cl}_2 + 3\text{O} + \text{H}_2\text{O}$. Roscoe accordingly decomposed a solution of potassium chlorate directly by hydrofluosilicic acid, decanted it from the precipitate of potassium silicofluoride, K_2SiF_6 , concentrated the solution of chloric acid, and then distilled it, perchloric acid being then obtained (see following footnote). That chloric acid is capable of passing into perchloric acid is also seen from the fact that potassium permanganate is decolorised, although slowly, by the action of a solution of chloric acid. Perchloric acid is also formed by the action of an electric current on solutions of chlorine and chlorine monoxide. Perchloric acid was obtained by Count Stadion and afterwards by Serullas, and was studied by Roscoe and others.

⁴⁵ Perchloric acid, being volatile, is partially decomposed by distillation. The solution obtained after distillation may be concentrated by evaporation in open vessels. In the distillation the solution reaches a temperature of 200° , and a very constant liquid hydrate of the composition $\text{HClO}_4 \cdot 2\text{H}_2\text{O}$ is then obtained in the distillate. If this hydrate is mixed with sulphuric acid, it begins to decompose at 100° , but nevertheless a portion of

substance which fumes in the air and has a specific gravity 1.78 at 15° (sometimes, after being kept for some time, it decomposes with a violent explosion). It explodes violently when brought into contact with charcoal, paper, wood, and other organic substances. If a small quantity of water be added to this hydrate, and it be cooled, a crystallo-hydrate, $\text{ClHO}_4 \cdot \text{H}_2\text{O}$, separates out. This is much more stable, but the liquid hydrate, $\text{HClO}_4 \cdot 2\text{H}_2\text{O}$, is still more so. The acid dissolves in water in all proportions, and its solutions are distinguished for their stability.⁴⁶ When ignited, both the acid and its salts are decomposed, with the evolution of oxygen.⁴⁷

the acid passes over into the receiver without decomposing, forming a crystalline hydrate, $\text{HClO}_4 \cdot \text{H}_2\text{O}$, which melts at 50°. On carefully heating this hydrate it breaks up into perchloric acid, which distils over below 100°, and into the liquid hydrate, $\text{HClO}_4 \cdot 2\text{H}_2\text{O}$. The acid HClO_4 may also be obtained by adding one-fourth part of strong sulphuric acid to potassium chlorate, carefully distilling and subjecting the crystals of the hydrate, $\text{HClO}_4 \cdot \text{H}_2\text{O}$, obtained in the distillate, to a fresh distillation. Perchloric acid, HClO_4 , itself does not distil, and is decomposed on distillation until the more stable hydrate, $\text{HClO}_4 \cdot \text{H}_2\text{O}$, is formed; this decomposes into HClO_4 and $\text{HClO}_4 \cdot 2\text{H}_2\text{O}$, which latter hydrate distils without decomposition. This forms an excellent example of the influence of water on stability, and shows the property of chlorine of giving compounds of the type ClX_7 , of which all the above hydrates, $\text{ClO}_3(\text{OH})$, $\text{ClO}_2(\text{OH})_3$, and $\text{ClO}(\text{OH})_5$, are members. Probably further research will lead to the discovery of a hydrate $\text{Cl}(\text{OH})_7$.

⁴⁶ According to Roscoe the specific gravity of perchloric acid is 1.782 and that of the hydrate $\text{HClO}_4 \cdot \text{H}_2\text{O}$ in a liquid state (50°), 1.811; hence a considerable contraction takes place in the combination of HClO_4 with H_2O .

⁴⁷ The decomposition of salts analogous to potassium chlorate has been more fully studied by Potilitzin and P. Frankland. Professor Potilitzin, by decomposing, for example, lithium chlorate LiClO_3 , found (from the quantities of lithium chloride and oxygen) that at first the decomposition of the fused salt (368°) takes place according to the equation, $3\text{LiClO}_3 = 2\text{LiCl} + \text{LiClO}_4 + 5\text{O}$, and that towards the end the remaining salt is decomposed thus: $5\text{LiClO}_3 = 4\text{LiCl} + \text{LiClO}_4 + 10\text{O}$. The phenomena observed by Potilitzin obliged him to admit that lithium perchlorate is capable of decomposing simultaneously with lithium chlorate, with the formation of the latter salt and oxygen; and this was confirmed by direct experiment, which showed that lithium chlorate is always formed in the decomposition of the perchlorate. Potilitzin drew particular attention to the fact that the decomposition of potassium chlorate and of salts analogous to it, although these are exothermal (Chap. III., note 12) not only does not proceed spontaneously, but requires time and a rise of temperature in order to attain completion, which again shows that chemical equilibria are not determined by the heat effects of reactions only.

P. Frankland and J. Dingwall (1887) showed that at 448° (in the vapour of sulphur) a mixture of potassium chlorate and powdered glass is decomposed almost in accordance with the equation, $2\text{KClO}_3 = \text{KClO}_4 + \text{KCl} + \text{O}_2$, whilst the salt by itself evolves about half as much oxygen, according to the equation, $8\text{KClO}_3 = 5\text{KClO}_4 + 3\text{KCl} + 2\text{O}_2$. The decomposition of potassium perchlorate in admixture with manganese peroxide proceeds to completion, $\text{KClO}_4 = \text{KCl} + 2\text{O}_2$. But in decomposing by itself the salt at first gives potassium chlorate, approximately according to the equation, $7\text{KClO}_4 = 2\text{KClO}_3 + 5\text{KCl} + 11\text{O}_2$. Thus there is now no doubt that when potassium chlorate is heated, the perchlorate is formed, and that this salt, in decomposing with evolution of oxygen, again gives the former salt.

In the decomposition of barium hypochlorite, 50 per cent. of the whole amount passes

On comparing chlorine as an element not only with nitrogen and carbon but with all the other non-metallic elements, we find in it the following fundamental **properties of the halogens** or salt-producers. With metals, chlorine gives salts (such as sodium chloride, &c.), and with hydrogen, a very energetic and monobasic acid HCl, and the same quantity of chlorine is able by metalepsis to replace the hydrogen; with oxygen it forms unstable oxides of an acid character. These properties are possessed by three other elements, bromine, iodine, and fluorine. These are all members of one natural family. Each representative has its peculiarities, its individual properties and points of distinction, in combination and in the free state—otherwise they would not be independent elements; but the repetition in all of them of the same chief characteristics of the family enables one more quickly to grasp all their various properties and facilitates our acquaintance with them.

In order to have a guiding thread in forming comparisons between the elements, attention must, however, be turned not only to their points of resemblance, but also to those in which they differ most from each other. And the **atomic weights** of the elements must be considered as their most elementary property, since this is a quantity which is most firmly established, and must be taken account of in all the reactions of the element. The halogens have the following atomic weights—

$$\text{F}=19, \quad \text{Cl}=35.5, \quad \text{Br}=80, \quad \text{I}=127.$$

All the properties, physical and chemical, of the elements and their corresponding compounds must evidently be in a certain dependence on this fundamental point, if the grouping in one family be natural. And we find in reality that, for instance, the properties of bromine, whose atomic weight is almost the mean between those of iodine and chlorine, occupy a mean position between those of these two elements.

into chlorate, in that of strontium hypochlorite (Potilitzin, 1890) 12.5 per cent., and with calcium hypochlorite about 2.5 per cent. Besides which, Potilitzin showed that the decomposition of the hypochlorites and also of the chlorates is always accompanied by the formation of a certain quantity of the oxides and by the evolution of chlorine, the chlorine being displaced by the oxygen disengaged.

The decomposition of potassium chlorate, being a reaction evolving heat, easily lends itself, for this reason, to the contact action of manganese peroxide and other similar admixtures; for such very feeble influences as those of contact may become evident either in those cases (for instance, detonating gas, hydrogen peroxide, &c.), when the reaction is accompanied by the evolution of heat, or when (for instance, $\text{H}_2 + \text{I}_2$, &c.) little heat is absorbed or evolved. In these cases it is evident that the existing equilibrium is not very stable, and that a small alteration in the conditions at the surfaces of contact may suffice to upset it. In order to conceive the *modus operandi* of contact phenomena, it is enough to imagine, for instance, that at the surface of contact the movement of the atoms in the molecules changes from a circular to an elliptical path.

The second measurable property of the elements is their equivalence or their capacity for forming **compounds of definite forms**. Thus carbon or nitrogen in this respect differs widely from the halogens. Although the form ClO_2 corresponds with NO_2 and CO_2 , yet the last is the highest oxide of carbon, whilst that of nitrogen is N_2O_5 , and for chlorine, if there were an anhydride of perchloric acid, its composition would be Cl_2O_7 , which is quite different from that of carbon. In respect to the form of their compounds the halogens, like all elements of one family or group, are perfectly analogous with each other, as is seen from their hydrogen compounds :

Their oxygen compounds exhibit a similar analogy. Fluorine alone does not give any oxygen compounds. The iodine and bromine compounds corresponding with HClO_3 and HClO_4 are HBrO_3 and HBrO_4 , HIO_3 and HIO_4 . On comparing the properties of these acids, we can even predict that fluorine will not form any oxygen compound. For iodine is easily oxidised—for instance, by nitric acid—whilst chlorine is not directly oxidised. The oxygen acids of iodine are comparatively more stable than those of chlorine; and, generally speaking, the affinity of iodine for oxygen is much greater than that of chlorine. Here also bromine occupies an intermediate position. In fluorine we may therefore expect a still smaller affinity for oxygen than in chlorine—and up to now it has not been combined with oxygen. If any oxygen compounds of fluorine should be obtained, they will naturally be exceedingly unstable. The relation of these elements to hydrogen is the reverse of the above. Fluorine has so great an affinity for hydrogen that it decomposes water at the ordinary temperature; whilst iodine has so little affinity for hydrogen that hydriodic acid, HI , is formed with difficulty, is easily decomposed, and frequently acts as a reducing agent.

From the form of their compounds the halogens are **univalent elements** with respect to hydrogen and septivalent with respect to oxygen, N being trivalent to hydrogen (it gives NH_3) and quinquevalent to oxygen (it gives N_2O_5), and C quadrivalent to both H and O, as it forms CH_4 and CO_2 . And as not only their oxygen compounds, but also their hydrogen compounds, have acid properties, the halogens are **elements of an exclusively acid character**. In no other elements is the acid-giving property so strongly developed as in the halogens.^{47a}

^{47a} Among the general properties of the haloids must be mentioned the faculty for a mutual union between the metallic and metalloidal compounds formed by them, or the formation of complex haloid salts like the oxygen salts, where MX_n (M a metal, X a haloid) combines with RX_n (R either a metal or metalloid) to form $\text{MRX}_{(n+m)}$ or some

In describing certain peculiarities characterising the halogens, we shall at every step encounter a confirmation of the above-mentioned general relations.

As **fluorine** decomposes water with the evolution of oxygen, in the form of ozone, $F_2 + H_2O = 2HF + O$, for a long time all efforts to obtain it in the free state by means of methods similar to those used for the preparation of chlorine proved fruitless.⁴⁸ Thus by the action of hydrofluoric acid on manganese peroxide, or by decomposing a solution of hydrofluoric acid by an electric current, either oxygen or a mixture of oxygen and fluorine was obtained instead of fluorine. Probably a certain quantity of fluorine^{48a} was set free by the action of oxygen or an electric current on incandescent and fused calcium fluoride, but at a high temperature fluorine acts even on platinum, and therefore it was not isolated. When chlorine acted on silver fluoride, AgF , in a vessel of natural fluor spar, CaF_2 , fluorine was also liberated; but it was mixed with chlorine, and it was impossible to study the properties of the resultant gas. Brauner (1881) also obtained fluorine by igniting cerium fluoride, $2CeF_4 = 2CeF_3 + F_2$; but this, like all preceding efforts, only showed fluorine to be a gas which decomposes water and is capable of acting in a number of instances like chlorine, but gave no possibility of testing its properties. It was evident that it was necessary to avoid as far as possible the presence of water and a rise of temperature; this Moissan succeeded in doing in 1886. He decomposed anhydrous hydrofluoric acid (to which a small quantity of potassium fluoride had been added to make it a better conductor), liquefied at a temperature of -23° and contained in a platinum or copper U-shaped tube, by the action of a powerful electric current (twenty Bunsen's elements in series). Hydrogen was then evolved at the negative pole, and fluorine appeared at the positive pole (of iridium-platinum) as a pale green gas which

other simple multiple of them. Here M may be hydrogen and then the corresponding acid will be formed; for instance, $H_2SiF_4 = 2HF + SiF_4$, $HCuCl_2 = HCl + CuCl$, $HPtCl_3 = HCl + PtCl_2$, $H_2PtCl_6 = 2HCl + PtCl_4$, $H_2SnBr_6 = 2HBr + SnBr_4$, $HTeI_5 = HI + TeI_4$; or with their corresponding salts, where H is replaced by a metal; for example, K_2SiF_6 , K_2HgCl_4 , $(NH_4)_2PtCl_6$, H_2FeCl_6 , &c. The molecules of such double salts usually, as Werner remarked, contain—in the limit—six atoms of the haloid (see also Chap. XIII., note 3a, formation of KCl_4I).

⁴⁸ Even before free fluorine was obtained (1886) it was evident from experience gained in the efforts made to obtain it, and from analogy, that it would decompose water.

^{48a} It is most likely that in this experiment of Fremy's, which corresponds with the action of oxygen on calcium chloride, fluorine was set free, but that a converse reaction also proceeded, $CaO + F_2 = CaF_2 + O$, that is, the calcium distributed itself between the oxygen and fluorine. MnF_4 , which is capable of splitting up into MnF_2 and F_2 , is formed by the action of a strong solution of hydrofluoric acid on manganese peroxide, but under the action of water the fluorine gives hydrofluoric acid, and probably this is aided by the affinity of the manganese fluoride and hydrofluoric acid.

decomposed water with the formation of ozone and hydrofluoric acid, and combined directly with silicon (forming silicon fluoride, SiF_4), boron (forming BF_3), sulphur, &c. Its density shows that its molecule is F_2 . Fluorine liquefies under great cold into a yellow mobile liquid, boiling at -187° and solidifying at -210° . Liquid fluorine mixes with liquid air. Its density is 1.14, and it does not act upon glass, ice, or water, but it immediately bursts into flame with hydrogen or hydrocarbons (Moissan and Dewar, 1897). But the action of fluorine on metals at the ordinary temperature is comparatively feeble, because the metallic fluoride formed coats the remaining mass of the metals; however, Na, Fe, and others burn in fluorine. Hydrocarbons (such as naphtha), alcohol, &c., are immediately decomposed by fluorine, with the formation of hydrofluoric acid. Fluorine with hydrogen explodes violently, forming hydrofluoric acid;⁴⁹ even HCl is decomposed by fluorine, forming HF and Cl.

In 1894 Brauner obtained fluorine directly by igniting the easily formed^{49a} double lead salt, $\text{HF}, 3\text{KF}, \text{PbF}_4$, which first, at 230° , decomposes with the evolution of HF, and then splits up, forming $3\text{KF}, \text{PbF}_2$ and fluorine, F_2 , which is recognised by the fact that it liberates iodine from KI and easily combines with silicon, forming SiF_4 . Here, as a matter of fact, the higher degree of combination, PbF_4 , decomposes into

⁴⁹ According to Moissan, fluorine is disengaged by the action of an electric current on fused hydrogen potassium fluoride, KHF_2 . The present state of chemical knowledge is such that the knowledge of the properties of an element is much more general than the knowledge of the free element itself. It is useful and satisfactory to learn that even fluorine in the free state has not succeeded in eluding experiment and research, that the efforts to isolate it have been crowned with success, but the sum total of chemical data concerning fluorine as an element gains but little by this achievement. We may add that Moissan (1892) found that free fluorine decomposes H_2S , HCl, HBr, CS_2 , and CNH with a flash; it does not act upon O_2 , N_2 , CO, and CO_2 ; Mg, Al, Ag, and Ni, when heated, burn in it, as also do S, Se, P (forms PF_3); it reacts upon H_2 even in the dark, with the evolution of 36,600 units of heat. Soot and carbon in general (but not the diamond), when heated in gaseous fluorine, forms **fluoride of carbon**, CF_4 (Moissan, 1890); this compound is also formed at 300° by the double decomposition of CCl_4 and AgF ; it is a gas which liquefies at 10° under a pressure of five atmospheres. With an alcoholic solution of KHO, CF_4 gives K_2CO_3 , according to the equation, $\text{CF}_4 + 6\text{KHO} = \text{K}_2\text{CO}_3 + 4\text{KF} + 3\text{H}_2\text{O}$. CF_4 is not soluble in water, but is readily soluble in CCl_4 and alcohol. In 1900 Moissan and Lebeau showed that fluorine in combining with sulphur forms *hexafluoride of sulphur*, SF_6 , in the form of an inactive gas (see Chap. XX.).

^{49a} T. Nikolukin (1885), Classen, and others obtained PbCl_4 and a double ammonium salt of tetrachloride of lead (starting from the binoxide), $\text{PbCl}_4, 2\text{NH}_4\text{Cl}$; Hutchinson and Pallard obtained a similar salt of acetic acid (1893), corresponding to PbX_4 , by treating red lead with strong acetic acid; the composition of this salt is $\text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_4$ and it melts (and decomposes) at about 175° . Brauner (1894) obtained tetrafluoride of lead, PbF_4 , and the corresponding acid H_4PbF_8 . For example, by treating potassium plumbate (Chap. XVIII., note 55) with strong HF, and also the above-mentioned tetra-acetate with a solution of KHF_2 , Brauner obtained crystalline HK_3PbF_8 , which is the salt from which he obtained fluorine.

the lower, PbF_2 , and fluorine just as Cu_2Cl_2 decomposes into Cu_2Cl and chlorine.

Among the compounds of fluorine, calcium fluoride, CaF_2 , is somewhat widely distributed in nature as **fluor spar**,⁵⁰ whilst **cryolite**, or aluminium sodium fluoride, Na_3AlF_6 , is found more rarely (in large masses in Greenland). Cryolite, like fluor spar, is insoluble in water, and gives hydrofluoric acid with sulphuric acid. Small quantities of fluorine have also in a number of cases been found in the bodies of animals, in the blood, urine, and bones. If fluorides occur in the bodies of animals, they must have been introduced in food, and must occur in plants and in water. And as a matter of fact, river, and especially sea, water always contains a certain, although small, quantity of fluorine compounds.

Hydrofluoric acid, HF, cannot be obtained from fluor spar in glass retorts, because glass is acted on by, and destroys, the acid. It is prepared in lead, or, when it is required pure, in platinum vessels, because although lead acts on hydrofluoric acid, it does so only very feebly on the surface, and when once a coating of fluoride and sulphate of lead is formed no further action takes place. Powdered fluor spar and sulphuric acid evolve hydrofluoric acid (which fumes in the air) even at the ordinary temperature, $\text{CaF}_2 + \text{H}_2\text{SO}_4 = \text{CaSO}_4 + 2\text{HF}$. At 130° fluor spar is completely decomposed by sulphuric acid. The acid is then evolved as vapour, which may be condensed by a freezing mixture into an anhydrous acid. The condensation is aided by pouring water into the receiver of the condenser, as the acid is readily soluble in water.

In the liquid anhydrous form hydrofluoric acid boils at $+19^\circ$, and its specific gravity at 12.8° is 0.9849.⁵¹ It dissolves in water with the

⁵⁰ It is called spar because it occurs as crystals of a clearly laminar structure, and is therefore easily split up into pieces bounded by planes. It is called fluor spar because when used as a flux it renders ores fusible, owing to its reacting with silica, $\text{SiO}_2 + 2\text{CaF}_2 = 2\text{CaO} + \text{SiF}_4$; the silicon fluoride escapes as a gas and the lime combines with a further quantity of silica, giving a vitreous slag. Fluor spar occurs in mineral veins and rocks, sometimes in considerable quantities. It always crystallises in the cubic system, sometimes in very large semi-transparent cubic crystals, which are either colourless or of different colours. It is insoluble in water. It melts under the action of heat and crystallises on cooling. The specific gravity is 3.1. When steam is passed over incandescent fluor spar, lime and hydrofluoric acid are formed: $\text{CaF}_2 + \text{H}_2\text{O} = \text{CaO} + 2\text{HF}$. A double decomposition is also easily produced by fusing fluor spar with sodium or potassium hydroxide, or even with their carbonates; the fluorine then passes over to the potassium or sodium, and the oxygen to the calcium. Potassium fluoride is soluble in water, and precipitates CaF_2 from solutions of salts of calcium; for instance, $\text{Ca}(\text{NO}_3)_2 + 2\text{KF} = \text{CaF}_2 \text{ (precipitate)} + 2\text{KNO}_3$. Twenty-six thousand parts of water dissolve one part of fluor spar.

⁵¹ According to Gore. Fremy obtained anhydrous hydrofluoric acid by decomposing lead fluoride at a red heat by means of hydrogen, or by heating the double salt HKF_2 , which crystallises easily (in cubes) from a solution of hydrofluoric acid half of which has been saturated with potassium hydroxide.

evolution of a considerable amount of heat, and gives a solution of constant boiling-point which distils over at 120° , showing that the acid is able to combine with water. The specific gravity of the compound is 1.15, and its composition $\text{HF}, 2\text{H}_2\text{O}$.⁵² With an excess of water a dilute solution distils over first. Strong solutions and the acid itself must be kept in platinum vessels, but the dilute acid may be conveniently preserved in vessels made of gutta-percha, or even in glass vessels having an interior coating of paraffin. Hydrofluoric acid does not act on hydrocarbons and many other substances, but it acts in a highly corrosive manner on metals, glass, porcelain, and the majority of rock substances.⁵³ It also attacks the skin, and is distinguished by its very poisonous properties, so that in working with the acid a strong draught must be kept up, to prevent the possibility of the fumes being inhaled. The non-metals do not act on hydrofluoric acid, but all metals—with the exception of mercury, silver, gold, and platinum, and, to a certain degree, lead—decompose it with the evolution of hydrogen. With bases it gives directly metallic fluorides, and behaves in many respects like hydrochloric acid. There are, however, several distinct individual differences, which are furthermore much greater than those between hydrochloric, hydrobromic, and hydriodic acids. Thus the silver compounds of the latter are insoluble in water, whilst silver fluoride, AgF , is soluble. Calcium fluoride, on the contrary, is insoluble in water, whilst calcium chloride, bromide, and iodide are not only soluble,

⁵² All the properties of hydrofluoric acid recall those of hydrochloric acid, and the comparative ease with which hydrofluoric acid is liquefied (it boils at $+19^{\circ}$, hydrochloric acid at -83°) must therefore be explained by a polymerisation taking place at low temperatures, as will be afterwards explained, H_2F_2 being formed, and therefore in a liquid state it differs from hydrochloric acid, in which a phenomenon of a similar kind has not yet been observed. Solutions containing 70 per cent. of HF do not freeze at -70° , but at -45° a 58 per cent. solution forms a hydrate, $\text{HF}, \text{H}_2\text{O}$, which melts at -35° (Metzner, 1899).

⁵³ The corrosive action of hydrofluoric acid on glass and similar silicious compounds is based upon the fact that it acts on silica, SiO_2 , as we shall consider more fully in describing that compound (Chap. XVIII.), forming gaseous silicon fluoride, $\text{SiO}_2 + 4\text{HF} = \text{SiF}_4 + 2\text{H}_2\text{O}$. Silica, indeed, forms the binding (acid) element of glass and of the mass of mineral substances forming the salts of silica. When it is removed the cohesion is destroyed. This is made use of in the arts, and in the laboratory, for etching designs and scales, &c., on glass. In **engraving on glass** the surface is covered with a varnish composed of four parts of wax and one part of turpentine. This varnish is not acted on by hydrofluoric acid, and it is soft enough to allow of designs being drawn upon it whose lines lay bare the glass. The drawing is made with a steel point, and the glass is afterwards laid in a lead trough in which a mixture of fluor spar and sulphuric acid is placed. The sulphuric acid must be used in considerable excess, as otherwise transparent lines are obtained (owing to the formation of hydrofluosilicic acid). After being exposed for some time, the varnish is removed (melted) and the design drawn by the steel point is found reproduced in dull lines. The drawing may be also made by the direct application of a mixture of a silicofluoride and sulphuric acid, which forms hydrofluoric acid.

but attract water with great energy. Neither hydrochloric, nor hydrobromic, nor hydriodic acid acts on sand and glass, whilst hydrofluoric acid corrodes them, forming gaseous silicon fluoride, SiF_4 . The other halogen acids form normal salts, KCl , NaCl , with Na or K , whilst hydrofluoric acid gives acid salts—for instance, HKF_2 (and by dissolving KF in liquid HF , the compound $\text{KHF}_2 \cdot 2\text{HF}$ is obtained). This latter property is in close connection with the fact that at the ordinary temperature the vapour density of hydrofluoric acid is nearly 20, which corresponds with a formula H_2F_2 , as was shown by Mallet (1881); but a de-polymerisation occurs with a rise of temperature, and the density approaches 10, corresponding with the formula HF .⁵⁴

The analogy between chlorine and the other two halogens, bromine and iodine, is much more perfect. Not only have their hydrates or halogen acids much in common, but they themselves resemble chlorine in many respects,⁵⁵ and even the properties of the corresponding

⁵⁴ Mallet (1881) determined the density at 30° and 100° , previous to which Gore (1869) had determined the vapour density at 100° , whilst Thorpe and Hambly (1888) made fourteen determinations between 26° and 88° , and showed that within this limit of temperature, the density gradually diminishes, just as with the vapours of acetic acid, nitrogen dioxide, and others. The tendency of HF to polymerise into H_2F_2 is probably connected with the property of many fluorides of forming acid salts—for example, KHF_2 and H_2SiF_6 . We saw above that HCl has the same property (forming, for instance, H_2PtCl_6 , &c.), and hence this property of hydrofluoric acid does not stand isolated from the properties of the other halogens (see note 47a).

⁵⁵ For instance, the experiment with Dutch metal foil (note 16) may be made with bromine just as well as with chlorine. A very instructive experiment on the direct combination of the halogens with metals may be made by throwing a small piece (a shaving) of aluminium into a vessel containing liquid bromine; the aluminium, being lighter, floats on the bromine, and after a certain time reaction sets in accompanied by the evolution of heat, light, and fumes of bromine. The incandescent piece of metal moves rapidly over the surface of the bromine in which the resultant aluminium bromide dissolves. For the sake of comparison we shall proceed to give several thermochemical data (Thomson) for analogous actions of (1) chlorine, (2) bromine, and (3) iodine, with respect to metals, the halogen being expressed by the symbol X , and the plus sign connecting the reacting substances. All the figures are given in thousands of calories, and refer to molecular quantities in grams and to the ordinary temperature.

	1	2	3

$\text{Zn} + \text{X}_2$	97	76	49
$\text{Pb} + \text{X}_2$	83	64	40
$\text{Al} + \text{X}_2$	161	120	70

In every case chlorine gives more heat than bromine, and bromine more than iodine.

metallic compounds of bromine and iodine are very much alike. Thus, the chlorides, bromides, and iodides of sodium and potassium crystallise in the cubic system, and are soluble in water; the chlorides of calcium, aluminium, magnesium, and barium are just as soluble in water as the bromides and iodides of these metals. The iodides and bromides of silver and lead are sparingly soluble in water, like the chlorides of these metals. The oxygen compounds of bromine and iodine also present a very strong analogy to the corresponding compounds of chlorine. A hypobromous acid is known corresponding with hypochlorous acid. The salts of this acid have the same bleaching property as the salts of hypochlorous acid. Iodine was discovered in 1811 by Courtois in kelp, and was shortly afterwards investigated by Clement, Gay-Lussac, and Davy. Bromine was discovered in 1826 by Balard in the mother liquor of sea water.

Bromine and iodine, like chlorine, occur in sea water in combination with metals. However, the amount of bromides, and especially of iodides, in sea water is so small that their presence can only be discovered by means of sensitive reactions.⁵⁶ In the extraction of salt from sea water the bromides remain in the mother liquor. Iodine and bromine also occur combined with silver, in admixture with silver chloride, as a rare ore found mainly in America. Certain mineral waters (those of Kreuznach and Staro-russki) contain metallic bromides and iodides, always in admixture with an excess of sodium chloride. Those upper strata of the Stassfurt rock salt (Chapter X.) which are a source of potassium salts also contain metallic bromides,⁵⁷ which collect in the mother liquors left after the crystallisation of the potassium salts; and this now forms the chief source (together with certain American springs) of the bromine in common use. Bromine may be easily liberated from a mixture of bromides and chlorides, owing to the fact that chlorine displaces bromine from its compounds with sodium, magnesium, calcium, &c. Colourless solutions of bromides of the

According to Esbreicher (1896), the following are the data for the liquefied halogen acids:—

	HCl	HBr	HI
Temperature of fusion	— 111.1°	— 87.9°	— 50.8°
Boiling-point	— 83.7°	— 64.9°	— 34.1°

We may remark that the latent heat of vaporisation of the molecular weight Br_2 is about 7.2, and that of iodine 6.0 thousand heat units, whilst the latent heat of fusion of Br_2 is about 0.3, and that of I_2 about 3.0 thousand heat units. From this it is evident that the difference between the amounts of heat evolved does not depend on the difference in physical state. For instance, the vapour of iodine in combining with Zn to form ZnI_2 would give $49 + 8 + 3$, or about sixty thousand heat units, or $1\frac{1}{2}$ time less than $\text{Zn} + \text{Cl}_2$

⁵⁶ One litre of sea water contains about 20 grams of chlorine, and about 0.07 gram of bromine. The Dead Sea contains about ten times as much bromine.

⁵⁷ But there is no iodine in Stassfurt carnallite.

metals turn an orange colour after the passage of chlorine, owing to the disengagement of bromine.⁵⁸ Bromine may be extracted on a large scale by a similar method, but it is simpler to add a small quantity of manganese peroxide and sulphuric acid to the mother liquid direct. This sets free a portion of the chlorine, and this chlorine liberates the bromine.

Bromine is a **dark brown liquid**, giving brown fumes, and having a poisonous suffocating smell, whence its name (from the Greek $\beta\rho\omega\mu\omicron\varsigma$, signifying evil-smelling). The vapour density of bromine shows that its molecule is Br_2 . In the cold, bromine freezes into brown-grey scales. The melting-point of pure bromine is -7.05° .⁵⁹ The density

⁵⁸ The chlorine must not, however, be in large excess, as otherwise the bromine would contain chlorine. Commercial bromine not infrequently contains chlorine, in the form of bromine chloride; this is more soluble in water than bromine, from which it may thus be freed. To obtain pure bromine the commercial product is washed with water, dried by means of sulphuric acid, and distilled, the portion coming over at 58° being collected; the greater part is then converted into potassium bromide and dissolved, and the remainder added to the solution in order to separate iodine, which is removed by shaking with carbon bisulphide. By heating the potassium bromide thus obtained with manganese peroxide and sulphuric acid, bromine is obtained quite free from iodine, which, however, is not present in certain kinds of commercial bromine (the Stassfurt, for instance). By treatment with potash, the bromine is then converted into a mixture of potassium bromide and bromate, and the mixture (which is in the proportion given in the equation) is distilled with sulphuric acid, bromine being then evolved: $5\text{KBr} + \text{KBrO}_3 + 6\text{H}_2\text{SO}_4 = 6\text{KHSO}_4 + 3\text{H}_2\text{O} + 3\text{Br}_2$. After dissolving the bromine in a strong solution of calcium bromide and precipitating with an excess of water, it loses all the chlorine it contained, because chlorine forms calcium chloride with CaBr_2 .

⁵⁹ There existed for long a difference of opinion as to the melting-point of pure bromine. By some investigators it was given as between -7° and -8° , and by others as between -20° and -25° . There is now no doubt, thanks to the researches of Ramsay and Young (1885), that pure bromine melts at about -7° . For solid bromine the vapour pressure p in mm. at t was found to be—

$p =$	20	25	30	35	40	45 mm.
$t =$	-16.6°	-14°	-12°	-10°	-8.5°	-7°

For liquid bromine—

$p =$	50	100	200	400	600	760 mm.
$t =$	-5.0°	$+8.2^\circ$	23.4°	40.4°	51.9°	58.7°

These curves intersect at -7.05° . Besides which, in comparing the vapour pressures of many liquids (for example, those given in Chap. II., note 27), Ramsay and Young observed that the ratio of the absolute temperatures ($t + 273$) corresponding with equal pressures *varies* for every pair of substances as a *rectilinear function* of t , and, therefore, for the above pressure p , Ramsay and Young determined the ratio of $t + 273$ for water and bromine, and found that the straight lines expressing these ratios for liquid and solid bromine intersect also at 7.05° ; thus, for example, for solid bromine—

$p =$	20	25	30	35	40	45
$273 + t =$	256.4	259	261	263	264.6	266
$273 + t' =$	295.3	299	302.1	304.8	307.2	309.3
$c =$	1.152	1.154	1.157	1.159	1.161	1.163

where t' indicates the temperature of water corresponding with a vapour pressure p , and c is the ratio of $273 + t'$ to $273 + t$. The magnitude of c is evidently expressed with great

of liquid bromine at 0° is 3.187, and at 15° about 3.0. The boiling-point of bromine is about 58.7° (Ramsay). Bromine, like chlorine, is soluble in water; 1 part of bromine at 5° requires 27 parts of water, and at 15° , 29 parts of water for its solution. The aqueous solution of bromine is of an orange colour, and when cooled to -2° yields crystals containing 10 molecules of water to 1 molecule of bromine.⁶⁰ Alcohol dissolves a greater quantity of bromine, and ether a still greater amount. But after a certain time products of the action of the bromine on these organic substances are formed in the solutions. Aqueous solutions of the bromides also absorb a large amount of bromine.

With respect to **iodine**, this is almost exclusively extracted from the mother liquors after the crystallisation of natural sodium nitrate (Chili saltpetre) and from the ashes of the seaweed cast upon the shores of France, Great Britain, and Spain, sometimes in considerable quantities, by the high tides. The majority of these seaweeds are of the genera *Fucus*, *Laminaria*, &c. The fused ashes of these seaweeds are called 'kelp' in Scotland and 'varech' in Normandy. A somewhat considerable quantity of iodine is contained in these seaweeds, and in sea-sponges (partly in the form of special organic compounds discovered by Gauthier, also in the air and in sea water, although in very small quantities). After being burnt (or subjected to dry distillation) an ash is left which contains chiefly salts of potassium, sodium, and calcium. The metals occur in the seaweed as salts of organic acids. On being burnt these organic salts are decomposed, forming carbonates of potassium and sodium. Hence, sodium carbonate is found in the ash of sea plants. The ash is dissolved in hot water, and on evaporation sodium carbonate and other salts separate, but a portion of the substances remains in solution. These mother liquors left after the separation of the sodium carbonate contain chlorine, bromine, and iodine in combination with metals, the chlorine and iodine being in excess

accuracy by the straight line, $c = 1.1703 + 0.0011t$. In exactly the same way we find the ratio for liquid bromine and water to be $c_1 = 1.1585 + 0.00057t$. The intersection of these straight lines also corresponds with -7.06° , which again confirms the melting-point given above for bromine. In this manner it is possible with the existing store of data to accurately establish and **verify** the melting-point of substances. Ramsay and Young established the thermal constants of iodine by exactly the same method.

⁶⁰ The observations made by Paterno and Nasini (by Raoult's method, Chap. I., note 49) on the temperature of the formation of ice (-1.115° , with 1.391 gram of bromine in 100 grams of water) in an aqueous solution of bromine, showed that bromine is contained in solutions as the molecule Br_2 . Similar experiments conducted on iodine (Kloboukoff, 1889, and Beckmann, 1890) show that in solution the molecule is I_2 .

B. Roozeboom investigated the hydrate of bromine as completely as the hydrate of chlorine (notes 9 and 10). The temperature of the complete decomposition of the hydrate is $+6.2^{\circ}$; the density of $\text{Br}_2 \cdot 10\text{H}_2\text{O}$ is 1.49.

over the bromine. Thirteen thousand kilos of kelp give about 1,000 kilos of sodium carbonate and 15 of iodine.

The liberation of the iodine from the mother liquor is effected with comparative ease, because chlorine disengages iodine from potassium iodide and its other combinations with the metals. Not only chlorine but also sulphuric acid liberate iodine from sodium iodide. Sulphuric acid, in acting on an iodide, sets free hydriodic acid, but the latter then decomposes (see further on), especially in the presence of substances capable of evolving oxygen, such as chromic acid, nitrous acid, or even ferric salts.⁶¹ Owing to its sparing solubility in water, the iodine liberated separates as a precipitate. To obtain pure iodine it is distilled, the first and last portions of the distillate being neglected and the middle portion only being collected. Iodine passes directly from a state of vapour into a crystalline form, and settles on the cool portions of the apparatus in tabular crystals, having a blackish-grey colour and metallic lustre.

The specific gravity of the crystals of iodine is 4.93 at 4°. It melts at 115.1° and boils at 183.05°. ⁶² Its vapour is formed at a much lower

⁶¹ In general, $2\text{HI} + \text{O} = \text{I}_2 + \text{H}_2\text{O}$, if the oxygen proceed from a substance from which it is easily evolved. For this reason compounds corresponding with the higher stages of oxidation or chlorination frequently give a lower stage when treated with hydriodic acid. Ferric oxide, Fe_2O_3 , is a higher oxide, and ferrous oxide, FeO , a lower oxide; the former corresponds with FeX_3 , and the latter with FeX_2 , and this passage from the higher to the lower takes place under the action of hydriodic acid. Thus hydrogen peroxide and ozone (Chap. IV.) are able to liberate iodine from hydriodic acid. Compounds of copper oxide, CuO or CuX_2 , give compounds of the suboxide Cu_2O , or CuX . Even sulphuric acid, which corresponds to the higher stage SO_3 , is able to act thus, forming the lower oxide SO_2 . The liberation of iodine from hydriodic acid proceeds with still greater ease under the action of substances capable of disengaging oxygen. In practice, many methods are employed for liberating iodine from acid liquids containing, for example, sulphuric acid and hydriodic acid. Nitrous acid and the higher oxides of nitrogen are most commonly used; they then pass into nitric oxide. Iodine may even be disengaged from hydriodic acid by the action of iodic acid, &c. But there is a limit in these reactions of the oxidation of hydriodic acid because, under certain conditions, especially in dilute solutions, the iodine set free is itself able to act as an oxidising agent—that is, it exhibits the character of the halogens. The iodine is liberated from iodates by acid sulphites, for instance: $2\text{NaIO}_3 + 3\text{Na}_2\text{SO}_3 + 2\text{NaHSO}_3 = \text{I}_2 + \text{H}_2\text{O} + 5\text{Na}_2\text{SO}_4$, that is, the iodic acid is reduced by the sulphurous acid, which passes into sulphuric acid. In Chili a mother liquor containing NaIO_3 is obtained in the extraction of nitre, and iodine is obtained from it in the above manner.

⁶² For the final purification of iodine, Stas dissolved it in a strong solution of potassium iodide, and precipitated it by the addition of water, while Ladenburg (1902) purified iodine in the form of a precipitate of AgI by shaking it up with an excess of a strong solution of ammonia, as 100 grams of ammonia only dissolve 0.0045 AgI at 16°, and the solubility of AgCl is 1,000 times greater. The iodine is converted into ZnI_2 by treating with pure zinc and sulphuric acid, and the action of nitrous acid upon the solution of ZnI_2 liberates the iodine. Ladenburg found that the atomic weight of this iodine was $\text{I} = 126.96$, while Stas gives that of the iodine he purified as $\text{I} = 126.85$, taking 0 as 16. Possibly Ladenburg's iodine yet retained some trace

temperature, and is of a violet colour, whence iodine receives its name (*ιοειδής*, violet-coloured). The smell of iodine recalls the characteristic smell of hypochlorous acid; it has a sharp, sour taste. It destroys the skin and organs of the body, and is therefore frequently employed for cauterising and as an irritant for the skin. In small quantities it turns the skin brown, but the coloration disappears after a certain time, partly owing to the volatility of the iodine. Water dissolves only $\frac{1}{5000}$ part of its weight of iodine. A brown solution is thus obtained, which bleaches, but much more feebly than either bromine or chlorine. Water which contains salts, and especially iodides, in solution dissolves iodine in increased quantities, and the resultant solution is of a dark brown colour. Alcohol and ether dissolve a small amount of iodine, and in so doing acquire a brown colour, but the solubility of iodine in alcohol is considerably increased by the presence of a small quantity of an iodine compound—for instance, ethyl iodide.⁶³ Solutions of iodine in carbon bisulphide and chloroform are rose colour, but with a larger proportion of iodine they assume a violet colour. The rose colour given by a small amount of iodine to chloroform is an easy means for detecting the presence of free iodine formed (for instance, by the action of Cl on KI). The blue coloration which free iodine gives with **starch** may also, as has already been frequently mentioned (see Chap. IV.), serve for the detection of iodine.

In reviewing the chief characteristics of the compounds formed by bromine and iodine, it is first of all seen that their composition and their physical and chemical properties are analogous to the corresponding chlorine compounds, and that they all vary in the same order with the atomic weight of the component haloid or molecular weight of the compound. Thus bromine introduces properties which stand as the mean of those communicated by chlorine and iodine. If the weight of

of chlorine or bromine, and this is all the more likely, as the drying was conducted with calcium chloride, and free iodine probably gives some traces of CaI_2 and Cl in the presence of CaCl_2 ; this would hence again introduce some chlorine into the iodine (see note 66). Traces of Cl and Br should diminish the atomic weight of the iodine, and therefore I think the true atomic weight cannot be less than 127 and probably even slightly above 127.

⁶³ The solubility of iodine in solutions containing iodides and compounds of iodine in general, may serve, on the one hand, as an indication that solution is due to a similarity between the solvent and dissolved substance, and, on the other, as an indirect proof of that view as to solutions which was cited in Chap. I., because in many instances unstable highly iodised compounds, resembling crystallo-hydrates, have been obtained from such solutions. Thus tetramethylammonium iodide, $\text{N}(\text{CH}_3)_4\text{I}$, combines with I_2 and I_4 . Even a solution of iodine in a saturated solution of potassium iodide presents indications of the formation of a definite compound KI_3 . Thus, an alcoholic solution of KI_3 does not give up iodine to carbon bisulphide, although this solvent takes up iodine from an alcoholic solution of iodine itself (Girault, Jørgensen, and others). See Chapter XIII., note 3a.

the molecule is large, the substance has a higher specific gravity and higher melting and boiling points. Chlorine in a free state boils at about -35° , bromine at 60° , and iodine only above 180° . According to the Avogadro-Gerhardt law, the vapour densities of these elements in a gaseous state are proportional to their atomic weights, and here, at all events approximately, the densities in a liquid (or solid) state are also almost in the ratio of their atomic weights. Dividing the atomic weight of chlorine (35.5) by its specific gravity in a liquid state (1.3), we obtain a volume of 27, for bromine ($80/3.1$) 26, and for iodine ($127/4.9$) 26.⁶⁴

Notwithstanding the great analogy of the bromides and iodides with the corresponding chlorides,⁶⁵ chlorine displaces their bromine or iodine, and bromine liberates iodine from iodides. However, the researches of Potilitzin (1880) showed that a **reverse** displacement of chlorine by bromine may occur both in solutions and in ignited metallic chlorides in an atmosphere of bromine vapour—that is, a distribution of the metal (according to Berthollet's doctrine) takes place between the halogens, although, however, the larger portion still unites with the chlorine, which shows its greater affinity for metals as compared with those of bromine and iodine.⁶⁶ The latter usually behave with respect

⁶⁴ The equality of the atomic volumes of the halogens themselves is all the more remarkable because in all the halogen compounds the volume increases with the substitution of fluorine by chlorine, bromine, and iodine. Thus, for example, the volume of sodium fluoride (obtained by dividing the weight expressed by its formula by its specific gravity) is about 15, that of sodium chloride 27, that of sodium bromide 32, and that of sodium iodide 41. The volume of silicon chloroform, SiHCl_3 , is 82, and those of the corresponding bromine and iodine compounds are 108 and 122 respectively.

⁶⁵ But the density (boiling-point, &c.) of a bromine compound is always greater than that of a chlorine compound, whilst that of an iodine compound is still greater.

⁶⁶ A. L. Potilitzin showed that on heating various metallic chlorides in a closed tube, with an equivalent quantity of bromine, a distribution of the metal between the halogens always occurs, and that the amounts of chlorine replaced by the bromine in the ultimate product are proportional to the atomic weights of the metals taken and inversely proportional to their equivalence. Thus, if $\text{NaCl} + \text{Br}$ be taken, then out of 100 parts of chlorine, 5.54 are replaced by the bromine, whilst with $\text{AgCl} + \text{Br}$, 27.28 parts are replaced. These figures are in the ratio 1 : 4.9, and the atomic weights $\text{Na} : \text{Ag}$ are as 1 : 4.7. In general terms, if a chloride MCl_n be taken, it gives with $n\text{Br}$ a percentage substitution of $4M/n^2$, where M is the atomic weight of the metal. This law was deduced from observations on the chlorides of Li , K , Na , Ag ($n=1$), Ca , Sr , Ba , Co , Ni , Hg , Pb ($n=2$), Bi ($n=3$), Sn ($n=4$), and Fe_2 ($n=6$).

In these determinations of **Potilitzin** we see not only a brilliant confirmation of *Berthollet's doctrine*, but also a new effort to determine the affinities of elements. The chief object of these researches consisted in proving whether a displacement occurs in those cases where heat is absorbed, and in this instance it should be absorbed, because the formation of all metallic bromides is attended with the evolution of less heat than that of the chlorides, as is seen by the figures given in note 55.

If the mass of the bromine be increased, then the amount of chlorine displaced also increases. For example, if masses of bromine of 1 and 4 equivalents act on a molecule

to metallic oxides in exactly the same manner as chlorine. Gay-Lussac, by igniting potassium carbonate in iodine vapour, obtained (as with chlorine) an evolution of oxygen and carbonic anhydride, $\text{K}_2\text{CO}_3 + \text{I}_2 = 2\text{KI} + \text{CO}_2 + \text{O}$, only the reactions between the halogens and oxygen are more easily reversible with bromine and iodine than with chlorine. Thus, at a red heat, oxygen displaces iodine from barium iodide. Aluminium iodide burns in a current of oxygen (Deville and Troost), and a similar, although not so clearly marked, relation exists for aluminium chloride, and shows that the halogens have a distinctly smaller affinity for those metals which form feeble bases. This is still more the case with the non-metals, which form acids and evolve much more heat with oxygen than with the halogens (note 13). But in all these instances the affinity (and amount of heat evolved) of iodine and bromine is less than that of chlorine, because the atomic weights are greater. The smaller store of energy in iodine and bromine is seen still more clearly in the relation of the halogens to hydrogen. In a gaseous state they all enter, with more or less ease, into direct combination with gaseous hydrogen—for example, in the presence of spongy platinum, forming halogen acids, HX —but the latter are far from being equally stable; hydrogen chloride is the most stable and hydrogen iodide the least so, hydrogen bromide occupying an intermediate position. A very high temperature is required to decompose hydrogen chloride even partially, whilst hydrogen iodide is decomposed by light even at the ordinary temperature and very easily at a red heat. Hence the reaction, $\text{I}_2 + \text{H}_2 = \text{HI} + \text{HI}$, is very easily reversible, and hydrogen iodide easily dissociates.⁶⁷ Judging by the direct measurement of the heat evolved

of sodium chloride, then the percentages of the chlorine displaced will be 6.08 per cent. and 12.46 per cent. respectively; in the action of 1, 4, 25, and 100 molecules of bromine on a molecule of barium chloride, there will be displaced 7.8, 17.6, 35.0, and 45.0 per cent. respectively of chlorine. If an equivalent quantity of hydrochloric acid act on metallic bromides in closed tubes, and in the absence of water at a temperature of 300° , the percentages of the substitution of the bromine by the chlorine in the double decomposition taking place between univalent metals are inversely proportional to their atomic weights. For example, $\text{NaBr} + \text{HCl}$ gives at the limit 21 per cent. of displacement, KCl 12 per cent., and AgCl $4\frac{1}{4}$ per cent. Essentially the same action takes place in an aqueous solution, although the phenomenon is complicated by the participation of the water. The reactions proceed spontaneously in one or the other direction at the ordinary temperature but at different rates. In the action of a dilute solution (1 equivalent per 5 litres) of sodium chloride on silver bromide at the ordinary temperature, the amount of bromine replaced in six and a half days is 2.07 per cent., and with potassium chloride 1.5 per cent. With an excess of the chloride the magnitude of the substitution increases. These conversions also proceed with the absorption of heat. The reverse reactions, evolving heat, proceed incomparably more rapidly, but also have a certain limit.

⁶⁷ **The dissociation of hydriodic acid** has been studied in detail by Hautefeuille and Lemoine, from whose researches we extract the following information. The decomposition of hydriodic acid is appreciable but slow at 180° ; the rate and limit of

(22,000 heat units) in the formation of HCl , the conversion of 2HCl into $\text{H}_2 + \text{Cl}_2$ requires the expenditure of 44,000 heat units. The decomposition of 2HBr into $\text{H}_2 + \text{Br}_2$ only requires, if the bromine be obtained in a gaseous state, a consumption of about 24,000 units, whilst in the decomposition of 2HI into $\text{H}_2 + \text{I}_2$ as vapour about 3,000 heat units are *evolved*; ⁶⁸ these facts, without doubt, stand in causal

decomposition increase with a rise of temperature. The reverse action—that is, $\text{I}_2 + \text{H}_2 = 2\text{HI}$ —proceeds not only under the influence of spongy platinum (Corenwinder), which also accelerates the decomposition of hydriodic acid, but also by itself, although slowly. The limit of the reverse reaction is the same either with or without spongy platinum. An increase of pressure has a very powerful accelerative effect on the rate of formation of hydriodic acid, and therefore spongy platinum by condensing gases has the same effect as increase of pressure. At the atmospheric pressure the decomposition of hydriodic acid reaches the limit at 250° in several months, and at 440° in several hours. The limit at 250° is about 18 per cent. of decomposition—that is, out of 100 parts of hydrogen previously combined in hydriodic acid, about 18 may be disengaged at this temperature (this hydrogen may be easily measured, and the degree of dissociation determined), but not more; the limit at 440° is about 26 per cent. If the pressure under which 2HI passes into $\text{H}_2 + \text{I}_2$ is $4\frac{1}{2}$ atmospheres, then the limit is 24 per cent.; under a pressure of $\frac{1}{5}$ atmosphere the limit is 29 per cent. The small influence of pressure on the dissociation of hydriodic acid (compared with that of N_2O_4 , Chap. VI., note 46) is due to the fact that the reaction $2\text{HI} = \text{I}_2 + \text{H}_2$ is not accompanied by a change of volume. In order to show the influence of time, we shall cite the following figures referring to 350° : (1) Reaction $\text{H}_2 + \text{I}_2$: after 3 hours, 88 per cent. of hydrogen remained free; after 8 hours, 69 per cent.; 34 hours, 48 per cent.; 76 hours, 29 per cent.; and after 327 hours, 18.5 per cent. (2) The reverse decomposition of 2HI : after 9 hours, 3 per cent. of hydrogen was set free, and after 250 hours, 18.6 per cent.—that is, the limit was reached. The addition of extraneous hydrogen diminishes the limit of the reaction of decomposition, or increases the formation of hydriodic acid from iodine and hydrogen, as would be expected from Berthollet's doctrine (Chap. X.). Thus at 440° , 26 per cent. of hydriodic acid is decomposed if there be no admixture of hydrogen, while if H_2 be added, then at the limit only half as large a mass of HI is decomposed. Therefore, if an infinite mass of hydrogen be added there will be no decomposition of the hydriodic acid. Light aids the decomposition of hydriodic acid very powerfully. At the ordinary temperature 80 per cent. is decomposed under the influence of light, whilst under the influence of heat alone this limit corresponds with a very high temperature. The distinct action of light, spongy platinum, and of impurities in the glass (especially of sodium sulphate, which decomposes hydriodic acid), not only render the investigations difficult, but also show that in reactions like $2\text{HI} = \text{I}_2 + \text{H}_2$, which are accompanied by slight heat effects, all foreign and feeble influences may strongly affect the progress of the action (note 47).

⁶⁸ The thermal determinations of Thomsen (at 18°) gave, in thousands of calories, $\text{Cl} + \text{H} = +22$; $\text{HCl} + \text{Aq}$ (that is, on dissolving HCl in a large amount of water) $= +17.3$, and therefore $\text{H} + \text{Cl} + \text{Aq} = +39.3$. In taking molecules, all these figures must be doubled. $\text{Br} + \text{H} = +8.4$; $\text{HBr} + \text{Aq} = 19.9$; $\text{H} + \text{Br} + \text{Aq} = +28.3$. According to Berthelot, 7.2 are required for the vaporisation of Br_2 , hence $\text{Br}_2 + \text{H}_2 = 16.8 + 7.2 = +24$, if Br_2 is taken as vapour for comparison with Cl_2 . $\text{H} + \text{I} = -6.0$, $\text{HI} + \text{Aq} = 19.2$; $\text{H} + \text{I} + \text{Aq} = +13.2$, and, according to Berthelot, the heat of fusion of $\text{I}_2 = 3.0$, and that of vaporisation 6.0 thousand heat units, and therefore $\text{I}_2 + \text{H}_2 = -2(6.0) + 3 + 6 = -3.0$, if the iodine be taken as vapour. Berthelot, on the basis of his determinations, gives, however, +0.8 thousand heat unit. Similar contradictory results are often met with in thermochemistry owing to the imperfection of the existing methods, and particularly to the necessity of depending on indirect methods for obtaining the fundamental figures. Thus

connection with the great stability of hydrogen chloride, the easy decomposability of hydrogen iodide, and the intermediate properties of hydrogen bromide. From this it would be expected that chlorine is capable of decomposing water with the evolution of oxygen, whilst iodine has not the energy to produce this disengagement,⁶⁹ although it is able to liberate the oxygen from the oxides of potassium and sodium, the affinity of these metals for the halogens being very considerable. For this reason oxygen, especially in compounds from which it can be readily evolved (for instance, ClHO , CrO_3 , &c.), readily decomposes hydrogen iodide. A mixture of hydrogen iodide and oxygen burns in the presence of an ignited substance, forming water and iodine. Drops of nitric acid in an atmosphere of hydrogen iodide cause the disengagement of violet fumes of iodine and brown fumes of nitrogen peroxide. In the presence of alkalies and an excess of water, however, iodine is able to effect oxidation like chlorine—that is, it decomposes water; the action is here aided by the affinity of hydrogen iodide for the alkali and water, just as sulphuric acid helps zinc to decompose water. But the relative instability of hydriodic acid is best seen in comparing the acids in a gaseous state. If the halogen acids be dissolved in water, they evolve so much heat that they approach much nearer to each other in properties. This is seen from thermochemical data, for in the formation of HX in solution (in a large excess of water) from the *gaseous* elements, there is *evolved* for HCl 39,000, for HBr 32,000, and for HI 18,000 heat units;⁷⁰ but it is especially evident from the fact that solutions of hydrogen bromide and iodide in water have many points in common with solutions of hydrogen chloride, even in their capacity to form hydrates and fuming solutions of constant boiling-point.

In consequence of what has been said above, it follows that **hydro-**

Thomsen decomposed a dilute solution of potassium iodide by gaseous chlorine; the reaction gave +26·2, whence, having first determined the heat effects of the reactions $\text{KHO} + \text{HCl}$, $\text{KHO} + \text{HI}$ and $\text{Cl} + \text{H}$ in aqueous solutions, it was possible to find $\text{H} + \text{I} + \text{Aq}$; then, knowing $\text{HI} + \text{Aq}$, to find $\text{I} + \text{H}$. It is evident that unavoidable errors may accumulate.

⁶⁹ One can believe, however, on the basis of Berthollet's doctrine, and the observations of Potilitzin (note 66), that a certain slow decomposition of water by iodine takes place. According to this view, the observations of Dossios and Weith showing that the solubility of iodine in water increases after the lapse of several months, will be comprehensible. Hydriodic acid is then formed, and increases the solubility. If the iodine be extracted from such a solution by means of carbon bisulphide, then, as the authors showed, after the action of nitrous anhydride, iodine may be again detected in the solution by means of starch. It can easily be understood that a number of similar reactions, requiring much time and taking place to a slight extent, have up to now eluded the attention of investigators, who even still doubt the universal application of Berthollet's doctrine, or only see the thermochemical side of reactions, or else neglect to pay attention to the element of time and the influence of mass.

⁷⁰ On the basis of the data given in note 68.

bromic and hydriodic acids, being substances which are but slightly stable, cannot be evolved in a gaseous state under many of those conditions under which hydrochloric acid is formed. Thus if sulphuric acid in solution acts on sodium iodide, all the same phenomena take place as with sodium chloride; but if sodium iodide be mixed with strong sulphuric acid, then the oxygen of the latter decomposes the hydriodic acid set free, with liberation of iodine, $\text{H}_2\text{SO}_4 + 2\text{HI} = 2\text{H}_2\text{O} + \text{SO}_2 + \text{I}_2$. This reaction takes place in the reverse direction in the presence of a *large quantity* of water (2,000 parts of water per 1 part of SO_2), in which case not only is the affinity of hydriodic acid for water brought to light, but also the action of water in directing chemical reactions in which it participates.⁷¹ Therefore, with a halogen salt, it is easy to obtain gaseous hydrochloric acid by the action of sulphuric acid, but neither hydrobromic nor hydriodic acid can be so obtained in the free state (as gases).⁷² Other methods have to be resorted to for their preparation, and recourse must not be had to compounds of oxygen, which are so easily able to destroy these acids. Therefore hydrogen sulphide, phosphorus, &c., which themselves easily take up oxygen, lead to the conversion of bromine and iodine into hydrobromic and hydriodic acids in the presence of water. For example, in the action of phosphorus the essence of the matter is that the oxygen of the water goes to the phosphorus, and the union of the remaining elements leads to the formation of hydrobromic or hydriodic acid; but the matter is complicated by the reversibility of the reaction, the affinity for water, and other circumstances which are understood by following Berthollet's doctrine. Chlorine (and bromine also) directly decomposes hydrogen sulphide, forming hydrochloric acid and liberating sulphur, both in a gaseous form and in solutions, whilst iodine only decomposes hydrogen sulphide in weak solutions, when its affinity for hydrogen is aided by the affinity of hydrogen iodide for water. In a gaseous state iodine does not act on hydrogen sulphide,⁷³ whilst sulphur is able to decompose gaseous hydriodic acid, forming hydrogen sulphide and a compound of sulphur and iodine which with water forms hydriodic acid.⁷⁴

⁷¹ A number of similar cases confirm what has been said in Chap. X.

⁷² This is prevented by the reducibility of sulphuric acid. If volatile acids be taken they pass over, together with the hydrobromic and hydriodic acids, when distilled; whilst many non-volatile acids which are not reduced by hydrobromic and hydriodic acids only act feebly (like phosphoric acid), or do not act at all (like boric acid).

⁷³ This is in agreement with the thermochemical data, because if all the substances are taken in the gaseous state (for sulphur the heat of fusion is 0.3, and the heat of vaporisation 2.3) we have $\text{H}_2 + \text{S} = 4.7$; $\text{H}_2 + \text{Cl}_2 = 44$; $\text{H}_2 + \text{Br}_2 = 24$, and $\text{H}_2 + \text{I}_2 = -3$ thousand heat units; hence the formation of H_2S gives less heat than that of HCl and HBr , but more than that of HI .

⁷⁴ Here there are three elements, hydrogen, sulphur, and iodine, each pair of which is able to form a compound, HI , H_2S , and SI , besides which the latter may unite in

If hydrogen sulphide be passed through water containing iodine, the reaction $\text{H}_2\text{S} + \text{I}_2 = 2\text{HI} + \text{S}$ proceeds so long as the solution is dilute; but when the mass of free HI increases the reaction stops, because the iodine then passes into solution.^{74a}

To obtain⁷⁵ gaseous hydrobromic and hydriodic acids it is most convenient to take advantage of the reactions between phosphorus, the halogens, and water, the latter being present in small quantity (otherwise the halogen acids formed are dissolved by it); the halogen is gradually added to the phosphorus moistened with water. Thus, if red phosphorus be placed in a flask and moistened with water, and bromine be added drop by drop (from a tap funnel), hydrobromic acid will be abundantly and uniformly disengaged.⁷⁶ Hydrogen iodide is prepared

various proportions. The complexity of chemical mechanics is seen in such examples as these. It is evident that only the study of the simplest cases can give the key to the more complex problems, and on the other hand it is evident from the examples cited in the last pages that, without penetrating into the conditions of chemical equilibria, it would be impossible to explain chemical phenomena. By following the footsteps of Berthollet the possibility of unravelling these problems will be reached; but work in this direction has only been begun during the last ten years, and much remains to be done in collecting experimental material, for which occasions present themselves at every step. In speaking of the halogens I wished to turn the reader's attention to problems of this kind.

^{74a} A solution having a composition approximating to $2\text{HI} + 4\text{I}_2 + 9\text{H}_2\text{O}$ (according to Bineau) does not react with H_2S , notwithstanding the quantity of free iodine. Therefore only weak solutions of hydriodic acid can be obtained by passing hydrogen sulphide into water with iodine. Essentially the same thing takes place when sulphurous anhydride, in a dilute solution, gives hydriodic acid and sulphuric acid with iodine. On concentration a reverse reaction takes place. The equilibrated systems and the part played by water are everywhere distinctly seen.

⁷⁵ Methods of formation and preparation are nothing more than particular cases of chemical reaction. If the knowledge of chemical mechanics were more complete than it now is, it would be possible to foretell all cases of preparation *with every detail* (of the quantity of water, temperature, pressure, mass, &c.). The study of practical methods of preparation is therefore one of the paths for the study of chemical mechanics. The action of iodine on phosphorus and water is a case like that mentioned in note 74, and the matter is here further complicated by the possibility of the formation of the compound PH_3 with HI, as well as the production of PI_2 , PI_3 , and the affinity of hydriodic acid and the acids of phosphorus for water. The theoretical interest of equilibria in all their complexity is naturally very great, but it falls into the background in presence of the primary interest of discovering practical methods for the isolation of substances, and the means of employing them for the requirements of man. It is only after the satisfaction of these requirements that interests of the other order arise, which in their turn must exert an influence on the former. For these reasons, whilst considering it opportune to point out the theoretical interest of chemical equilibria, the chief attention of the reader is directed in this work to questions of practical importance, as it is chiefly designed for beginners and to awaken in them an interest in the whole of chemistry.

⁷⁶ Hydrobromic acid is also obtained by the action of bromine on paraffin heated to 180° , and on other hydrocarbons. The liquid tribromide of phosphorus, directly obtained from phosphorus and bromine, also gives hydrobromic acid when treated with water. Bromide of potassium or sodium, when treated with sulphuric acid in the presence of phosphorus, also gives hydrobromic acid, but hydriodic acid is decomposed by this method. In order to free hydrobromic acid from bromine vapour it is passed over moist

by adding 1 part of common (yellow) dry phosphorus to 10 parts of dry iodine in a glass flask. On shaking the flask, union proceeds quietly between them (light and heat being evolved), and when the mass of iodide of phosphorus which is formed has cooled, water is added, drop by drop (from a tap funnel) and hydrogen iodide is evolved directly without the aid of heat. These methods of preparation will be at once understood when it is remembered that phosphorus chloride gives hydrogen chloride with water. It is exactly the same here—the oxygen of the water passes over to the phosphorus, and the hydrogen to the iodine; thus, $\text{PI}_3 + 3\text{H}_2\text{O} = \text{PH}_3\text{O}_3 + 3\text{HI}$.⁷⁷

In the gaseous state hydrobromic and hydriodic acids are closely analogous to hydrochloric acid; they are liquefied by pressure and cold, they fume in the air, form solutions and hydrates of constant boiling-point, and react on metals, oxides and salts, &c.⁷⁸ Only the relatively

phosphorus and then dried either by phosphoric anhydride or calcium bromide (calcium chloride cannot be used, as hydrochloric acid would be formed). Neither hydrobromic nor hydriodic acid can be collected over mercury, on which they act, but they may be directly collected in a dry vessel by leading the gas-conducting tube to the bottom of the vessel, both gases being much heavier than air. Merz and Holtzmann (1889) propose to prepare HBr directly by heating a mixture of vapour of Br with H. According to the method proposed by Newth (1892) a mixture of bromine and hydrogen is led through a tube containing a platinum spiral, which is heated to redness after the air has been displaced from the tube.

Hydriodic acid is obtained in the same manner as hydrobromic. Iodine is heated in a small flask, and its vapour is carried over by hydrogen into a strongly heated tube. The gas passing from the tube is found to contain a considerable amount of HI, together with some free iodine. At a low red heat about 17 per cent. of the iodine vapour enters into combination; at a higher temperature, 78 to 79 per cent.; and at a strong heat about 82 per cent.

⁷⁷ But generally more phosphorus is taken than is required for the formation of PI_3 , because otherwise a portion of the iodine distils over. If less than one-tenth part of iodine be taken, much phosphonium iodide, PH_4I , is formed. This proportion was established by Gay-Lussac and Kolbe. Hydriodic acid is also prepared in many other ways. Bannoff dissolves two parts of iodine in one part of a previously prepared strong (sp. gr. 1.67) solution of hydriodic acid, and pours it on to red phosphorus in a retort. In taking P and I it must be remembered that reverse reaction (Oppenheim) may take place between the hydriodic acid and phosphorus, in which the compounds PH_4I and PI_2 are formed.

The reaction between phosphorus, iodine, and water must be carried out with caution, as they may react with explosion. With red phosphorus the reaction proceeds quietly, but nevertheless requires care. L. Meyer showed that with an excess of iodine the reaction proceeds without the formation of by-products (PH_4I), according to the equation, $\text{P} + 5\text{I} + 4\text{H}_2\text{O} = \text{PH}_3\text{O}_4 + 5\text{HI}$. For this purpose 100 grams of iodine and 10 grams of water are placed in a retort, and a paste of 5 grams of red phosphorus and 10 grams of water is added little by little (at first with great care).

⁷⁸ The specific gravities of their solutions, as deduced by me on the basis of Topsøe and Berthelot's determinations for $15^\circ/4^\circ$, are as follows:—

	10	20	30	40	50	60 per cent.
HBr	1.071	1.156	1.258	1.374	1.505	1.650
HI	1.075	1.164	1.267	1.399	1.567	1.769

Hydrobromic acid forms two hydrates, $\text{HBr} \cdot 2\text{H}_2\text{O}$ and $\text{HBr} \cdot \text{H}_2\text{O}$, which have been

ready decomposability of hydrobromic acid, and especially of hydriodic acid, clearly distinguish these acids from hydrochloric acid. For this reason, hydriodic acid acts in a number of cases as a deoxidiser or reducer, and frequently even serves as a means for the transference of hydrogen. Thus Berthelot, Baeyer, Wreden, and others, by heating unsaturated hydrocarbons in a solution of hydriodic acid, obtained either compounds with hydrogen nearer to the limit C_nH_{2n+2} or even the saturated compounds themselves. For example, benzene, C_6H_6 , when heated in a closed tube with a strong solution of hydriodic acid, gives hexylene, C_6H_{12} . The ready decomposability of hydriodic acid accounts for the fact that iodine does not act by metalepsis on hydrocarbons, for the hydrogen iodide liberated gives with the product of metalepsis, RI , formed, iodine and the hydrogen compound, RH , again. And therefore, to obtain the products of iodine substitution, either iodic acid, HIO_3 (Kekulé), or mercuric oxide, HgO (Weselsky), is added, as these immediately react on the hydrogen iodide, thus: $HIO_3 + 5HI = 3H_2O + 3I_2$, or, $HgO + 2HI = HgI_2 + H_2O$. From these considerations it will readily be understood that iodine acts like chlorine (or bromine) on ammonia and sodium hydroxide, for in these cases the hydriodic acid produced forms NH_4I and NaI . With a solution of iodine in alcohol, or even the solid element, ammonia immediately forms a highly explosive solid black product of metalepsis, NHI_2 , generally known as **iodide of nitrogen**, although it still contains hydrogen (this was proved beyond doubt by Szuhay, 1893), which may be replaced by silver (with the formation of $NAgI_2$): $3NH_3 + 2I_2 = 2NH_4I + NHI_2$. However, the composition of the last product is variable, and with an excess of water, NI_3 seems to be formed. Iodide of nitrogen is just as explosive as nitrogen chloride.^{78a} In the action of iodine on sodium hydroxide no bleaching

studied by Roozeboom with as much completeness as the hydrate of hydrochloric acid (Chap. X., note 37).

With metallic silver, solutions of hydriodic acid give hydrogen with great ease, forming silver iodide. Mercury, lead, and other metals act in a similar manner.

^{78a} Iodide of nitrogen, NHI_2 , is obtained as a brown pulverulent precipitate on adding a solution of iodine (in alcohol, for instance) to a solution of ammonia. If it be collected on a filter-paper, it does not decompose so long as the precipitate is moist; but when dry it explodes violently, so that it can only be experimented upon in small quantities. Usually the filter-paper is torn into bits while moist, and the pieces laid upon a brick; on drying an explosion proceeds, not only from friction or a blow, but even spontaneously. The more dilute the solution of ammonia, the greater is the amount of iodine required for the formation of the precipitate of NHI_2 . A low temperature facilitates its formation. NHI_2 dissolves in ammonia water, and when heated, the solution forms HIO_3 and iodine. With KI , iodide of nitrogen gives iodine, NH_3 and KHO . These reactions (Selivanoff) are explained by the formation of HIO , thus: $NHI_2 + 2H_2O = NH_3 + 2HIO$ and then $KI + HIO = I_2 + KHO$. Selivanoff (see note 29) usually observed a temporary formation of hypiodous acid, HIO , in the reaction of ammonia upon iodine, so that here the formation of NHI_2 is preceded by that of HIO —i.e., first $I_2 + H_2O = HIO + HI$, and then

compound is formed (whilst bromine gives one), but a direct reaction is always accomplished with the formation of an iodate, $6\text{NaHO} + 3\text{I}_2 = 5\text{NaI} + 3\text{H}_2\text{O} + \text{NaIO}_3$ (Gay-Lussac). Solutions of other alkalies, and even a mixture of water and oxide of mercury, act in the same manner.⁷⁹ This direct formation of **iodic acid**, $\text{HIO}_3 = \text{IO}_2(\text{OH})$, shows the propensity of iodine to give compounds of the type IX_5 . Indeed, this capacity of iodine to form compounds of a high type emphasises itself in many ways; for instance, with fluorine it directly forms IF_4 . But it is most important to turn attention to the fact that iodic acid is easily and directly formed by the action of oxidising substances on iodine. Thus, for instance, strong nitric acid directly converts iodine into iodic acid, whilst it has no oxidising action on chlorine.^{79a} This shows a greater affinity for oxygen in iodine than in chlorine, and this conclusion is confirmed by the fact that iodine displaces chlorine from its oxygen acids,⁸⁰ and that in the presence of water chlorine oxidises iodine.⁸¹

not only does the HI combine with NH_3 , but also $2\text{HIO} + \text{NH}_3 = \text{NHI}_2 + 2\text{H}_2\text{O}$. With dilute sulphuric acid, iodide of nitrogen (like NCl_3) forms hypoiodous acid, but it immediately passes into iodic acid.

⁷⁹ Free hypoiodous acid, HIO , is not known (see note 78a), but organic compounds, RIO , of the same type are known. To illustrate the peculiarities of their properties we will mention one of these compounds, namely, *iodosobenzene*, $\text{C}_6\text{H}_5\text{IO}$, obtained by Willgerodt (1892) and others, by the action of caustic alkalies upon phenyliododichloride, $\text{C}_6\text{H}_5\text{ICl}_2$ (according to the equation, $\text{C}_6\text{H}_5\text{ICl}_2 + 2\text{MOH} = \text{C}_6\text{H}_5\text{IO} + 2\text{MCl} + \text{H}_2\text{O}$). Iodosobenzene is an amorphous yellow substance; it explodes at 210° , decomposing with the evolution of iodine vapour, and dissolves in hot water and alcohol. If acids do not oxidise $\text{C}_6\text{H}_5\text{IO}$, they give saline compounds in which iodosobenzene appears as a basic oxide of a diatomic metal, $\text{C}_6\text{H}_5\text{I}$. Thus, for instance, when an acetic acid solution of iodosobenzene is treated with a solution of nitric acid, it gives large monoclinic crystals of a nitric acid salt having the composition $\text{C}_6\text{H}_5(\text{NO}_3)_2$ [like $\text{Ca}(\text{NO}_3)_2$]. Iodosobenzene displaces iodine from potassium iodide (in a solution acidulated with acetic or hydrochloric acid)—i.e., it acts with its oxygen like HClO . The action of peroxide of hydrogen, chromic acid, and other similar oxidising agents gives $\text{C}_6\text{H}_5\text{IO}_2$, which is a neutral substance—i.e., is incapable of giving salts with acids (compare Chap. XIII., note 43).

^{79a} The oxidation of iodine by strong nitric acid was discovered by Connell; Millon showed that it is effected, although more slowly, by the action of the hydrates of nitric acid up to $\text{HNO}_3, \text{H}_2\text{O}$, but that the solution $\text{HNO}_3, 2\text{H}_2\text{O}$, and weaker ones, do not oxidise, but simply dissolve, iodine. The participation of water in reactions is seen in this instance. It is also seen, for example, in the fact that dry ammonia combines directly with iodine—for instance, at 0° forming the compound $\text{I}_2, 4\text{NH}_3$ —whilst iodide of nitrogen is only formed in presence of water.

⁸⁰ Bromine also displaces chlorine—for instance, from chloric acid, directly forming bromic acid. If a solution of potassium chlorate is taken (75 parts per 400 parts of water), and iodine is added to it (80 parts), and then a small quantity of nitric acid, chlorine is disengaged on boiling, and potassium iodate formed in the solution. In this instance the nitric acid first evolves a certain portion of the chloric acid, and the latter, with the iodine, evolves chlorine. Potilitzin (1887) remarked, however, that not only do bromine and iodine displace the chlorine from chloric acid and potassium chlorate, but also that chlorine displaces bromine from sodium bromate, and, furthermore, the reaction does not proceed as a direct substitution of the halogens, but it is accompanied by the formation of free acids; for example, $5\text{NaClO}_3 + 3\text{Br}_2 + 3\text{H}_2\text{O} = 5\text{NaBr} + 5\text{HClO}_3 + \text{HBrO}_3$.

⁸¹ If iodine be stirred up in water, and chlorine passed through the mixture, the

Even ozone or a silent discharge passed through a mixture of oxygen and iodine vapour is able to directly oxidise iodine⁸² into iodic acid. It is disengaged from solutions as a hydrate, HIO_3 , which loses water at 170° , and gives an anhydride, I_2O_5 . Both these substances are crystalline (sp. gr. of I_2O_5 , 5.037, and of HIO_3 , 4.869 at 0°), colourless and soluble in water;⁸³ both decompose at a red heat into iodine and oxygen, are in many cases powerfully oxidising—for instance, they oxidise sulphurous anhydride, hydrogen sulphide, carbonic oxide, (Ditte) &c.—form chloride of iodine and water with hydrochloric acid, and with bases form salts, not only the normal, MIO_3 , but also acid salts; for example, KIO_3 , HIO_3 , and $\text{KIO}_3 \cdot 2\text{HIO}_3$.^{83a} With hydriodic acid, iodic acid immediately reacts, disengaging iodine, $\text{HIO}_3 + 5\text{HI} = 3\text{H}_2\text{O} + 3\text{I}_2$.

As with chlorine, so with iodine, a **periodic acid**, HIO_4 , is formed. This acid is produced in the form of its salts by the action of chlorine on alkaline solutions of iodates, and also by the action of iodine on chloric acid.⁸⁴ It crystallises from solutions as a hydrate containing

iodine will be dissolved; the liquid becomes colourless, and contains, according to the relative amounts of water and chlorine, either IHCl_2 , or ICl_3 , or HIO_3 . If there be a small amount of water, then the iodic acid may separate out directly as crystals, but a complete conversion (Bornemann) only occurs when not less than ten parts of water are taken to one part of iodine— $\text{ICl} + 3\text{H}_2\text{O} + 2\text{Cl}_2 = \text{HIO}_3 + 5\text{HCl}$. In general water must not be regarded simply as a 'medium' but as a chemical agent. In my opinion those who neglect this fact, especially from the consideration of dilute solutions, deny the lessons of Berthollet's law and fall into the dreams of Bergmann.

⁸² Schönbein and Ogier proved this. Ogier found that, at 45° , ozone immediately oxidises iodine vapour, forming first of all the oxide I_2O_3 , which is decomposed, by water or on heating, into iodic anhydride and iodine. Iodic acid is formed at the positive pole when a solution of hydriodic acid is decomposed by a galvanic current (Riche). It is also formed in the combustion of hydrogen mixed with a small quantity of hydriodic acid (Salet).

⁸³ Kämmerer showed that a solution of sp. gr. 2.127 at 14° , containing $2\text{HIO}_3 \cdot 9\text{H}_2\text{O}$, solidified completely in the cold. On comparing solutions $\text{HI} + m\text{H}_2\text{O}$ with $\text{HIO}_3 + m\text{H}_2\text{O}$, we find that the specific gravity increases but the volume decreases, whilst in the passage of solutions $\text{HCl} + m\text{H}_2\text{O}$ to $\text{HClO}_3 + m\text{H}_2\text{O}$, both the specific gravity and the volume increase, which is also observed in certain other cases (for example, H_3PO_3 and H_3PO_4).

^{83a} Ditte (1890) obtained many iodates of great variety. A neutral salt, $2(\text{LiIO}_3) \cdot \text{H}_2\text{O}$, is obtained by saturating a solution of lithia with iodic acid. There is an analogous ammonium salt, $2(\text{NH}_4\text{IO}_3) \cdot \text{H}_2\text{O}$. He also obtained hydrates of a more complex composition, such as $6(\text{NH}_4\text{IO}_3) \cdot \text{H}_2\text{O}$ and $6(\text{NH}_4\text{IO}_3) \cdot 2\text{H}_2\text{O}$. Salts of the alkaline earths, $\text{Ba}(\text{IO}_3)_2 \cdot \text{H}_2\text{O}$ and $\text{Sr}(\text{IO}_3)_2 \cdot \text{H}_2\text{O}$, may be obtained by a reaction of double decomposition from the normal salts of the type $2(\text{MeIO}_3) \cdot \text{H}_2\text{O}$. A mixture of solutions of nitrate of zinc and an alkaline iodate precipitates $\text{Zn}(\text{IO}_3)_2 \cdot 2\text{H}_2\text{O}$.

⁸⁴ If a mixture of sodium iodate with a solution of sodium hydroxide is heated, and chlorine passed through the solution, a sparingly soluble salt separates out, which corresponds with **periodic acid**, and has the composition $\text{Na}_4\text{I}_2\text{O}_9 \cdot 3\text{H}_2\text{O}$:

This compound is sparingly soluble in water, but dissolves easily in a very dilute solution of nitric acid. If silver nitrate is added to this solution a precipitate is formed

$2\text{H}_2\text{O}$ (corresponding with $\text{HClO}_4, 2\text{H}_2\text{O}$); but as it forms salts containing up to five atoms of metals, this water must be regarded as water of constitution. Therefore $\text{IO}(\text{OH})_5 = \text{HIO}_4, 2\text{H}_2\text{O}$ corresponds with the highest form of halogen compounds, IX_7 .⁸⁵ In decomposing (at 200°) or acting as an oxidiser, periodic acid first gives iodic acid, but it may also be ultimately decomposed.

Compounds formed between chlorine and iodine must be classed among the most interesting halogen bodies.⁸⁶ These elements combine together directly with evolution of heat, and form **iodine monochloride**, ICl , or **iodine trichloride**, ICl_3 .⁸⁷ As water reacts on these substances, forming iodic acid and iodine, they have to be prepared

which consists of the corresponding compound of silver, $\text{Ag}_4\text{I}_2\text{O}_9, 3\text{H}_2\text{O}$. If this sparingly soluble silver compound be dissolved in hot nitric acid, orange crystals of a salt having the composition AgIO_4 separate on evaporation.

The composition of all the salts of periodic acids are expressed by this type IX_7 . Kimmins (1889) refers all the salts of periodic acid to four types—the meta-salts of HIO_4 (salts of Ag, Cu, Pb), the meso-salts of H_3IO_5 (Pb, Ag_2H , CdH), the para-salts of H_5IO_6 (Na_2H_3 , Na_3H_2), and the di-salts of $\text{H}_4\text{I}_2\text{O}_9$ (K_4 , Ag_4 , Ni_2). The first three are direct compounds of the type IX_7 , namely, $\text{IO}_3(\text{OH})$, $\text{IO}_2(\text{OH})_3$, and $\text{IO}(\text{OH})_5$, and the last are types of diperiodic salts, which correspond with the type of the meso-salts, in the same way as pyrophosphoric salts correspond with orthophosphoric salts—i.e., $2\text{H}_3\text{IO}_5 - \text{H}_2\text{O} = \text{H}_4\text{I}_2\text{O}_9$.

⁸⁵ Periodic acid, which was discovered by Magnus and Ammermüller, and the salts of which were afterwards studied by Langlois, Rammelsberg, and many others, presents examples of hydrates in which it is evident that there is not that distinction between the water of hydration and of crystallisation which was at first considered to be so clear. In $\text{HClO}_4, 2\text{H}_2\text{O}$, the water, $2\text{H}_2\text{O}$, is not displaced by bases, and must be regarded as water of crystallisation, whilst in $\text{HIO}_4, 2\text{H}_2\text{O}$ it must be regarded as water of hydration. We shall afterwards see that the system of the elements obliges us to consider the halogens as substances giving a highest saline type, GX_7 , when G signifies a halogen, and X oxygen ($\text{O}=\text{X}_2$), OH, and other like elements.

⁸⁶ With respect to hydrogen, oxygen, chlorine, and other elements, bromine occupies an intermediate position between chlorine and iodine, and there is therefore no particular need for considering at length the compounds of bromine. This is the great advantage of a natural grouping of the elements.

⁸⁷ They were both obtained by Gay-Lussac and many others. Recent data respecting iodine monochloride, ICl , entirely confirm the numerous observations of Trapp (1854), and even confirm his statement as to the existence of two isomeric (liquid and crystalline) forms (Stortenbeker). With a small excess of iodine, iodine monochloride remains liquid, but in the presence of traces of iodine trichloride it easily crystallises. Tanatar (1893) showed that of the two modifications of ICl , one is stable, and melts at 27° ; while the other, which easily passes into the first, and is formed in the absence of ICl_3 , melts at 14° . Schützenberger amplified the data concerning the action of water on these chlorides (note 88), and Christomanos gave the fullest data regarding the trichloride.

Stortenbeker (1888) investigated the equilibrium of the system containing the molecules I_2 , ICl , ICl_3 , and Cl_2 , in the same way that Roozeboom (Chap. X., note 38) examined the equilibrium of the molecules HCl , $\text{HCl}, 2\text{H}_2\text{O}$, and H_2O . He found that iodine monochloride appears in two states: one (the ordinary) is stable and melts at 27.2° , while the other is obtained by rapid cooling, and melts at 13.9° , and easily passes into the first form. Iodine trichloride melts at 101° only in a closed tube under a pressure of 16 atmospheres.

from dry iodine and chlorine.⁸⁸ Both substances are formed in a number of reactions; for example, by the action of aqua regia on iodine, of chlorine on hydriodic acid, of hydrochloric acid on periodic acid, of iodine on potassium chlorate (with the aid of heat, &c.). Trapp obtained iodine monochloride, in beautiful red crystals, by passing a rapid current of chlorine into molten iodine. The monochloride then distils over and solidifies, melting at 27°. By passing chlorine over the crystals of the monochloride, it is easy to obtain iodine trichloride in orange crystals, which melt at 34° and volatilise at 47°, but in so doing decompose (into Cl₂ and ClI). The chemical properties of these chlorides entirely resemble those of chlorine and iodine, as would be expected, because, in this instance, a combination of similar substances has taken place, just as in the formation of solutions or alloys. Thus, for instance, the unsaturated hydrocarbons (for example, C₂H₄), which are capable of directly combining with chlorine and iodine, also directly combine with iodine monochloride.

⁸⁸ By the action of water on iodine monochloride and trichloride a compound IHCl₂ is obtained, which does not seem to be altered by water. Besides this compound, iodine and iodic acid are always formed, $10\text{ICl} + 3\text{H}_2\text{O} = \text{HIO}_3 + 5\text{IHCl}_2 + 2\text{I}_2$.

CHAPTER XII

SODIUM

Sodium sulphate Na_2SO_4 , obtained when a mixture of sulphuric acid and common salt is strongly heated (Chapter X.),¹ forms a colourless saline mass consisting of fine crystals, soluble in water. It is the product of many other double decompositions, sometimes carried out on a large scale; for example, when ammonium sulphate is heated with common salt, in which case the sal-ammoniac is volatilised, also by the action of cold upon a mixture of strong solutions of sulphate of magnesium and sodium chloride, &c. A similar reaction also takes place when, for instance, a mixture of lead sulphate and common salt is heated; this mixture readily fuses, and if the temperature is further raised heavy vapours of lead chloride appear. When the disengagement of these vapours ceases, the remaining mass, on being treated with water, yields a solution of sodium sulphate mixed with a solution of undecomposed common salt. A portion of the lead sulphate remains unchanged. The cause and nature of the reaction are just the same as those indicated when considering the action of sulphuric acid on NaCl . Here too it may be shown that the double decomposition is determined by the removal of PbCl_2 from the sphere of action of the remaining substances. This is seen from the fact that sodium sulphate, on being dissolved in water and mixed with a solution of any lead salt (and even with a solution of lead chloride, although this latter is but sparingly soluble in water), gives a white precipitate of lead sulphate. The reaction in the solution depends upon the insolubility of the lead sulphate, and the decomposition which takes place on heating is due to the volatility of the lead chloride. Silver sulphate, Ag_2SO_4 , in solution with common salt, gives silver chloride, because the latter

¹ While describing in some detail the properties of sodium chloride, hydrochloric acid, &c., I wish to impart, by separate examples, an idea of the properties of saline substances, but the dimensions of this work and its purpose and aim do not permit of entering into particulars concerning every salt, acid, or other substance. The fundamental object of this work—an account of the characteristics of the elements and an acquaintance with the forces acting between atoms—would not be attained by the multiplication of the number of as yet ungeneralised properties and relations, but they extend our horizon and excite a spirit of inquiry.

is insoluble in water, $\text{Ag}_2\text{SO}_4 + 2\text{NaCl} = \text{Na}_2\text{SO}_4 + 2\text{AgCl}$. Sodium carbonate, mixed in solution with the sulphates of iron, copper, manganese, magnesium, &c., gives in solution sodium sulphate, and in the precipitate a carbonate of the corresponding metal, because these salts of carbonic acid are insoluble in water; for instance, $\text{MgSO}_4 + \text{Na}_2\text{CO}_3 = \text{Na}_2\text{SO}_4 + \text{MgCO}_3$. In precisely the same way sodium hydroxide acts on solutions of the majority of the salts of sulphuric acid, containing metals the hydroxides of which are insoluble in water—for instance, $\text{CuSO}_4 + 2\text{NaHO} = \text{Cu}(\text{HO})_2 + \text{Na}_2\text{SO}_4$.²

Thus where sulphates and salts of sodium are in contact, it may be expected that sodium sulphate will be formed and separated if the conditions are favourable; for this reason it is not surprising that sodium sulphate is often found in the native state. Some of the springs and salt lakes in the steppes beyond the Volga, and in the Caucasus, contain a considerable quantity of sodium sulphate, and yield it by simple evaporation of the solutions. Beds of this salt are also met with; thus at a depth of only 5 feet, about 38 versts to the east of Tiflis, at the foot of the range of the 'Wolf's mane' (*Voltchia griva*) mountains, a deep stratum of very pure Glauber's salt, $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$, has been found.³ A layer two metres thick of the same salt lies at the bottom of several lakes (an area of about 10 square kilometres) in the Kouban district near Batalpaschinsk, and here its working was begun in 1887. In Spain, near Aranjuez and in many parts of the Western States of North America, mineral sodium sulphate has likewise been found, and is already being worked. In the Karabougask Bay, which is cut off from the Caspian Sea by sandbanks, the sea water is concentrated by evaporation, and deposits Glauber's salt under the action of cold.

The methods of obtaining salts by means of double decomposition from others already prepared are so general that in describing a given salt there is no necessity to enumerate the cases hitherto observed of its being formed through various double decompositions. The possibility of this occurrence ought to be foreseen, according to Berthollet's

² Anhydrous (ignited) sodium sulphate, Na_2SO_4 , is known in trade as 'sulphate' or salt-cake, and in mineralogy as *thénardite*. The crystalline decahydrated salt is termed in mineralogy *mirabilite*, and in trade Glauber's salt. On fusing it, the monohydrate, $\text{Na}_2\text{SO}_4 \cdot \text{H}_2\text{O}$, is obtained, together with a supersaturated solution.

³ The salts may be obtained, not only by methods of substitution of various kinds, but also by many other combinations. Thus sodium sulphate may be formed from sodium oxide and sulphuric anhydride, by oxidising sodium sulphide, Na_2S , or sodium sulphite, Na_2SO_3 , &c. When sodium chloride is heated in a mixture of the vapours of water, air, and sulphurous anhydride, sodium sulphate is formed. According to this method, sodium sulphate, Na_2SO_4 , is obtained from NaCl without the preliminary manufacture of H_2SO_4 . Lumps of NaCl pressed into the form of bricks are loosely packed into a cylinder and subjected, above 400° , to the action of steam, air, and SO_2 . Under these conditions, HCl , sulphate, and a certain amount of unaltered NaCl are obtained.

doctrine, from the properties of the salt in question. On this account it is most important to know the properties of salts; all the more so because up to the present time those very properties (solubility, formation of definite crystallo-hydrates, &c.) which may be made use of for separating them from other salts have not been generalised.⁴ These properties yet remain subjects for investigation, and are rarely—by analogy only—to be foreseen.⁵

Sulphate of sodium, Na_2SO_4 (it fuses at 843°), is soluble in water at all temperatures, but it separates out from its solutions in an anhydrous form only at temperatures above 32.5° , and then the solubility of the salt falls as the temperature rises, so that a saturated solution, when heated, deposits a portion of the salt, this being for 100 grams of water :

At	40°	50°	100°	230°	320°
Na_2SO_4	48.8	46.7	42.5	43.9	21.7 grams

⁴ Given a salt MX, formed by metal M and haloid X, it is possible to predict many of its reactions with great certainty without having recourse to experiment, but only on the strength of analogy and of the general laws governing the course of chemical change. But the solubility of the salt in water and other liquids, its faculty for giving one or another crystallo-hydrate, and their solubility and mode of transformation into each other, cannot yet be foreseen, because this subject has been methodically investigated in only a few cases, and then chiefly owing to the interest provoked by Gibbs's 'theory of phases' (see Chap. XXIV., note 9a), and the researches of van't Hoff, Bakhuis Roozeboom, Meyerhoffer, and others, on equilibrium (see Chap. XI., note 9; Chap. XIV., note 50; Chap. XXII., note 23, &c.). Although recognising the great utility of the present tendency of this subject in facilitating the generalisation of scientific observations and in preparing the way for a true theory, I limit myself in this work to fragmentary information on this complicated subject, because I consider that as yet it should only be studied after an acquaintance with the principles of chemistry has been acquired—all the more so because in text-books of physical chemistry the question is as yet chiefly concerned with the expression of phenomena and not with their prediction; as is seen, for instance, from the fact that the cause of the profound difference between a rise in solubility with the temperature for some substances and a fall for others yet remains entirely unknown. So long as this fall formed an isolated phenomenon (for Na_2SO_4 at first) it might be accepted, with the help of certain concessions, but now it is known to occur with the majority of the sulphates (see, for instance, Chap. I., note 23a, CaSO_4 , the sulphates of Ce, La, Di, Th, &c.; Étard, Muthmann, and others), and it is evident that this fall in the solubility (with a rise of temperature) is a very common phenomenon, the explanation of which can hardly be expected by simply applying the 'theory of phases,' but which must be taken into consideration for explaining the nature of solutions in order to comprehend the relations and forces acting in the formation of solutions and crystallo-hydrates. In my opinion no right issue is possible without recognising the agency of a chemism (special attraction or affinity) in the matter, and the 'theory of phases' only explains and describes the physico-chemical aspect of the subject.

⁵ The data given for the solubility of Na_2SO_4 at temperatures below 100° are taken almost exclusively from the old works of Gay-Lussac, and partly (for the heptahydrated salt) from Levelle, because, among the more recent determinations, I have found none either fuller or indicating the existence of any important errors in the former data. I think that in such an historical instance as Na_2SO_4 it would be most desirable to have fresh, full, and exact data for the solubility at different temperatures.

The data for temperatures above 100° were obtained (Étard, 1892) in sealed vessels under the pressure of the vapour,⁶ and show that the solubility varies little between 100° and 230° ,⁷ but that it falls rapidly between 32.5° and 100° , and also above 230° . Under ordinary conditions the crystallo-hydrate of the composition $\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$ separates out at all temperatures below 32.5° . It is known as Glauber's salt, and contains 78.9 grams of anhydrous salt per 100 grams of water. At these temperatures the anhydrous salt is entirely converted into the decahydrated salt, or dissolves in the presence of water.⁸ The strength (concentration) corresponding to the decahydrated salt (73 per cent.) is never attained by solutions under any conditions of temperature, and if

⁶ Perhaps this increase of pressure participates in the phenomenon, and therefore it would be desirable to have determinations of the solubility of Na_2SO_4 at temperatures above 100° under different pressures. I may mention that a fall of solubility, with a rise of temperature, is known for many salts (Chap. I., note 24), and that Étard considers the composition, $\text{Na}_2\text{SO}_4, 18\text{H}_2\text{O}$, to be constant for saturated solutions between 100° and 230° .

⁷ Tilden (1884) gives the following data: at 100° , 43 parts of salt per 100 of water; at 140° , 42 parts; at 160° , 43 parts; at 180° , 44 parts, and at 230° , 46 parts. The discrepancy between these and Étard's figures can only be removed by fresh determinations. This is all the more desirable as it concerns the question of solutions and such a classical example as Glauber's salt. It is evident that beyond analysis, i.e., determining the composition of saturated solutions, the variation of volumes and densities, the influence of pressure, the presence or absence of an excess of salt (solid *phase*), separation of salt by alcohol, supersaturation, vapour pressures of solutions and hydrates, &c., must also be investigated in this case. Wyrouboff (1890) showed that the anhydrous salt occurs in two dimorphous states, one of which is unstable and the other stable; the crystals of the former evince a strong double refraction, while those of the latter are almost isotropic. The former occurs in nature under the name of *thénardite*, and the latter is completely obtained either after fusing or heating to 200° the first modification. By evaporating solutions of Na_2SO_4 at temperatures above 40° Wyrouboff obtained a mixture of both modifications, in which the proportion of the second variety increased with the temperature, so that at 100° only a very small amount of the unstable variety remained in the mixture. Wyrouboff endeavours to explain the anomalies observed in the solubility of Na_2SO_4 above 32.5° by these variations; and although there are not yet sufficient grounds for accepting these views, still the fact of this dimorphism should be taken into consideration in investigating the solubility of Na_2SO_4 . It may be mentioned that the sp. gr. of Na_2SO_4 is 2.66; that of $\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$, 1.46; and that of solutions containing p per cent. of the anhydrous salt at $15^{\circ}/4^{\circ}$, $9,992 + 90.2p + 0.35p^2$ if the sp. gr. of water at 4° be taken as 10,000. It follows from these figures that the solutions are formed from water and salt (hydrated or anhydrous) with a contraction of volume, that is, that an increase of volume takes place when the salt separates out.

⁸ Direct experiment made by the author showed that if a saturated solution of Na_2SO_4 be taken at the ordinary temperature, and some anhydrous salt be added to it, a portion of the salt will crystallise out from the solution, part of the water being used up in converting the anhydrous into the decahydrated salt; so that if the residue be collected and dried it will be found to contain more anhydrous salt than was added to the solution. If the anhydrous salt is rinsed with water below 32.5° , in insufficient quantity to dissolve the salt, the first portions of water are consumed in crystallising the salt, and solution is only accomplished by an excess of water. Thus, anhydrous salt + water = decahydrated salt + solution. This is a form of distribution. The anhydrous salt hardens like gypsum if a small quantity of a saturated solution is poured over it.

the crystals which separate out are heated, although they melt at a constant temperature of 32.484° ,⁹ yet they immediately deposit a portion of the salt in an anhydrous form, so that the temperature 32.5° must be regarded as being the limiting or *transition* temperature, above which the decahydrated salt cannot exist, and below which its solutions do not give the anhydrous salt. The solubility between 0° and this transition temperature is the same, no matter whether the anhydrous or the decahydrated salt be taken, 100 grams of water dissolving :

At	0°	10°	20°	30°
Na_2SO_4	5.0	9.0	19.4	40.0 grams
$\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$	12.1	23.0	58.3	183.9 ,,

The solubility at the transition temperature, 32.5° , reaches 55 grams (according to Levallois and others 52.7 grams, or even 50.65 grams) of Na_2SO_4 per 100 grams of water, and if such a saturated solution (or one nearly so) be poured off from the excess of salt, or, better still, if a solution saturated at a higher temperature be cooled without access of air (which might contain crystals of the decahydrated salt, which would evoke crystallisation), then no salt will separate out, and a *supersaturated* solution will be obtained containing more salt than that given above for low temperatures. If such a solution is cooled to between $+5^{\circ}$ and $+7^{\circ}$, it deposits crystals of a heptahydrated salt, $\text{Na}_2\text{SO}_4, 7\text{H}_2\text{O}$, which is far more soluble than the decahydrated salt, 100 grams of water dissolving, according to Levelle :

At	0°	10°	20°	26°
Na_2SO_4	19.6	30.5	44.7	55.0 grams.
$\text{Na}_2\text{SO}_4, 7\text{H}_2\text{O}$	44.8	78.9	140.0	202.6 grams.

It is evident that a saturated solution of the heptahydrated salt will be supersaturated for the decahydrated salt, and therefore the smallest trace of the latter will evoke the crystallisation of the supersaturated solution with the formation of the decahydrated salt and evolution of heat.^{9a} No separation of salt is caused by the introduction of a trace

⁹ Richards gave this figure (according to the mercurial thermometer), and observed the extreme constancy of this temperature, and therefore proposed employing it for verifying thermometers, more especially as large quantities of $\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$ may be prepared with great ease.

^{9a} As heat is absorbed during the solution of the salt, it is evolved when the salt crystallises out from solution. According to Pickering's experiments (1886), the molecular weight in grams (that is, 142 grams) of anhydrous sodium sulphate, on being dissolved in a large mass of water, at 0° absorbs (hence the — sign) $-1,100$ heat units; at 10° , -700 ; and at 20° (gives out), $+25$. For the salt, $\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$, at 10° , $-4,000$; and at 20° , $-3,160$. Hence it is evident that the decahydrated salt dissolving in water gives a decrease of temperature. Solutions in hydrochloric acid give a still greater decrease, probably because a certain quantity of sodium chloride is formed.

of the solid anhydrous or heptahydrated salt into the solution.¹⁰ The addition of alcohol, in which all sulphates are only slightly soluble, to the supersaturated solution, leads to the separation of the heptahydrated salt. The latter is only formed from solutions below 27°. Separate crystals of this salt, at this and higher temperatures, become opaque, and already contain a mixture of the anhydrous and decahydrated salt. This clearly shows the instability of the equilibrium which exists in this salt (see Chap. XIV., note 50).

Both the deca- and hepta-hydrated salts effloresce and readily lose water, even at the ordinary temperature.

Sodium sulphate, Na_2SO_4 , only enters into a few reactions of combination with other salts, and chiefly with salts of the same acid, forming double sulphates. Thus, for example, if a solution of sodium sulphate is mixed with a solution of aluminium, magnesium, or ferrous sulphate, it gives crystals of a double salt when evaporated. Sulphuric acid itself forms with sodium sulphate a compound like these double salts. It is formed with great ease when sodium sulphate is dissolved in sulphuric acid and the solution evaporated. On evaporation, crystals of the **acid salt** separate, $\text{Na}_2\text{SO}_4 + \text{H}_2\text{SO}_4 = 2\text{NaHSO}_4$. This separates from hot solutions, while the crystallo-hydrate, $\text{NaHSO}_4, \text{H}_2\text{O}$,^{10a} separates from cold solutions. The crystals, when exposed to damp air, decompose into H_2SO_4 , which deliquesces, and Na_2SO_4 (Graham, Rose); alcohol also extracts sulphuric acid from the acid salt. This shows the feeble force which holds the sulphuric acid to the sodium sulphate.¹¹ Both acid sodium sulphate and all mixtures of the normal salt and sulphuric acid lose water when heated, and are converted into sodium **pyrosulphate**, $\text{Na}_2\text{S}_2\text{O}_7$, at a low red heat.^{11a} This anhydrous

¹⁰ The anhydrous salt must be calcined for this purpose. If it be obtained by the efflorescence of the hydrated salts, it can, according to Gernez, lead to the formation of crystals of the heptahydrated salt. If much of the anhydrous salt is taken it hardens, as mentioned in note 8.

^{10a} The very large and well-formed crystals of this salt resemble the hydrate $\text{H}_2\text{SO}_4, \text{H}_2\text{O}$, or $\text{SO}(\text{OH})_4$. In general the replacement of hydrogen by sodium modifies many of the properties of acids less than its replacement by other metals. This most probably depends on the volumes being nearly equal.

¹¹ In solution (Berthelot) the acid salt in all probability decomposes most in the greatest mass of water. The specific gravity (according to the determinations of Marignac) of solutions at 15°/4° is given by $9,992 + 77.92p + 0.231p^2$. From these figures, and from the specific gravities of sulphuric acid, it is evident that, on mixing solutions of this acid and sodium sulphate, *expansion* will always take place; for instance, $\text{H}_2\text{SO}_4 + 25\text{H}_2\text{O}$ with $\text{Na}_2\text{SO}_4 + 25\text{H}_2\text{O}$ increases from 483 volumes to 486. In addition to which, in weak solutions heat is absorbed, as shown in Chap. X., note 27. Nevertheless, even more acid salts may be formed and obtained in a crystalline form. For instance, on cooling a solution of 1 part of sodium sulphate in 7 parts of sulphuric acid, crystals of the composition $\text{NaHSO}_4, \text{H}_2\text{SO}_4$ are separated (Schultz, 1868). This compound fuses at about 100°, and the ordinary acid salt, NaHSO_4 , at 149°.

^{11a} On decreasing the pressure, sodium hydrogen sulphate, NaHSO_4 , dissociates

salt, at a bright red heat, parts with the elements of sulphuric anhydride, the normal sodium sulphate remaining behind: $\text{Na}_2\text{S}_2\text{O}_7 = \text{Na}_2\text{SO}_4 + \text{SO}_3$.

Sodium sulphate may by double decomposition be converted into a sodium salt of any other acid, by means of heat—taking advantage of the volatility—or by means of solution—taking advantage of the different degrees of solubility of the different salts. Thus, for instance, owing to the insolubility of barium sulphate, sodium hydroxide or caustic soda may be prepared from sodium sulphate, if barium hydroxide be added to its solution, $\text{Na}_2\text{SO}_4 + \text{Ba}(\text{HO})_2 = \text{BaSO}_4 + 2\text{NaHO}$. And by taking any salt of barium, BaX_2 , the corresponding salt of sodium may be obtained, $\text{Na}_2\text{SO}_4 + \text{BaX}_2 = \text{BaSO}_4 + 2\text{NaX}$. Barium sulphate, being a very sparingly soluble salt, is obtained in this way as a precipitate, whilst the sodium hydroxide, or salt, NaX , is obtained in solution, because **nearly all salts of sodium are soluble**. The doctrine of double saline decompositions permits all such cases to be foreseen.

Sodium sulphate by itself is very stable, and it is only at a temperature sufficient to melt iron that it gives up the elements SO_3 , and then only partially. However, the oxygen may be separated from sodium sulphate, as from all other sulphates, by means of many substances, such as charcoal and sulphur, but hydrogen is not able to produce this reducing action. If sodium sulphate be heated with charcoal, then carbonic oxide and anhydride are evolved, and there is produced, according to the conditions, either the lower oxygen compound, sodium sulphite, Na_2SO_3 (for instance, in the formation of glass); or else the decomposition proceeds further, and sodium sulphide, Na_2S , is formed, according to the equation, $\text{Na}_2\text{SO}_4 + 2\text{C} = 2\text{CO}_2 + \text{Na}_2\text{S}$.

On the basis of this reaction the sulphate of sodium prepared at chemical works is converted into **soda ash**—that is, **sodium carbonate**, Na_2CO_3 , which is used for many purposes. In the form of carbonates, the metallic oxides behave in many cases just as they do in the state of oxides or hydroxides, owing to the feeble acid properties of carbonic acid. However, the majority of the salts of carbonic acid are insoluble, whilst sodium carbonate is one of the few soluble salts of this acid and therefore reacts with facility. Hence sodium carbonate is employed for many purposes, in which its alkaline properties come into play. Thus, even under the action of feeble organic acids it immediately parts with its carbonic acid, and gives a sodium salt of the acid taken. Its solutions exhibit an alkaline reaction on litmus. It aids the passage of certain organic substances (tar, acids) into solution, and is therefore

much more easily than at the ordinary pressure; it loses water and forms the pyro-sulphate, $\text{Na}_2\text{S}_2\text{O}_7$; this reaction is utilised in chemical works.

used, like caustic alkalies and soap (which latter also acts by virtue of the alkali it contains), for the removal of certain organic substances, especially in bleaching cotton and similar fabrics. Besides which a considerable quantity of sodium carbonate is used for the preparation of sodium hydroxide or caustic soda, which has also a very wide application. In large chemical works where sodium carbonate is manufactured from Na_2SO_4 , it is usual first to manufacture sulphuric acid, and then by its aid to convert common salt into sodium sulphate, and lastly to convert the sodium sulphate thus obtained into carbonate and caustic soda. Hence these works prepare both alkaline substances (soda ash and caustic soda) and acid substances (sulphuric and hydrochloric acids), the two classes of chemical products which are distinguished for the greatest energy of their reactions, and are therefore most frequently applied to technical purposes. Factories manufacturing soda in this manner are generally called alkali works.

The process of the conversion of sodium sulphate into sodium carbonate consists in strongly heating a mixture of the sulphate with charcoal and calcium carbonate. The following reactions then take place: the sodium sulphate is first deoxidised by the charcoal, forming sodium sulphide and carbonic anhydride, $\text{Na}_2\text{SO}_4 + 2\text{C} = \text{Na}_2\text{S} + 2\text{CO}_2$. The sodium sulphide thus formed then enters into double decomposition with the calcium carbonate taken, and gives calcium sulphide, CaS , and sodium carbonate, $\text{Na}_2\text{S} + \text{CaCO}_3 = \text{Na}_2\text{CO}_3 + \text{CaS}$.

Besides which, under the action of the heat, a portion of the excess of calcium carbonate is decomposed into lime and carbonic anhydride, $\text{CaCO}_3 = \text{CaO} + \text{CO}_2$, and the carbonic anhydride with the excess of charcoal forms carbon monoxide, which towards the end of the operation shows itself by the appearance of a blue flame. Thus from a mass containing sodium sulphate we obtain a mass which includes sodium carbonate, calcium sulphide, and calcium oxide, but none of the sodium sulphide formed on first heating the mixture. The entire process, which proceeds at a high temperature, may be expressed by a combination of the three above-mentioned equations, if it be considered that the product contains one equivalent of calcium oxide to two equivalents of calcium sulphide.¹² The sum of the reactions may then be expressed

¹² Calcium sulphide, CaS , like many metallic sulphides which are soluble in water, is decomposed by it (Chap. X.), $\text{CaS} + \text{H}_2\text{O} = \text{CaO} + \text{H}_2\text{S}$, because hydrogen sulphide is a very feeble acid. If calcium sulphide be acted on by a large mass of water, lime may be precipitated, and a state of equilibrium will be reached when the system $\text{CaO} + 2\text{CaS}$ remains unchanged by water. Lime, being a product of the action of water on CaS , limits this action. Therefore, if in black ash the lime were not in excess, a part of the sulphide would be in solution. In this manner, in the manufacture of sodium carbonate the conditions of equilibrium which enter into double decompositions have been made use of (see above), and the aim is to form directly the unchangeable product, $\text{CaO}, 2\text{CaS}$.

thus: $2\text{Na}_2\text{SO}_4 + 3\text{CaCO}_3 + 9\text{C} = 2\text{Na}_2\text{CO}_3 + \text{CaO}, 2\text{CaS} + 10\text{CO}$. Indeed, the quantities in which the substances are mixed together at chemical works approach the proportions required by this equation. The entire process of decomposition is carried on in reverberatory furnaces, into which a mixture of 1,000 parts of sodium sulphate, 1,040 parts of calcium carbonate (as a somewhat porous limestone), and 500 parts of small coal is introduced from above. This mixture is first heated in the portion of the furnace which is furthest removed from the fire-grate; it is then brought to the part nearest the fire-grate, when it is stirred during heating. The partially fused mass obtained at

FIG. 78.—Reverberatory furnace for the manufacture of sodium carbonate. F, the grate, A, the bridge, M, the hearth for the ultimate calcination of the mixture of sodium sulphate, coal, and calcium carbonate, which is charged from above into the part of the furnace furthest removed from the fire F. P, P, doors for stirring and bringing the mass towards the grate F by means of stirrers R. At the end of the operation the semi-fused mass is charged into trucks C.

the end of the process is cooled, and then subjected to methodical lixiviation¹³ to extract the sodium carbonate, the mixture of calcium

This was first regarded as a special insoluble compound, but there is no evidence of its independent existence.

¹³ **Methodical lixiviation** is the extraction, by means of water, of a soluble substance from the mass containing it. It is carried on so as not to obtain weak aqueous solutions, and in such a way that the residue shall not contain any of the soluble substance. This problem is of great practical importance in many industries. It is required to extract from the mass all that is soluble in water. This is easily effected if water is first poured on the mass, the strong solution thus obtained decanted, then water again poured on, time being allowed for it to act, then again decanted, and so on until fresh water does not take up anything. But then such weak solutions are finally obtained that it would be very disadvantageous to evaporate them. This is avoided by pouring the fresh hot water destined for the lixiviation, not on to the fresh mass, but upon a mass which has already been subjected to a first lixiviation by weak solutions. In this way the fresh water gives a weak solution. The strong solution which goes to the evaporating pan flows from those parts of the apparatus which contain the fresh, as yet unlixivated, mass, and thus in the latter parts the weak alkali formed in the other parts of the apparatus becomes saturated as far as possible with the soluble substance. Generally several intercommunicating vessels (standing at the same level) are constructed, into which the fresh mass which is intended for lixiviation is charged in turn; the water is poured in, the alkali drawn off, and the lixiviated residue removed. The illustration represents such an apparatus, consisting of four communicating vessels. The water poured into one of them flows through the two nearest and issues from the third. The fresh mass being placed in one of these boxes or vessels, the stream of water passing

oxide and sulphide forming the so-called 'soda waste' or 'alkali waste.'¹⁴

through the apparatus is directed in such a manner as to finally issue from this vessel containing the fresh unlixivated mass. The fresh water is added to the vessel containing the material which has been almost completely exhausted. Passing through this vessel it is conveyed by the pipe (syphon passing from the bottom of the first box to the top of the second) communicating with the second; it finally passes (also through a syphon pipe) into the box (the third) containing the fresh material. The water will extract all that is soluble in the first vessel, leaving only an insoluble residue. This vessel is then ready to be emptied, and refilled with fresh material. The levels of the liquids in the various vessels will naturally be different, in consequence of the various strengths of the solutions which they contain.

Sodium carbonate does not pass into solution alone; there is also some caustic soda with it, formed by the action of lime on the carbonate of sodium, and also sodium

FIG. 79.—Apparatus for the methodical lixiviation of black ash, &c. Water flows into the tanks from the pipes, *r*, *r'*, and the saturated liquid is drawn off from *c*, *c*.

sulphide and certain other compounds. The sodium carbonate solution therefore is not obtained in a very pure state. The solution is concentrated by evaporation, which is conducted by means of the waste heat from the soda furnaces, together with that of the gases given off.

Part of the sodium carbonate is recrystallised in order to purify it more thoroughly. In order to do this a saturated solution is left to crystallise, at a temperature below 30°, in a current of air, in order to promote the separation of the water vapour. The large transparent crystals (efflorescent in air) of $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$, which have already been spoken of (Chap. I.), are then formed.

¹⁴ The whole of the sulphur used in the production of the sulphuric acid employed in decomposing the common salt is contained in this residue. This is the great burden and expense of the soda works which use Leblanc's method. As an instructive example from a chemical point of view, it is worth while mentioning here two of the various methods of recovering the sulphur from the soda waste. Chance's process is treated in Chap. XX., note 6.

Kynaston (1885) treats the soda waste with a solution (sp. gr. 1.21) of magnesium chloride, which disengages sulphuretted hydrogen: $\text{CaS} + \text{MgCl}_2 + 2\text{H}_2\text{O} = \text{CaCl}_2 + \text{Mg}(\text{OH})_2 + \text{H}_2\text{S}$. Sulphurous anhydride is passed through the residue in order to form

The above-mentioned method for making soda was discovered in the year 1808 by the French doctor *Leblanc*, and is known as the **Leblanc process**. The particulars of the discovery are somewhat remarkable. Sodium carbonate, having a considerable application in industry, was for a long time prepared exclusively from the ash of marine plants (Chap. XI., on iodine). Even up to the present time this process is carried on in Normandy. In France, where for a long time the manufacture of large quantities of soap (so-called Marseilles soap) and various fabrics required a large amount of soda, the quantity prepared at the coast was insufficient to meet the demand. For this reason, during the wars at the beginning of the last century, when the import of foreign goods into France was interdicted, the want of sodium carbonate was felt. The French Academy offered a prize for the discovery of a profitable method of preparing it from common salt. Leblanc then proposed the above-mentioned process, which is remarkable for its great simplicity.¹⁵

the insoluble calcium sulphite: $\text{CaCl}_2 + \text{Mg}(\text{OH})_2 + \text{SO}_2 = \text{CaSO}_3 + \text{MgCl}_2 + \text{H}_2\text{O}$. The solution of magnesium chloride obtained is again used, and the washed calcium sulphite brought into contact at a low temperature with hydrochloric acid (a weak aqueous solution) and hydrogen sulphide, the whole of the sulphur then separating:

But most efforts have been directed towards avoiding the formation of soda waste, that is, to obtaining soda from NaCl without converting it into Na_2SO_4 , and consequently without manufacturing H_2SO_4 , as will be presently described.

¹⁵ Among the drawbacks of the Leblanc process are (1) the accumulation of 'soda waste' (note 14) owing to the impossibility, at the comparatively low price of sulphur (especially in the form of pyrites), of finding uses for the sulphur and sulphur compounds for which this waste is sometimes treated, and (2) the insufficient purity of the sodium carbonate for many purposes. The advantages of the Leblanc process, besides its simplicity and cheapness, are that almost the whole of the acids obtained as by-products have a commercial value; for chlorine and bleaching powder are produced from the large amount of hydrochloric acid which appears as a by-product; caustic soda also is very easily made, and the demand for it increases every year.

As an example of the other numerous and varied methods of manufacturing soda from sodium chloride, the following may be mentioned: Sodium chloride is decomposed by oxide of lead, PbO , forming lead chloride and sodium oxide, which, with carbonic anhydride, yields sodium carbonate (Scheele's process). In Cornu's method, sodium chloride is treated with lime, and then exposed to the air, when it yields a small quantity of sodium carbonate. In E. Kopp's process, sodium sulphate (125 parts) is mixed with oxide of iron (80 parts) and charcoal (55 parts), and the mixture heated in reverberatory furnaces. Here a compound, $\text{Na}_6\text{Fe}_4\text{S}_3$, is formed, which is insoluble in water, absorbs oxygen and carbonic anhydride, and then forms sodium carbonate and ferrous sulphide; when roasted this gives sulphurous anhydride, the indispensable material for the manufacture of sulphuric acid, and ferric oxide, which is again used in the process. Gossage prepares Na_2S from Na_2SO_4 (by heating it with carbon), dissolves it in water and subjects the solution to the action of an excess of CO_2 in coke towers, thus obtaining H_2S (a gas which gives SO_2 under perfect combustion, or sulphur when incompletely burnt) and bicarbonate of sodium; $\text{Na}_2\text{S} + 2\text{CO}_2 + 2\text{H}_2\text{O} = \text{H}_2\text{S} + 2\text{HNaCO}_3$. The latter gives soda and CO_2 when ignited. This process should, in my opinion, be

Of the other industrial processes for manufacturing sodium carbonate, the **ammonia process** is the most worthy of mention.¹⁶ In this the vapours of ammonia, and then an excess of carbonic anhydride, are directly introduced into a concentrated solution of sodium chloride in order to form the acid ammonium carbonate, NH_4HCO_3 . Then, by means of the double saline decomposition of this salt, sodium chloride is decomposed, and in virtue of its slight solubility acid sodium carbonate, NaHCO_3 , is precipitated and ammonium chloride, NH_4Cl , obtained in solution (with a portion of the sodium chloride and acid sodium carbonate). The reaction proceeds in the solution, owing to the sparing solubility of the NaHCO_3 , according to the equation: $\text{NaCl} + \text{NH}_4\text{HCO}_3 = \text{NH}_4\text{Cl} + \text{NaHCO}_3$. The ammonia is recovered from the solution by heating it with lime or magnesia,^{16a} and the precipitated acid sodium carbonate is converted into the normal salt by heating. It is thus obtained in a very pure state and cheaper, because the NH_3 can be almost all recovered, there is no soda waste, and the preliminary manufacture of a large quantity of sulphuric acid is unnecessary.¹⁷

suitable for the treatment of native Na_2SO_4 , like that which is found in the Caucasus, all the more so because H_2S gives sulphur as a by-product.

In recent times soda (and chlorine, see Chap. II., note 1) is prepared from strong solutions of salt by the action of an electric current, but this method in reality gives NaHO and not soda. According to Hempel (1890) soda in crystals is deposited when an electric current and a stream of carbonic acid gas are passed through a saturated solution of NaCl .

Sodium carbonate may likewise be obtained from cryolite (Chap. XVII., note 23), the method of treating which will be mentioned under Aluminium.

¹⁶ This process (Chap. XVII.) was first pointed out by Turek, worked out by Schloesing, and finally applied industrially by Solvay. The first (1883) large soda factories erected in Russia for working this process are on the banks of the Kama at Bereznjak, near Ousolia, and belong to Lubimoff and Solvay. In 1890 a large factory was erected by P. K. Oushkoff on the Kama, near Elagoubi, to work the Leblanc process.

^{16a} Mond (see Chap. XI., note 3a) separates the NH_4Cl from the residual solutions by cooling (Chap. X., note 44), then ignites the sal-ammoniac and passes the vapour over MgO , and so re-obtains the NH_3 and forms MgCl_2 : the former goes back for the manufacture of soda, while the latter is employed either for making HCl or Cl_2 .

¹⁷ Commercial soda ash (calcined, anhydrous) is rarely pure; the crystallised soda is generally purer. In order to purify it further, it is shaken up with a strong solution of ammonia, and the residue recrystallised and calcined. The impurities will then remain in the mother liquors, &c.

Some numerical data may be given for sodium carbonate. The specific gravity of the anhydrous salt is 2.48, that of the decahydrated salt 1.46. Of the heptahydrated salt two varieties are known (Löwel, Marignac, Rammelsberg), which are formed by allowing a saturated solution to cool under a layer of alcohol; the one is less stable (like the corresponding sulphate) and at 0° has a solubility of 32 parts (of anhydrous salt) in 100 of water; the other is more stable, and its solubility is 20 parts (of anhydrous salt) per 100 of water. The solubility of the decahydrated salt in 100 of water is at 0° , 7.0; at 20° , 21.7; and at 30° , 37.2 parts (of anhydrous salt). At 80° the solubility is only 46.1; at 90° , 45.7; and at 100° , 45.4 parts (of anhydrous salt). That is, the solubility falls as

Sodium carbonate loses all its water on being heated, and when anhydrous fuses at a bright red heat (1098°). A small quantity of sodium carbonate placed in the loop of a platinum wire volatilises in the heat of a gas flame, and therefore in the furnaces of glass works, part of the soda is always transformed into the condition of vapour. Sodium carbonate resembles sodium sulphate in its relation to water.¹⁸ Here also the greatest solubility is at the temperature of 37° ; both salts, on crystallising at the ordinary temperature, combine with ten molecules of water, and such crystals of soda, like crystals of Glauber's salt, fuse. Sodium carbonate also forms a supersaturated solution, and, according to the conditions, gives various combinations with water of crystallisation (Chap. I., note 24).

At a red heat superheated steam liberates carbonic anhydride from sodium carbonate and forms caustic soda, $\text{Na}_2\text{CO}_3 + \text{H}_2\text{O} = 2\text{NaHO} + \text{CO}_2$. Here the carbonic anhydride is replaced by water: this depends on the feebly acid character of carbonic anhydride. By direct heating, sodium carbonate is only slightly decomposed into sodium oxide and carbonic anhydride; thus, when sodium carbonate is fused, about 1 per cent. of carbonic anhydride is disengaged.¹⁹ The carbonates of many other metals—for instance, of calcium, copper, magnesium, iron, &c.—on being heated lose all their carbonic anhydride. This shows the very considerable basic energy which sodium possesses. With the soluble salts of most metals, sodium carbonate gives precipitates either of insoluble carbonates of the metals, or else of the hydroxides (in this latter case carbonic anhydride is disengaged); for instance, with barium salts it precipitates an insoluble barium carbonate ($\text{BaCl}_2 + \text{Na}_2\text{CO}_3 = 2\text{NaCl} + \text{BaCO}_3$) and with the aluminium salts it precipitates aluminium hydroxide, carbonic anhydride being disengaged: $3\text{Na}_2\text{CO}_3 + \text{Al}_2(\text{SO}_4)_3 + 3\text{H}_2\text{O} = 3\text{Na}_2\text{SO}_4 + 2\text{Al}(\text{OH})_3 + 3\text{CO}_2$. Sodium carbonate, like all the salts of carbonic acid, evolves carbonic anhydride on treatment with all acids which are to any extent energetic. But if an acid diluted with water be gradually added to a solution of sodium

the temperature rises, like that of Na_2SO_4 . The specific gravity (note 7) of solutions of sodium carbonate (according to the data of Gerlach and Kohlrausch) at $15^{\circ}/4^{\circ}$ is expressed by the formula, $s = 9.992 + 104.5p + 0.165p^2$. Weak solutions occupy a volume not only less than the sum of the volumes of the anhydrous salt and the water, but even less than the water contained in them. For instance, 1,000 grams of a 1 per cent. solution occupy (at 15°) a volume of 990.4 c.c. (sp. gr. 1.0097), but contain 990 grams of water, occupying at 15° a volume of 990.8 c.c. Such cases are comparatively rare (but occur also with sodium hydroxide).

¹⁸ The resemblance is so great that the composition of Na_2SO_4 and Na_2CO_3 may be classed under the type $(\text{NaO})_2\text{R}$, where $\text{R} = \text{SO}_2$ or CO . Many other sodium salts also contain 10 mol. H_2O .

¹⁹ According to the observations of Pickering. According to Rose, when solutions of sodium carbonate are boiled, a certain amount of carbonic anhydride is disengaged.

carbonate, *at first* such an evolution does not take place, because the excess of the carbonic anhydride forms **acid sodium carbonate (sodium bicarbonate)**, NaHCO_3 ,²⁰ which is, however, unstable. Not only when heated alone, but even on being slightly heated in solution, and also at the ordinary temperature in damp air, it loses carbonic anhydride and forms the normal salt. And at the same time it is easy to obtain it in a pure crystalline form, if a strong solution of sodium carbonate be cooled and a stream of carbonic anhydride gas passed through it. The acid salt is less soluble in water than the normal,²¹ and therefore a strong solution of the latter gives crystals of the acid salt if carbonic anhydride be passed through it. The acid salt may be yet more conveniently formed from effloresced crystals of sodium carbonate, which, on being considerably heated, very readily absorb carbonic anhydride.²² The acid salt crystallises well, but not, however, in such large crystals as the normal salt; it has a brackish and not an alkaline taste like that of the normal salt; its reaction is feebly alkaline, nearly neutral. At 70° under the atmospheric pressure its solution begins to lose carbonic anhydride, and on boiling the evolution becomes very abundant. From

²⁰ The composition of this salt, however, may be also represented as a combination of carbonic acid, H_2CO_3 , with the normal salt, Na_2CO_3 , just as the latter also combines with water. Such a combination is all the more likely because there exists another salt, $\text{Na}_2\text{CO}_3, \text{NaHCO}_3, 2\text{H}_2\text{O}$ (sodium sesquicarbonate), obtained by cooling a boiling solution of sodium bicarbonate, or by mixing this salt with the normal salt; but the formula of this salt cannot be derived from the molecular formula of normal carbonic acid, as the formula of the bicarbonate can. At the same time the sesqui-salt has all the properties of a definite compound; it crystallises in transparent crystals, has a constant composition, and its solubility (and at 0° in 100 of water, 12.6 of anhydrous salt) differs from the solubility of the normal and acid salts; it is found in nature, and is known by the names of *trona* and *urao*. This salt is very stable in air, and may be used for purifying sodium carbonate on the large scale.

²¹ A hundred parts of water at 0° dissolve 7 parts of the acid salt, which corresponds with 4.3 parts of the anhydrous normal salt, but at 0° , 100 parts of water dissolve 7 parts of the latter. The solubility of the bi- or acid salt varies with considerable regularity; 100 parts of water dissolve, at 15° , 9 parts of the salt, and, at 30° , 11 parts.

The ammonium, and more especially the calcium, salt is much more soluble in water. The ammonia process (see p. 542) is founded upon this. Ammonium bicarbonate (acid carbonate) has at 0° a solubility of 12 parts in 100 of water, and at 30° , of 27 parts. Also its saturated solution is more stable than a solution of sodium bicarbonate. In fact, saturated solutions of these salts have a gaseous pressure like that of a mixture of carbonic anhydride and water—at 50° , for the sodium salt it is 750 millimetres, and for the ammonium salt, 563 millimetres.

²² Crystalline sodium carbonate (broken into lumps) also absorbs carbonic anhydride, but the water contained in the crystals is then disengaged: $\text{Na}_2\text{CO}_3, 10\text{H}_2\text{O} + \text{CO}_2 = 2\text{NaHCO}_3 + 9\text{H}_2\text{O}$, and dissolves part of the carbonate. When it is required to avoid the formation of this solution, a mixture of ignited and crystalline sodium carbonate is taken. Sodium bicarbonate is prepared chiefly for medicinal use, and is then often termed *carbonate of soda*, and also, for instance, in the so-called soda powders, for preparing certain artificial mineral waters, for the manufacture of digestive lozenges like those made at Essentuki, Vichy, &c.

the preceding remarks it is clear that in most reactions this salt, especially when heated, acts similarly to the normal salt, but has, naturally, some distinction from it. Thus, for example, if a solution of sodium carbonate be added to a normal magnesium salt, a turbidity (precipitate) of magnesium carbonate, MgCO_3 , is formed. No such precipitate is formed by the acid salt, because magnesium carbonate is soluble in the presence of an excess of carbonic anhydride.

Sodium carbonate is generally used for the preparation of **caustic soda** ²³—that is, the hydrate of sodium oxide, or the alkali which corresponds to sodium. For this purpose the action of lime on a solution of sodium carbonate is generally made use of. The process is as follows: a weak, generally 10 per cent., solution of sodium carbonate is taken, ²⁴ and boiled in a cast-iron, wrought-iron, or silver boiler (sodium hydroxide does not act on these metals), and lime is added, little by little, during the boiling. This latter is soluble in water, although but very slightly. The clear solution becomes turbid on the addition of the lime because a precipitate is formed; this precipitate consists of calcium carbonate, which is almost insoluble in water, whilst caustic soda is formed and remains in solution; the reaction is expressed by the equation: $\text{Na}_2\text{CO}_3 + \text{Ca}(\text{HO})_2 = \text{CaCO}_3 + 2\text{NaHO}$. After the necessary quantity of lime has been added, ²⁵ the solution is allowed to stand, and is

²³ In chemistry, sodium oxide is termed 'soda,' which word must be carefully distinguished from the word 'sodium,' meaning the metal. Commercially it is also called 'caustic soda.'

²⁴ With a small quantity of water, the reaction either does not take place, or even proceeds in the reverse way—that is, sodium and potassium hydroxides remove carbonic anhydride from calcium carbonate (Liebig, Watson, Mitscherlich, and others). The influence of the mass of water is evident. According to Gerberts, however, strong solutions of sodium carbonate are decomposed by lime, which is very interesting if confirmed by further investigation.

²⁵ As long as any undecomposed sodium carbonate remains in solution, excess of acid added to the solution disengages carbonic anhydride, and the solution after dilution gives with a barium salt a white precipitate soluble in acids, showing the presence of a carbonate in solution (if there be sulphate present, it also forms a white precipitate, but this is insoluble in acids). For the decomposition of sodium carbonate, milk of lime—that is, slaked lime suspended in water—is employed. Formerly pure sodium hydroxide was prepared (according to Berthollet's process) by dissolving the impure substance in alcohol (sodium carbonate and sulphate are not soluble), but now that metallic sodium has become cheap and is purified by distillation, *pure caustic soda* is prepared by acting on a small quantity of water with sodium (note 33a). Sodium hydroxide may also be purified by allowing strong solutions to crystallise (in the cold) (note 27).

In alkali works where the Leblanc process is used, caustic soda is prepared directly from the alkali remaining in the mother liquors after the separation of the sodium carbonate by evaporation (note 14). If excess of lime and charcoal have been used, much sodium hydroxide may be obtained. After the removal of as much as possible of the sodium carbonate, a red (from iron oxide) liquid is left, containing sodium hydroxide mixed with compounds of sulphur and of cyanogen, and also containing iron. This red alkali is evaporated and air blown through it, which oxidises the impurities (for this

then decanted off and evaporated in cast or wrought iron boilers, or, if a perfectly pure product is required, in silver pans.²⁶ The evaporation cannot be conducted in china, glass, or similar vessels, because caustic soda attacks these materials, although but slightly. The solution does not crystallise on evaporation, because the solubility of caustic soda when hot is very great, but if a concentrated solution (sp. gr. about 1.38) is cooled it deposits crystals consisting of $2\text{NaHO}, 7\text{H}_2\text{O}$, which fuse at $+6^\circ$.²⁷ If the evaporation is conducted so long as water is disengaged—which requires a considerable amount of heat—on cooling, the hydroxide, NaHO , solidifies in a semi-transparent crystalline mass,²⁸ which eagerly absorbs moisture and carbonic anhydride from the air.²⁹ Its specific gravity is 2.13, and³⁰ it is easily soluble in water, with

purpose sodium nitrate or bleaching powder, &c., is sometimes added) and leaves fused caustic soda. The fused mass is allowed to settle in order to separate the ferruginous precipitate, and is then poured into iron drums, where the sodium hydroxide solidifies. Such caustic soda contains about 10 per cent. of water in excess and some saline impurities, but when properly manufactured is almost free from carbonate and from iron. The greater part of the caustic soda, which forms so important an article of commerce, is manufactured in this manner.

²⁶ Löwig gave a method of preparing sodium hydroxide from sodium carbonate by heating it to a dull red heat with an excess of ferric oxide. Carbonic anhydride is given off, and warm water extracts the caustic soda from the remaining mass. This reaction, as experiment shows, proceeds very easily, and is an example of contact action similar to that of ferric oxide on the decomposition of potassium chlorate. In order to represent this clearly it is sufficient, for instance, to imagine that in the sodium carbonate the elements CO_2 move in a circle round the elements Na_2O , but at the points of contact with Fe_2O_3 the motion becomes elliptical with a long axis, and at some distance from Na_2O the elements of CO_2 are parted, not having the faculty of attaching themselves to Fe_2O_3 .

The action of an electric current on strong solutions of NaCl or on the fused salt gives chlorine at the anode and sodium at the cathode. If a mercury cathode is employed it dissolves the sodium, and if the amalgam is brought into contact with water or a previously formed solution of caustic soda, the whole of the sodium separates from the mercury with the evolution of hydrogen and formation of NaOH . There are many processes (Castner, Borchers, &c.) founded on this action (some employ a cathode of molten lead with fused NaCl).

²⁷ By allowing strong solutions of sodium hydroxide to crystallise in the cold, impurities—such as, for instance, sodium sulphate—may be separated from them. The fused crystallo-hydrate, $2\text{NaHO}, 7\text{H}_2\text{O}$, forms a solution having a specific gravity of 1.405 (Hermes). The crystals on dissolving in water produce cold, whilst NaHO produces heat. Besides which Pickering obtained hydrates with 1, 2, 4, 5, and 7 H_2O .

²⁸ In solid caustic soda there is generally an excess of water beyond that required by the formula NaHO . The caustic soda used in laboratories is generally cast in sticks, which are broken into pieces. It must be preserved in carefully closed vessels, because it absorbs water and carbonic anhydride from the air.

²⁹ By the way it changes in air it is easy to distinguish caustic soda from caustic potash, which in general resembles it. Both alkalies absorb water and carbonic anhydride from the air, but caustic potash forms a deliquescent mass of potassium carbonate, whilst caustic soda forms a dry powder of efflorescent salt.

³⁰ As the molecular weight of NaHO is 40, the volume of its molecule is $40 \cdot 2.13$, that is, 18.5, which very nearly approaches the volume of a molecule of water. The same rule

disengagement of a considerable quantity of heat.³¹ A saturated solution at the ordinary temperature has a specific gravity of about 1.5, contains about 45 per cent. of sodium hydroxide, and boils at 130°; at 55° water dissolves an equal weight of it.³² Caustic soda is not only soluble in water, but also in alcohol, and even ether. Dilute solutions of sodium hydroxide produce a soapy feeling on the skin because the active base of soap consists of caustic soda.³³ Strong solutions have a corroding action on animal tissues. As the NaHO prepared from soda always contains some impurities (soda, sulphuric acid, &c.), which it is difficult to separate entirely, and as it absorbs CO₂ from the

applies to the compounds of sodium in general—for instance, its salts have a molecular volume approaching the volume of the acids from which they are derived.

³¹ The molecular quantity of sodium hydroxide (40 grams), on being dissolved in a large mass (200 gram molecules) of water, develops, according to Berthelot, 9,780, and, according to Thomsen, 9,940, heat units. Solutions of NaHO + n H₂O, on being mixed with water, evolve heat if they contain less than 6H₂O, but absorb it if they contain more.

³² The specific gravity of solutions of sodium hydroxide at 15°/4° is given in the short table below:

NaHO, per cent.	.	5	10	15	20	30	40
Sp. gr.	.	1.057	1.113	1.169	1.224	1.331	1.436

1,000 grams of a 5 per cent. solution occupy a volume 946 c.c.; that is, less than the water serving to make the solution (see note 18).

³³ Sodium hydroxide and some other alkalies are capable of hydrolysing—saponifying, as it is termed—the compounds of acids with alcohols. If RHO [or R(HO) _{n}] represent the composition of an alcohol—that is, of the hydroxide of a hydrocarbon radicle—and QHO an acid, then the compound of the acid with the alcohol or the ethereal salt of the given acid will have the composition RQO. Ethereal salts, therefore, present a likeness to metallic salts, just as alcohols resemble basic hydroxides. Sodium hydroxide acts on ethereal salts in the same way as it acts on the majority of metallic salts—namely, it liberates alcohol, and forms the sodium salt of the acid contained in the ethereal salt. The reaction takes place in the following way:

Such a decomposition is termed **saponification**. Similar reactions were known very long ago, for the ethereal salts corresponding with glycerin, C₃H₅(OH)₃, are found (in animals and plants) as fats and oils. Caustic soda, acting on fat and oil, forms glycerin and the sodium salts of those acids which were in union with the glycerin in the fat, as Chevreul showed at the beginning of the last century. The sodium salts of the fatty acids are commonly known as **soaps**. That is to say, soap is made from fat and caustic soda, glycerin being separated and a sodium salt or soap formed. As glycerin is usually found in union with certain acids, so also are the sodium salts of the same acids found in soap. The greater part of the acids found in conjunction with glycerin in fats consists of the solid palmitic and stearic acids, C₁₆H₃₂O₂ and C₁₈H₃₈O₂, and the liquid oleic acid, C₁₈H₃₄O₂. Water acting on soap partly decomposes it (because the acids of the soap are feeble), and the alkali set free acts during the application of the soap. Hence it may be replaced by a very feeble alkali. Strong solutions of alkali corrode the skin and tissues. The reaction of the alkali with the acids contained in soap is reversible, and the alkali is only set free by the excess of water, according to the teaching of Berthollet.

atmosphere, pure caustic soda is now often prepared by the action of metallic sodium upon water, $2\text{Na} + 2\text{H}_2\text{O} = 2\text{NaHO} + \text{H}_2$,^{33a} and this reagent may now be bought ready made.

The chemical **reactions of sodium hydroxide** serve as a type for those of a whole class of alkalies—that is, of soluble basic hydroxides, MOH. The solution of sodium hydroxide is a very caustic liquid—that is to say, it acts in a destructive way on most substances, for instance, organic tissues. Hence caustic soda, like all soluble alkalies, is a poisonous substance; acids, for example, hydrochloric, serve as antidotes. The action of caustic soda on bones, fat, starch, and similar vegetable and animal substances explains its action on organisms. Thus bones, when plunged into a weak solution of caustic soda, fall to powder³⁴ and evolve a smell of ammonia, owing to the caustic soda changing the gelatinous organic substance of the bones (which, like albumin, contains carbon, hydrogen, nitrogen, oxygen, and sulphur), dissolving it and in part destroying it, whence ammonia is disengaged. Fats, tallow, and oils become saponified by a solution of caustic soda—that is to say, they form with it **soaps** soluble in water, or sodium salts of the organic acids contained in the fats.³⁵ The most characteristic reactions of sodium hydroxide are determined by the fact that it **saturates all acids, forming with them salts**, which are almost all soluble in water, and in this respect caustic soda is as characteristic among the bases as nitric acid among the acids. It is impossible to detect sodium by means of the formation of precipitates of insoluble sodium salts, as may be done with other metals, many of whose salts are but slightly soluble. The powerful alkaline properties of caustic soda determine its capacity for combining with even the feeblest acids, its property of disengaging ammonia from ammonium salts, its faculty of forming precipitates from solutions of salts of bases insoluble in water, &c. If a solution of the salt of almost any metal be mixed with caustic soda, a soluble sodium salt will be formed, and an insoluble hydroxide of the metal separated—for instance, copper nitrate yields copper hydroxide, $\text{Cu}(\text{NO}_3)_2 + 2\text{NaHO} = \text{Cu}(\text{HO})_2 + 2\text{NaNO}_3$. Even many

^{33a} It is prepared in a silver basin, cooled from the outside by water. A little water is first poured into the basin and sodium carefully added a little at a time, the basin being continually rocked to prevent any of the sodium attaching itself to the sides (which might be followed by an explosion). When a solution of caustic soda is already formed, the reaction proceeds more quietly, especially if the dish be cooled outside. It is still better to take alcohol and add the water and sodium gradually to it.

³⁴ On this is founded the process of Henkoff and Engelhardt for treating bones. The bones are mixed with ashes, lime, and water; it is true that in this case more potassium hydroxide than sodium hydroxide is formed, but the action is almost identical.

³⁵ As explained in note 33.

basic oxides precipitated by caustic soda **are capable** of combining with it and forming soluble compounds, and therefore caustic soda in the presence of salts of such metals first forms a precipitate of hydroxide, and then, employed in excess, dissolves this precipitate. This phenomenon occurs, for example, when caustic soda is added to the salts of aluminium. This shows the property of such an alkali as caustic soda of combining, not only with acids, but also with feeble basic oxides. For this reason caustic soda **acts on most elements** which are capable of forming acids or feeble bases; thus the metal aluminium gives hydrogen with caustic soda in consequence of the formation of alumina, which combines with the caustic soda—that is, in this case, the caustic alkali acts on the metal just as sulphuric acid does on Fe or Zn. If caustic soda acts in this manner on a metalloid capable of combining with the hydrogen evolved (aluminium does not give a compound with hydrogen), then such a hydrogen compound is formed. Thus, for instance, phosphorus acts in this way on caustic soda, yielding hydrogen phosphide. When the hydrogen compound disengaged is capable of combining with the alkali, then, naturally, a salt of the corresponding acid is formed. For example, chlorine and sulphur act in this way on caustic soda. Chlorine, with the hydrogen of the caustic soda, forms hydrochloric acid, and the latter forms common salt with the sodium hydroxide, while the other atom in the molecule of chlorine, Cl_2 , takes the place of the hydrogen, and forms the hypochlorite, NaClO . In the same way, by the action of sodium hydroxide on sulphur, hydrogen sulphide is formed, which acts on the soda and forms sodium **sulphide** (in addition to which sodium thiosulphate is also formed; see Chap. XX.). The action is often accelerated by the presence of the oxygen of the air, as by this means the formation of acids and oxides rich in oxygen is facilitated. Thus many metals and their lower oxides, in the presence of NaHO , absorb oxygen and form acids. Even manganese dioxide, when mixed with caustic soda, is capable of absorbing the oxygen of the air and forming sodium manganate, Na_2MnO_4 . Organic acids when heated with caustic soda give up to it the elements of carbonic anhydride, forming sodium carbonate, and separate that hydrocarbon group which exists, in combination with carbonic anhydride, in the organic acid.

Thus sodium hydroxide, like the soluble alkalies in general, ranks amongst the most chemically active substances, and but few substances are capable of resisting it. Even silicious rocks, as we shall see further on, are transformed by it and form vitreous slags when fused with it. Sodium hydroxide (like ammonium and potassium hydroxides), as a typical example of the basic hydrates, in distinction from many other

basic oxides, readily **forms acid salts** with acids (for instance, NaHSO_4 , NaHCO_3), and forms no basic salts at all; whilst many less energetic bases, such as the oxides of copper and lead, form basic salts easily, but acid salts only with difficulty. This capability of forming acid salts, particularly with polybasic acids, may be explained by the energetic basic properties of sodium hydroxide, contrasted with the small development of these properties in those bases which easily form basic salts. An energetic base is capable of retaining a considerable quantity of acid, which a slightly energetic base would not have the power of doing. Also, as will be shown in subsequent chapters, sodium belongs to the univalent metals, being exchangeable for hydrogen, atom for atom—that is, amongst metals sodium may, like chlorine amongst the non-metals, serve as the representative of the univalent properties. Most of the elements which are not capable of forming acid salts are divalent. Whence it may be gathered that in a dibasic acid—for instance, carbonic, H_2CO_3 , or sulphuric, H_2SO_4 —the hydrogen may be exchanged, atom for atom, for sodium, and yield an acid salt by means of the first substitution, and a normal salt by means of the second—for instance, NaHSO_4 , and Na_2SO_4 —whilst such bivalent metals as calcium and barium do not form acid salts, because one of their atoms at once takes the place of both hydrogen atoms, forming, for example, CaCO_3 and CaSO_4 .^{35a}

We have seen the transformation of common salt into sodium sulphate, of this latter into sodium carbonate, and of sodium carbonate into caustic soda. Lavoisier regarded sodium hydroxide as an element, because he was unacquainted with its decomposition with the formation of metallic sodium, which separates the hydrogen from water, re-forming caustic soda.

The preparation of **metallic sodium** was one of the greatest dis-

^{35a} It might be expected, from what has been mentioned above, that divalent metals would easily form acid salts with acids containing more than two atoms of hydrogen—for instance, with tribasic acids, such as phosphoric acid, H_3PO_4 —and such salts actually exist; but all such relations are complicated by the fact that the character of the base very often changes and becomes weakened with the increase of valency and the change of atomic weight; the feebler bases (like silver oxide), although corresponding with univalent metals, do not form acid salts, while the feeblest bases (CuO , PbO , &c.) readily form basic salts, and notwithstanding their valency do not form acid salts which are in any degree stable—that is, which are undecomposable by water. Basic and acid salts ought to be regarded rather as compounds similar to crystallo-hydrates, because such acids as sulphuric form with sodium, not only an acid and a normal salt, as might be expected from the valency of sodium, but also salts containing a greater quantity of acid. In sodium sesquicarbonate we saw an example of such compounds. Taking all this into consideration, we must say that the property of more or less easily forming acid salts depends more upon the energy of the base than upon its valency, and the best statement is that *the capacity of bases for forming acid and basic salts is characteristic of them*, just as the faculty of forming compounds with hydrogen is characteristic of elements.

coveries in chemistry, not only because through it the conception of elements became broader and more correct, but especially because in sodium, chemical properties were observed which were but feebly shown by the other metals more familiarly known. This discovery was made in 1807 by the English chemist **Davy** by means of the galvanic current. By connecting with the positive pole (of copper or carbon) a piece of caustic soda (moistened in order to obtain electrical conductivity), and boring a hole in it filled with mercury connected with the negative pole of a strong Volta's pile, Davy observed that on passing the current a peculiar metal dissolved in the mercury, less volatile than mercury, and capable of decomposing water, again forming caustic soda. In this way (by analysis and synthesis) Davy demonstrated the compound nature of alkalis. On being decomposed by the galvanic current, caustic soda disengages hydrogen and sodium at the negative pole and oxygen at the positive pole. Davy showed that the metal formed volatilises at a red heat, and this is its most important physical property in relation to its extraction, all later methods being founded on it. Besides this Davy observed that sodium easily oxidises, its vapour taking fire in air, and the latter circumstance was for a long time an obstacle to the easy preparation of this metal. The properties of sodium were subsequently more thoroughly investigated by Gay-Lussac and Thénard, who observed that metallic iron at a high temperature was capable of reducing caustic soda to sodium.³⁶ Brunner latterly discovered that not only iron, but also charcoal, has this property, although hydrogen has not.³⁷ But still the methods of extracting sodium were very troublesome, and consequently it was a great rarity. The

³⁶ Deville supposes that such a decomposition of sodium hydroxide by metallic iron depends solely on the dissociation of the alkali at a white heat into sodium, hydrogen, and oxygen. Here the part played by the iron is only that it retains the oxygen formed, otherwise the decomposed elements would again reunite upon cooling, as in other cases of dissociation. If it be supposed that the temperature at the commencement of the dissociation of the iron oxides is higher than that of sodium oxide, the decomposition may be explained by Deville's hypothesis. Deville demonstrates his views by the following experiment:—an iron bottle, filled with iron borings, was heated in such a way that the upper part became red hot, the lower part remaining cooler; sodium hydroxide was introduced into the upper part. The decomposition was then effected—that is, sodium vapours were produced (this experiment was really performed with potassium hydroxide). On opening the bottle it was found that the iron in the upper part was not oxidised, but only that in the lower part. This may be explained by the decomposition of the alkali into sodium, hydrogen, and oxygen taking place in the upper part, whilst the iron in the lower part absorbed the oxygen set free. If the whole bottle is subjected to the same moderate heat as the lower extremity, no metallic vapours are formed. In that case, according to the hypothesis, the temperature is insufficient for the dissociation of the sodium hydroxide.

³⁷ It has been previously remarked (Chap. II., note 9) that Beketoff showed the displacement of sodium by hydrogen, not from sodium hydroxide, but from the oxide Na_2O , when, however, only one half is displaced, with the formation of NaHO .

principal obstacle to its production was that an endeavour was made to condense the easily oxidising vapours of sodium in vacuo in complicated apparatus. For this reason, when Donny and Maresca, having thoroughly studied the matter, constructed a specially simple condenser, the production of sodium was much facilitated. The production of sodium was yet further simplified by Sainte-Claire Deville, who employed a mixture of anhydrous sodium carbonate (7 parts), charcoal (2 parts), and lime or chalk (7 parts). This latter ingredient is only added in order that the sodium carbonate, on fusing, shall not separate from the charcoal.³⁸ The chalk on being heated loses carbonic anhydride, leaving infusible lime, which is permeated by the sodium

FIG. 80.—Manufacture of sodium by Deville's process. A C, iron tube containing a mixture of soda, charcoal, and chalk. B, condenser.

carbonate and forms a thick mass, in which the charcoal is intimately mixed with the sodium carbonate. When the charcoal is heated with the sodium carbonate, at a white heat, carbonic oxide and vapours of sodium are disengaged, according to the equation :

In sodium works, an iron tube, about a metre long and a decimetre in diameter, made of boiler plate, is luted into a furnace having a strong

³⁸ Since the close of the eighties in England, where the preparation of sodium is at present carried out on a large commercial scale (from 1860 to 1870 it was only manufactured in a few works in France), it has been the practice to add iron to Deville's mixture; with the charcoal this gives carburetted iron, which still further facilitates the decomposition. Thus Castner heated a mixture of 44 parts of NaHO and 7 parts of carbide of iron in large iron retorts at 1,000° and obtained about 6½ parts of metallic sodium. The reaction proceeds more easily than with carbon or iron alone. Subsequently, in 1891, aluminium was prepared by electrolysis (see Chap. XVII.), and metallic sodium found new uses : for the manufacture of peroxide of sodium (see later on), for the manufacture of potassium and sodium cyanide from yellow prussiate (Chap. XIII., note 12), and for the preparation of pure NaHO, &c.

draught, capable of giving a high temperature, and is charged with the mixture required for the preparation of sodium. One end of the tube is closed with a cast-iron stopper A with clay luting, and the other with the cast-iron stopper C provided with an aperture. On heating, the moisture contained in the various substances is first given off, then carbonic anhydride and the products of the dry distillation of the charcoal, after which carbonic oxide and vapours of sodium appear. It is easy to observe the appearance of the latter, because on issuing from the aperture in the stopper C they take fire spontaneously and burn with a very bright yellow flame. The pipe of the condenser is then introduced into the aperture C. This condenser consists of two square cast-iron trays, A and A', fig. 81, with wide edges firmly screwed together. Between these two trays there is a space in which the condensation of the vapours of sodium is effected, the thin metallic walls of the condenser being cooled by the air but remaining hot enough to preserve the sodium in a liquid state, so that it does not choke the apparatus, but continually flows from it. The vapours of sodium, condensing in the cooler, flow in the shape of liquid metal into a vessel containing some difficultly volatile hydrocarbon (heavy naphtha oils). This is used in order to prevent the sodium oxidising as it issues from the condenser at the somewhat high temperature at which it escapes. In order to obtain sodium of a pure quality it is necessary to distil it once more; this may even be done in porcelain retorts, but the distillation must be conducted in a stream of some gas on which sodium does not act; for instance, in a stream of nitrogen; carbonic anhydride is not applicable, because sodium partially decomposes it, absorbing oxygen from it.^{38a}

FIG. 81.—Donny and Maresca's sodium condenser, consisting of two cast-iron plates screwed together.

Pure sodium is a lustrous metal, at the ordinary temperature as white as silver and as soft as wax, but it becomes brittle in the cold. In ordinary moist air it quickly tarnishes and becomes covered with a film of NaHO and Na_2CO_3 , formed at the expense of the water and CO_2 in the air. In perfectly dry air sodium retains its lustre for an indefinite time. Its density at the ordinary temperature is equal to 0.975, so that it is lighter than water; it fuses very easily at a temperature of 97° , and distils at a bright red heat (742° , according to Perman, 1889).

^{38a} The manufacture of metallic sodium by electrolysis, which has been tried in different ways, has not, as far as I know, proved as economical and convenient as the direct reduction of soda by a mixture of carbon and iron. Sodium is sometimes sold in lumps coated with paraffin.

Scott (1887) determined the density of sodium vapour and found it to be nearly 12 (if $H = 1$). This shows that its molecule contains one atom (like mercury and cadmium), Na.³⁹ It fuses with most metals, forming indefinite compounds called alloys. Thus, if sodium, having a clean surface) be thrown into mercury, especially when heated, there is a flash, and such a considerable amount of heat is evolved that part of the mercury is transformed into vapour.^{39a} Compounds or solutions of sodium in mercury, or **amalgams** of sodium, even when containing only 2 parts of sodium to 100 parts of mercury, are solid. Only those amalgams which are the very poorest in sodium are liquid. Such alloys of sodium with mercury⁴⁰ are often used instead of sodium in chemical

³⁹ This is also shown by the fall in the temperature of solidification of tin produced by the addition of sodium (and also Al and Zn); Heycock and Neville (1889).

^{39a} By dissolving sodium amalgams in water and acids, and deducting the heat of reaction of the sodium, Berthelot found that *for each atom of the sodium* in amalgams containing a larger amount of mercury than corresponds with NaHg₅, the amount of heat evolved increases, after which the heat of formation falls, and the heat evolved decreases. In the formation of NaHg₅ about 18,500 calories are evolved; when NaHg₃ is formed, about 14,000; and for NaHg about 10,000 calories. Kraft regarded the definite crystalline amalgam as having the composition of NaHg₆, but in accordance with Grimaldi's results, it is thought to be NaHg₅. A similar amalgam is very easily obtained if a 3 per cent. amalgam be left several days in a solution of sodium hydroxide until a crystalline mass is formed, from which the mercury may be removed by strongly pressing in chamois leather.

⁴⁰ Alloys are so similar to solutions that what is known for solutions may be applied to alloys and conversely. But in alloys, as substances passing from the liquid to the solid state, it is easier to discover the formation of definite chemical compounds. Their presence in alloys is not only proved by their being seen in the form of separate crystals, but also by a systematic investigation of any (physical and chemical) property of alloys presenting the most diverse composition; for instance, by investigating the melting-points, the heat evolved, the variation in volume (sp. gr.), electro-motive force, &c. Thus Prof. Kurnakoff in his researches on the alloys of Na with Hg, Cd, Pb, and Bi (1900) determined their fusing-points, and in this way found those definite compounds which are mentioned above. In general the alloys of sodium, owing to the comparative energy and peculiar properties of the metal, have been closely studied by Bailey (1892), Joannis (1892), Maly (1899), and others, and all recognised the formation of one or even several definite compounds in them, and the same is observed with almost any pair of metals. It is my personal opinion that this universal phenomenon (the formation of definite compounds between metals) in alloys speaks much in favour of the fact that definite compounds should also be formed in the intermixture of liquids (for instance, of alcohol or sulphuric acid with water) and in the solution of salts in water. As the formation of definite compounds in metallic alloys was known long ago, I endeavoured when investigating solutions (Chap. I.) to trace the formation of definite compounds in them also. In speaking of alloys and solutions in different parts of this work I only wish to point out the great interest these classes of compounds present, but details of this complex subject must be looked for in special works and text-books on physical chemistry, especially because they deal fully with the doctrine of phases (see note 4), in which connection solutions and alloys are most frequently studied at the present day. For I consider that the study of solutions and particularly of alloys, which is still in its infancy (as it is chiefly occupied in describing observations and in giving a picture of individual cases, and not in making predictions and generalisations), will in

investigations, because in combination with mercury sodium is not easily acted on by air, and is heavier than water, whilst at the same time it retains its principal properties, such, for instance, as the power to decompose water, forming NaHO.

It is easy to form alloys of mercury and sodium having a crystalline structure and a definite atomic composition. One of the most remarkable is the alloy having the composition NaHg₂, which fuses at +346° (N. S. Kurnakoff, 1900), although it contains Na and Hg which fuse at far lower temperatures, namely, 97° and -39° respectively. The alloy Na₂Hg (or Na₅Hg₂) crystallises in hexagonal plates and fuses at about 105°; that having the composition NaHg fuses at about 209°, while NaHg₅ fuses at 149°. This shows that all these alloys are more difficultly fusible than their component elements, which clearly proves that new chemical compounds are formed here as in many other alloys: this is confirmed by the fact that small additions of Hg to Na (for instance, in the formation of the alloy with 40 per cent. of Hg) lower the melting-point of sodium,^{40a} just as the addition of a salt to water lowers its freezing-point.

Metallic sodium has the power of dissolving—at low temperatures and without the evolution of hydrogen—in liquefied ammonia, forming a blue solution which at 0° deposits a copper-red compound, NH₃Na (as it were, substituted ammonium). This compound has been the subject of many researches, and was studied by Weil, Joannis, and Moissan (see Chap. VI., note 14).

The peculiar chemical energy proper to sodium as an element and a metal is not only expressed in its capacity of easily displacing hydrogen from water and hydroxyl to form an energetic alkali, and in its tendency to combine with many metals with the evolution of heat, but also in many other reactions leading to the formation of saline and energetic compounds. Among these we shall now turn our attention to the compounds of sodium with hydrogen⁴¹ and oxygen.

time explain much in respect to chemical forces and phenomena. It will then have to take its place in every elementary work on chemistry, but for the present we must limit ourselves to cursory notes on this yet little cultivated field of chemistry which promises such an abundant harvest in the future.

^{40a} The alloy of 100 grams of Na with 167 grams of Hg fuses 8·8° lower than sodium, and that with 147 grams of Hg 73·0° lower (i.e., at 23·4°), so that the fall (depression) is 0·497° per gram of Hg.

⁴¹ Potassium forms a similar compound with hydrogen, but lithium apparently, as far as is known, does not react; on the other hand, neither Na nor K combines directly with nitrogen, but lithium absorbs nitrogen. Hydrazoic acid, HN₃, has a corresponding salt, NaN₃, which easily decomposes, while the two above-mentioned remarkable substances, the amide of sodium NaH₂N (note 44a) and the blue liquid containing Na(NH₃)_n (Chap. VI., note 14), which is only stable at low temperatures in the presence of an excess of NH₃, both correspond to ammonia. Moissan (1897) passed acetylene

In 1874 Troost and Hautefeuille observed that sodium, which does not react at all with hydrogen at the ordinary temperature, absorbs this gas (238 vols. per 1 vol. of Na) at temperatures of 300° to 420° ; the volume of the metal increases and the hydrogen is not evolved on cooling, but dissociation takes place above 320° .⁴² It is evident that **hydride of sodium** is formed;⁴³ but it was only obtained pure by Moissan in 1902, when he placed metallic sodium in an iron tube heated from below to 360° and cooled from above, and passed dry hydrogen through it. The hydride of sodium (NaH) formed then settles on the cooler portion of the tube as a colourless crystalline sublimate. The NaH thus obtained easily oxidises in the air and reacts vigorously with chlorine, oxygen (burns in it), and many other gases and liquids. With NH_3 gas it forms an amide, NH_2Na , liberating hydrogen. With carbonic anhydride it directly gives sodium formate according to the equation: $\text{NaH} + \text{CO}_2 = \text{CHNaO}_2$. With methyl chloride it forms NaCl and CH_4 , and with C_2H_5 it gives C_2H_6 . These peculiar properties of sodium hydride appear the more remarkable when they are compared with the properties of other hydrides, and it may not be superfluous to note that HCl and NaH, corresponding to the molecule of free hydrogen H_2 , also correspond to NaCl, as should follow from the law of substitution and from the fact that H, Cl, and Na are all monatomic (univalent or uni-equivalent).

The most important chemical property of sodium is its power of easily decomposing water and **evolving hydrogen** from the majority of the hydrogen compounds, and especially from all acids and hydrates in which the presence of hydroxyl must be recognised. This depends on its power of combining with the elements which are in combination with

through this blue liquid and obtained a colourless liquid containing an acetylene derivative of sodium, C_2NaH , with the formation of NH_3 and ethylene (see Chap. XIV., note 62), which when heated gave C_2H_2 and *carbide of sodium*, C_2Na_2 , corresponding to acetylene. The compounds of Na with H, C, and N which have recently become known—thanks to the researches of Moissan—present a series of peculiar and remarkable reactions, and will probably serve as a means for many syntheses at some future time.

⁴² The dissociation pressures p of the hydrogen in millimetres of mercury are:

	$t = 330^{\circ}$	350°	400°	430°
for the compound of Na; $p = 28$		57	447	910
„ „ „ „ K 45		72	548	1100

⁴³ Troost and Hautefeuille gave the composition Na_3H to the compound and assumed that the phenomenon resembled the formation of alloys, i.e., that the hydrogen was contained as a metal, and that the sp. gr. of the alloy was 0.959 (whence the density of hydrogen would be 0.6, which is hardly probable). Moissan showed that NaH does not react with liquid ammonia, and as the sodium in it dissolves, this may be taken advantage of for removing the sodium and separating NaH from metallic sodium which has absorbed hydrogen and contains NaH in solution.

the hydrogen. We already know that sodium disengages hydrogen, not only from water, hydrochloric acid,⁴⁴ and all other acids, but also from ammonia,^{44a} with the formation of sodamide, NH_2Na , although it does not displace hydrogen from the hydrocarbons.⁴⁵ Sodium burns both in chlorine and in oxygen, evolving much heat. These properties are closely connected with its power of **taking up oxygen, chlorine,** and similar elements from most of their compounds. Just as it removes the oxygen from the oxides of nitrogen and from carbonic anhydride, so also does it decompose the majority of oxides at definite temperatures. Here the action is essentially the same as in the decomposition of water. Thus, for instance, when acting on magnesium chloride the

⁴⁴ H. A. Schmidt remarked that perfectly dry hydrogen chloride is decomposed with great difficulty by sodium, although the decomposition proceeds easily with potassium and with sodium in moist hydrogen chloride. Wanklyn also remarked that sodium burns with great difficulty in dry chlorine.

^{44a} **Sodamide**, NHNa (Chap. IV., note 14), discovered by Gay-Lussac and Thénard, has been fully investigated by A. W. Titherley (1894).

By heating sodium in dry ammonia, Gay-Lussac and Thénard obtained an olive-green readily fusible mass, **sodamide**, NH_2Na , hydrogen being separated. This substance with water forms sodium hydroxide and ammonia; with carbonic oxide, CO , it forms sodium cyanide, NaCN , and water, H_2O ; and with dry hydrogen chloride it yields sodium and ammonium chlorides. When heated, sodamide, NH_2Na , only partially decomposes, with evolution of hydrogen, the principal part of it giving ammonia and sodium nitride, Na_3N , according to the equation: $3\text{NH}_2\text{Na} = 2\text{NH}_3 + \text{NNa}_3$. The latter is an almost black powdery mass, decomposed by water into ammonia and sodium hydroxide.

According to Titherley's researches, iron or silver vessels should be used in preparing this body, because glass and porcelain are corroded at 300° – 400° , at which temperature ammonia gas acts upon sodium and forms the amide, with the evolution of hydrogen. The reaction proceeds slowly, but is complete if there be an excess of NH_3 . Pure NH_2Na is colourless (its coloration is due to various impurities), semi-transparent, shows traces of crystallisation, has a conchoidal fracture, and melts at 145° . Judging from the increase in weight of the sodium and the quantity of hydrogen which is disengaged, the composition of the amide is exactly NH_2Na . It partially volatilises (sublimes) in vacuo at 200° , and breaks up into $2\text{Na} + \text{N}_2 + 2\text{H}_2$ at 500° . NaHO is also formed to some extent by the resultant H_2O . Potassium and lithium form similar amides. With water, alcohol, and acids, NH_2Na gives NH_3 and NaHO , which react further. Anhydrous CaO absorbs NH_2Na when heated without decomposing it. When sodamide is heated with SiO_2 , NH_3 is disengaged, and silicon nitride formed. It acts still more readily upon boric anhydride when heated with it: $2\text{NH}_2\text{Na} + \text{B}_2\text{O}_3 = 2\text{BN} + 2\text{NaHO} + \text{H}_2\text{O}$. When slightly heated, $\text{NH}_2\text{Na} + \text{NOCl} = \text{NaCl} + \text{N}_2 + \text{H}_2\text{O}$ (NHNa_2 and NNa_3 are apparently not formed at a higher temperature). The organic halogen compounds react with the aid of heat, but with so much energy that the reaction frequently leads to the ultimate destruction of the organic groups and production of carbon.

⁴⁵ As sodium does not displace hydrogen from the hydrocarbons, it **may be preserved** in liquid hydrocarbons. **Naphtha** is generally used for this purpose, as it consists of a mixture of various liquid hydrocarbons. However, in naphtha sodium usually becomes coated with a crust composed of matter produced by the action of the sodium on certain of the substances contained in the liquid mixture. In order that sodium may retain its lustre in naphtha, secondary octyl alcohol is added. (This alcohol is obtained by distilling castor oil with caustic potash.) Sodium keeps well in a mixture of pure benzene and paraffin.

sodium displaces the magnesium. Sulphur, phosphorus, arsenic, and a whole series of other elements also combine with sodium.⁴⁶

With **oxygen** sodium unites in three degrees of combination, forming a suboxide Na_4O ,^{46a} an oxide, Na_2O , and a peroxide, NaO . They are thus termed because Na_2O is a stable basic oxide (with water it forms a basic hydroxide), whilst Na_4O and NaO do not form corresponding saline hydrates and salts. The suboxide is a grey inflammable substance which decomposes water, disengaging hydrogen; it is formed by the slow oxidation of sodium at the ordinary temperature. The peroxide is a yellow substance, fusing at a bright red heat; it is produced by burning sodium in an excess of oxygen, and it yields oxygen when treated with warm water:

The oxidation of sodium, under the action of heat in air or oxygen, leads only to the formation of **sodium peroxide** NaO (or Na_2O_2)

⁴⁶ Although sodium does not directly displace the hydrogen in hydrocarbons, still by indirect means compounds may be obtained which contain sodium and hydrocarbon groups. Some of these compounds have been produced, although not in a pure state. Thus, for instance, zinc ethyl, $\text{Zn}(\text{C}_2\text{H}_5)_2$, when treated with sodium, loses zinc and forms **sodium ethyl**, $\text{C}_2\text{H}_5\text{Na}$, but this decomposition is not complete, and the compound formed cannot be separated by distillation from the remaining zinc ethyl. In this compound the energy of the sodium is clearly manifest, for it reacts with substances containing haloids, oxygen, &c., and directly absorbs carbonic anhydride, forming a salt of a carboxylic acid (propionic).

^{46a} It is even doubtful whether the suboxide exists (see note 47).

⁴⁷ A compound, Na_2Cl , which corresponds with the suboxide, is apparently formed when a galvanic current is passed through fused common salt; the sodium liberated dissolves in the common salt, and does not separate out either on cooling or on treatment with mercury. It is therefore supposed to be Na_2Cl ; especially as the mass obtained gives hydrogen when treated with water: $\text{Na}_2\text{Cl} + \text{H}_2\text{O} = \text{H} + \text{NaHO} + \text{NaCl}$, that is, it acts like suboxide of sodium. If Na_2Cl really exists as a salt, then the corresponding base Na_4O , according to the rule with other bases of the composition M_4O , ought to be called a *quaternary oxide*.

⁴⁸ According to observations easily made, sodium when fused in air oxidises but does not burn, the combustion only commencing with the formation of vapour—that is, when considerably heated. Davy and Karsten obtained the oxide of sodium, Na_2O , by heating the metal with the hydroxide, when $\text{NaHO} + \text{Na} = \text{Na}_2\text{O} + \text{H}$, but N. N. Beketoff failed to obtain the pure oxide by this means. He prepared it by directly igniting the metal in dry air, afterwards heating with the metal in order to destroy the peroxide. The oxide produced, Na_2O , when heated in an atmosphere of hydrogen, gave a mixture of sodium and its hydroxide: $\text{Na}_2\text{O} + \text{H} = \text{NaHO} + \text{Na}$ (see Chap. II., note 9). Sodium oxide ought to be formed during the decomposition of sodium carbonate by oxide of iron (see note 26), and during the decomposition of sodium nitrite. According to Karsten, its specific gravity is 2.8, according to Beketoff, 2.3. The difficulty in obtaining it is owing to an excess of sodium forming the suboxide, and an excess of oxygen the peroxide.

as a yellowish mass. If it be carefully (without raising the temperature) dissolved in water at the ordinary temperature and rapidly cooled, it forms scaly crystals having the composition, $\text{NaO}, 4\text{H}_2\text{O}$, which may, like the peroxide itself, be kept unaltered in a closed vessel. But the CO_2 and water of the air act upon NaO and convert it into NaHO and Na_2CO_3 . Peroxide of sodium forms peroxide of hydrogen with acids, and then acts as an oxidising agent like the latter, but it does not part with its oxygen when heated, although it easily parts with it to substances capable of being oxidised.⁴⁹

Both Na_4O and NaO form sodium hydroxide with water, but only the oxide Na_2O is directly transformed into a hydrate. The other oxides liberate either hydrogen or oxygen: they also present a similar distinction with reference to many other agents. Thus carbonic anhydride combines directly with the oxide Na_2O , which when heated in the gas burns, forming sodium carbonate, whilst the peroxide yields oxygen in addition. When treated with acids, sodium and all its oxides form only the salts corresponding with sodium oxide—that is, of the formula or type NaX . Thus the oxide of sodium, Na_2O is **the salt-forming oxide** of this metal, just as water is in the case of hydrogen.

⁴⁹ Peroxide of sodium is now prepared on a large scale (by the action of air upon Na at 300°) for bleaching wool, silk, &c. (when it acts in virtue of the H_2O_2 formed). In preparing it on a large scale, aluminium vessels are used (Castner), and care is taken to prevent the metal taking fire (oxidation proceeds from the surface) and to keep the temperature in the furnaces below 450° (to preserve the aluminium vessels, which are not acted upon either by the sodium taken or by the peroxide). To ensure this the fresh air is only brought into contact with the vessels containing sodium in which the oxidation is completed, and the unoxidised metal is only oxidised by air from which the greater portion of the oxygen has already been exhausted. If NaNO_3 is melted, it gives Na_2O_2 with metallic Na . In a fused state the peroxide is reddish-yellow, but it becomes almost colourless when cold. When heated with iodine vapour, it loses oxygen: $\text{Na}_2\text{O}_2 + \text{I}_2 = \text{Na}_2\text{OI}_2 + \text{O}$. The compound Na_2OI_2 is akin to the compound Cu_2OCl_2 obtained by oxidising CuCl . This reaction is one of the few in which iodine directly displaces oxygen. The substance Na_2OI_2 is soluble in water, and when acidified gives free iodine and a sodium salt. Carbonic oxide is absorbed by heated sodium peroxide with formation of sodium carbonate, $\text{Na}_2\text{CO}_3(\text{Na}_2\text{O}_2 + \text{CO})$, whilst carbonic anhydride liberates oxygen from it. With nitrous oxide it reacts thus: $\text{Na}_2\text{O}_2 + 2\text{N}_2\text{O} = 2\text{NaNO}_2 + \text{N}_2$; with nitric oxide it combines directly, forming sodium nitrite, $\text{NaO} + \text{NO} = \text{NaNO}_2$. Sodium peroxide, when treated with water, does not give hydrogen peroxide, because the latter, in the presence of the alkali formed ($\text{Na}_2\text{O}_2 + 2\text{H}_2\text{O} = 2\text{NaHO} + \text{H}_2\text{O}_2$), decomposes into water and oxygen. In the presence of dilute sulphuric acid it forms H_2O_2 ($\text{Na}_2\text{O}_2 + \text{H}_2\text{SO}_4 = \text{Na}_2\text{SO}_4 + \text{H}_2\text{O}_2$). The oxidising properties of Na_2O_2 under the action of heat are seen, for instance, in the fact that when heated with iodine it forms sodium iodate; with PbO , Na_2PbO_3 ; with pyrites, sulphates, &c. When peroxide of sodium comes into contact with water, it evolves much heat, forming H_2O_2 , and decomposing with the disengagement of oxygen; but, as a rule, there is no explosion. But if Na_2O_2 is placed in contact with organic matter, such as sawdust, cotton, &c., it gives a violent explosion when heated, ignited, or acted on by water. Peroxide of sodium forms an excellent oxidising agent for the preparation of the higher products of oxidation of Mn , Cr , W , &c., and also for oxidising the metallic sulphides.

Although the peroxide H_2O_2 is derived from hydrogen, and Na_2O_2 from sodium, yet there are no corresponding salts known, and if they are formed they are probably as unstable as hydrogen peroxide. Although carbon forms carbonic oxide, CO , still it has only one salt-forming oxide—carbonic anhydride, CO_2 . Nitrogen and chlorine both give several salt-forming oxides and types of salts. But of the oxides of nitrogen, NO and NO_2 do not form salts, as do N_2O_3 , N_2O_4 , and N_2O_5 , although N_2O_4 does not form special salts, and N_2O_5 corresponds with the highest form of the saline compounds of nitrogen. Such distinction between the elements, according to their power of giving one or several saline forms, is a radical property of no less importance than the basic or acid properties of their oxides. Sodium as a typical metal does not form any acid oxides, whilst chlorine, as a typical non-metal, does not form bases with oxygen. Therefore sodium *as an element* may be thus characterised: it forms one very stable salt-forming oxide, Na_2O , having powerful basic properties, and its salts are of the general formula NaX , so that in its compounds it is, like hydrogen, a basic and univalent element.

CHAPTER XIII

POTASSIUM, RUBIDIUM, CÆSIUM, AND LITHIUM. SPECTRUM ANALYSIS.

JUST as the series of halogens, fluorine, bromine, and iodine correspond with the chlorine contained in common salt, so also there exists a corresponding series of elements: lithium, $\text{Li} = 7$, potassium, $\text{K} = 39$, rubidium, $\text{Rb} = 85$, and cæsium, $\text{Cs} = 133$, which are analogous to the sodium in common salt. These elements bear as great a resemblance to sodium, $\text{Na} = 23$, as fluorine, $\text{F} = 19$, bromine, $\text{Br} = 80$, and iodine, $\text{I} = 127$, do to chlorine, $\text{Cl} = 35.5$. Indeed, in a free state, these elements, like sodium, are soft metals which rapidly oxidise in moist air and decompose water at the ordinary temperature, forming soluble hydroxides having clearly defined basic properties and the composition RHO , like that of caustic soda. The resemblance between these metals is sometimes seen with striking clearness, especially in compounds such as salts of the form MX .¹ The corresponding salts of nitric, sulphuric, carbonic, and nearly all acids with these metals have many points in

¹ Tutton's researches (1894) upon the analogy of the crystalline forms of K_2SO_4 , Rb_2SO_4 and Cs_2SO_4 may be taken as a typical example of the comparison of analogous compounds. We cite the following data from these excellent researches (which are still being continued): the sp. gr. at $20^\circ/4^\circ$ of K_2SO_4 is 2.6633, that of Rb_2SO_4 , 3.6113, and that of Cs_2SO_4 , 4.2434. The coefficient of cubical expansion (the mean between 20° and 60°) for the K salt is 0.0053, for the Rb salt 0.0052, and for the Cs salt 0.0051. The linear expansion (the maximum for the vertical axis) along the axis of crystallisation is the same for all three salts, within the limits of experimental error. The replacement of potassium by rubidium causes the distance between the centres of the molecules in the direction of the three axes of crystallisation to increase equally, and less than with the replacement of rubidium by cæsium. The index of refraction for all rays and for every crystalline path (direction) is greater for the rubidium salt than for the potassium salt, and less than for the cæsium salt. The lengths for the rhombic crystalline axes for K_2SO_4 are in the ratio 0.5727 : 1 : 0.7418; for Rb_2SO_4 , 0.5723 : 1 : 0.7485, and for Cs_2SO_4 , 0.5712 : 1 : 0.7521. The development of the basal and brachy-pinacoids gradually increases in passing from K to Rb and Cs. The optical properties also follow the same order, both at the ordinary and at a higher temperature. Tutton draws the general conclusion that the crystallographic properties of the isomorphic rhombic sulphates, R_2SO_4 , are a function of the atomic weights of the metals contained in them (see Chap. XV.). Such researches as these should do much towards hastening the establishment of a true molecular mechanics of physico-chemical phenomena, and also serve as a means of showing and expressing variable properties as a function of the atomic weights of the component elements.

common. These metals, which resemble sodium so much in their reactions, are termed the **metals of the alkalies**.

Among the metals of the alkalies, the most widely distributed in nature, after sodium, is **potassium**. Like sodium, it does not appear either in a free state or as oxide or hydroxide, but in the form of salts, which, in the manner of their occurrence, present much in common with those of sodium. The compounds of potassium and sodium in the earth's crust occur as mineral **compounds of silica**. With silica, SiO_2 , potassium oxide, like sodium oxide, forms saline mineral substances resembling glass. If other oxides, such as lime, CaO , and alumina, Al_2O_3 , combine with these compounds, glass is formed, a vitreous stony mass, distinguished by its great stability, and its very slight variation under the action of water. It is such complex silicious compounds as these containing potash (potassium oxide), K_2O , or soda (sodium oxide), Na_2O , and sometimes both together, silica, SiO_2 , lime, CaO , alumina, Al_2O_3 , and other oxides, that form the chief constituents of the rocks of which the greater portion of the accessible crust (envelope) of the earth is made up. The primary rocks, like granite, porphyry, &c., are composed of such crystalline silicious rocks as these. The oxides entering into the composition of these rocks do not form a homogeneous amorphous mass like glass, but are distributed in a series of peculiar, and in the majority of cases crystalline, compounds, into which the primary rocks may be divided. Thus a felspar (orthoclase) in granite contains from 8 to 15 per cent. of potassium, whilst another variety (plagioclase), which also occurs in granite, contains 1·2 to 6 per cent. of potassium, and 6 to 12 per cent. of sodium. The mica in granite contains 3 to 10 per cent. of potassium. As already mentioned, and further explained in Chap. XVII., the friable, crumbling, and stratified formations which cover the ocean-bed and a large part of the earth's surface have been formed from these primary rocks by the action of the atmosphere and of water containing carbonic acid. It is evident that in the chemical alteration of the primary rocks by the action of water, the compounds of potassium, as well as the compounds of sodium, must have been dissolved by the water (as they are soluble in water), and that therefore the compounds of potassium must be accumulated together with those of sodium in sea water. And indeed compounds of potassium are always found **in sea water**, as we have already pointed out (Chapters I. and X.). This forms one of the sources from which they are extracted. After the evaporation of sea water, there remains a mother liquor, which contains potassium chloride and a large proportion of magnesium chloride. On cooling this solution, crystals separate out which contain chlorides of

magnesium and potassium. A double salt of this kind, called **carnallite**, $\text{KMgCl}_3 \cdot 6\text{H}_2\text{O}$, occurs at Stassfurt. This carnallite² is now employed as a material for the extraction of potassium chloride, and of all the compounds of this element.³ Besides which, potassium chloride itself is sometimes found at Stassfurt as **sylvine**.^{3a} By methods of

² Carnallite belongs to those double salts which are directly decomposed by water, and it only crystallises from solutions which contain an excess of magnesium chloride. It may be prepared artificially by mixing strong solutions of potassium and magnesium chlorides, when colourless crystals of sp. gr. 1.60 separate, whilst the Stassfurt salt is usually of a reddish tint, owing to the presence of traces of iron. At the ordinary temperature sixty-five parts of carnallite are soluble in a hundred parts of water in the presence of an excess of salt. It deliquesces in the air, forming a solution of magnesium chloride and leaving potassium chloride. At the close of the nineteenth century the yearly production of salt at Stassfurt and in the neighbourhood was as follows: Carnallite, $\text{KMgCl}_3 \cdot 6\text{H}_2\text{O}$, 1,700,000 tons; karnite, $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, 1,200,000 tons; sylvine, KCl , 150,000 tons; or altogether about 3,000,000 tons of natural potassium salts a year. The greater part of this production is consumed by the agriculturist as manure, especially for beetroot. Van't Hoff studied all the conditions of the formation of all the Stassfurt salts from sea water.

³ The method of separating sodium chloride from potassium chloride has been described in Chapter I. On evaporation of a mixture of the saturated solutions, sodium chloride separates; then, on cooling, potassium chloride separates, owing to the difference of the rate of variation of their solubilities with the temperature. The following are the most trustworthy figures for the solubility of **potassium chloride** in one hundred parts of water (for sodium chloride, see Chap. X., note 13):—

10°	20°	40°	60°	100°
32	35	40	46	57

When mixed with solutions of other salts the solubility of potassium chloride naturally varies, but not to any great extent.

^{3a} The specific gravity of the solid salt is 1.99—that is, less than that of sodium chloride—so that it floats on the surface of liquids of sp. gr. 2.05 (which may easily be obtained from mixtures of the halogen derivatives of the hydrocarbons), while NaCl sinks to the bottom. All the salts of sodium are specifically heavier than the corresponding salts of potassium, as are also their solutions having equal percentage compositions. If the specific gravity of water at 4° is taken as 10,000, then at 15° the specific gravity of a solution of p per cent. of potassium chloride is given by $9,992 + 63.29p + 0.226p^2$, and is therefore, for 10 per cent., 1.0647, and for 20 per cent., 1.1348, &c.

Potassium chloride combines with iodine trichloride to form a compound $\text{KCl} + \text{ICl}_3 = \text{KICl}_4$, which has a yellow colour, is fusible, loses iodine trichloride at a red heat, and gives potassium iodate and hydrochloric acid with water. It is not only formed by direct combination, but also by many other methods; for instance, by passing chlorine into a solution of potassium iodide so long as the gas is absorbed, $\text{KI} + 2\text{Cl}_2 = \text{KCl} + \text{ICl}_3$. Potassium iodide, when treated with potassium chlorate and strong hydrochloric acid, also gives this compound; another method for its formation is given by the equation: $\text{KClO}_3 + \text{I} + 6\text{HCl} = \text{KCl} + \text{ICl}_3 + 3\text{Cl} + 3\text{H}_2\text{O}$. This salt corresponds with KIO_2 (unknown) in which the oxygen is replaced by chlorine. If valency be taken as the starting-point in the study of chemical compounds, and the elements considered as having a constant atomicity (number of bonds)—that is, if K, Cl, and I be taken as univalent elements—then it is impossible to explain the formation of such a compound because, according to this view, univalent elements are only able to form with each other dual compounds, such as KCl , ClI , KI , &c., whilst here they are grouped together in the molecule KICl_4 . Wells, Wheeler, and Penfield (1892), and subsequently others, obtained a large number

double saline decomposition, the chloride of potassium may be converted into all the other potassium salts,⁴ some of which are of practical use. The potassium salts have, however, their greatest importance as an indispensable component of the food of plants.⁵

The primary rocks contain an almost equal proportion of potassium and sodium. But in sea water the compounds of the latter metal predominate. It may be asked, What became of the compounds of potassium in the disintegration of the primary rocks if so small a quantity went to the sea water? They remained with the other solid products of the decomposition of the primary rocks. When granite or any other similar rock formation is disintegrated, it yields, besides the soluble substances, mainly (insoluble) sand and finely divided clay, containing water, alumina, and silica. This clay is carried away by the water, and is then deposited in strata. It retains, and especially when mixed with vegetable remains, compounds of potassium in greater quantity than

of such poly-haloid salts. They may all be divided into two large classes, the tri-haloid and the penta-haloid salts. They have been obtained not only for K but also for Rb and Cs, and to some extent also for Na and Li. The general method of their formation consists in dissolving the ordinary halogen salt of the metal in water, and treating it with the requisite amount of free halogen. The poly-haloid salt separates out after evaporating the solution at a more or less low temperature. In this manner, among the tri-haloid salts, may be obtained: KI_3 , KBr_2I , KCl_2I , and the corresponding salts of rubidium and caesium; for instance, CsI_3 , CsBrI_2 , CsBr_2I , CsClBrI , CsCl_2I , CsBr_3 , CsClBr_2 , CsCl_2Br , and in general MX_3 , where X is a halogen. The colour of the crystals varies according to the halogen; thus CsI_3 is black, CrBr_3 yellowish red, CsBrI_2 reddish brown, CsBr_2I red, and CsCl_2Br yellow. The caesium salts are the most stable, and those of potassium the least so. The penta-haloid salts form a smaller class; of such salts potassium forms KCl_4I , rubidium RbCl_4I , caesium CsI_5 , CsBr , CsCl_4I , lithium LiCl_4I (with $4\text{H}_2\text{O}$), and sodium NaCl_4I (with $2\text{H}_2\text{O}$). The most stable are those salts containing the metal with the greatest atomic weight—caesium (see Chap. XI., note 63).

⁴ It is possible to extract the compounds of potassium directly from the primary rocks which are so widely distributed over the earth's surface and are so abundant in certain localities. From a chemical point of view this problem presents no difficulty; for instance, by fusing powdered orthoclase with lime and fluor spar (Ward's method) and then extracting the alkali with water (on fusion the silica gives an insoluble compound with lime), or by treating the orthoclase with hydrofluoric acid (in which case silicon fluoride is evolved as a gas), it is possible to transfer the alkali of the orthoclase to an aqueous solution, and to separate it in this manner from the insoluble oxides. However, as yet there is no profit in, nor necessity for, recourse to this treatment, as carnallite and potash form abundant materials for the extraction of potassium compounds by cheaper methods. Furthermore, the salts of potassium are now, in the majority of chemical reactions, replaced by salts of sodium. The replacement of potassium compounds by sodium compounds not only has the advantage that the salts of sodium are in general the cheaper, but also that, for a given reaction, a smaller quantity of a sodium salt is needed, because the combining weight of sodium (23) is less than that of potassium (39).

⁵ It has been shown, by direct experiment on the cultivation of plants in artificial soils and in solutions, that under conditions (physical, chemical, and physiological) otherwise identical, plants are able to thrive and become fully developed in the entire absence of sodium salts, but that their development is impossible without potassium salts.

those of sodium. This has been proved with absolute certainty to be the case, and is due to the **absorptive power of the soil**. If a dilute solution of a potassium compound be filtered through common mould used for growing plants, containing clay and the remains of vegetable decomposition, the mould will be found to have retained a somewhat considerable percentage of the potassium compounds. If a salt of potassium be taken, then, during the filtration, an equivalent quantity of a calcium salt—also found, as a rule, in soils—is set free. Such a process of filtration through the soil proceeds in nature, and the compounds of potassium are everywhere retained by the friable earth in considerable quantity. This explains the presence of so small an amount of potassium salts in the water of rivers, lakes, streams, and oceans, where the lime, soda, and magnesia have accumulated. The compounds of potassium retained by the friable mass of the earth are absorbed as an aqueous solution by the roots of **plants**. As everyone knows, plants when burnt leave an ash, and this ash, besides various other substances, always contains compounds of potassium. Many land plants contain a very small amount of sodium compounds,⁶ whilst potassium and its compounds occur in all kinds of vegetable ash. Among the generally cultivated plants, grass, potatoes, the turnip, and buckwheat are particularly rich in potassium compounds. The ash of plants, and especially of herbaceous plants, buckwheat straw, sunflower and potato leaves are used in practice for the extraction of potassium compounds. There is no doubt that potassium occurs in the plants themselves in the form of complex compounds, and often as salts of organic acids. In certain cases such salts of potassium are even extracted from the juice of plants. Thus, sorrel and oxalis, for example, contain in their juices the acid oxalate of potassium, C_2HKO_4 , which is employed for removing ink-stains. Grape juice contains the so-called cream of tartar, which is the acid tartrate of potassium, $C_4H_5KO_6$.⁷

⁶ If herbaceous plants contain much sodium salts, it is evident that these salts mainly come from the sodium compounds in the water absorbed by the plants.

⁷ As plants always contain mineral substances and cannot thrive in a medium which does not contain them, more especially in one which is free from the salts of the four basic oxides, K_2O , CaO , MgO , and Fe_2O_3 , and of the four acid oxides, CO_2 , N_2O_5 , P_2O_5 , and SO_3 , and as the amount of ash-forming substances in plants is small, the question inevitably arises as to what part these play in the development of plants. With the existing chemical data only one answer is possible to this question, and it is still only an hypothesis. This answer was particularly clearly expressed by Professor Gustavson, of the Petroffsky Agricultural Academy. Starting from the fact (Chap. XI., note 55) that a small quantity of aluminium renders possible or facilitates the reaction of bromine on hydrocarbons at the ordinary temperature, it is easy to arrive at the conclusion, which is very probable and in accordance with many data respecting the reactions of organic compounds, that the addition of mineral substances to organic compounds lowers the temperature of reaction, and in general facilitates chemical reactions in plants, thus

This salt also separates as a sediment from wine. When the plants, containing one or more of the salts of potassium, are burnt, the carbonaceous matter is oxidised, and in consequence the potassium is obtained in the ash as carbonate, K_2CO_3 , which is generally known as **potashes**. Hence potashes occur ready prepared in the ash of plants (like soda in the ash of seaweeds), and therefore the ash of land plants is employed as a source for the extraction of potassium compounds. Potassium carbonate is extracted by lixiviating the ash with water.⁸ Potassium carbonate may also be obtained from

aiding the conversion of the most simple nourishing substances into the complex component parts of the plant organism. The province of chemical reactions proceeding in organic substances in the presence of a small quantity of mineral substances has as yet been but little investigated, although there are already several disconnected data concerning reactions of this kind, and although a great deal is known with regard to such reactions among inorganic compounds. The essence of the matter may be expressed thus—two substances, A and B, do not react on each other of their own accord, but the addition of a small quantity of a third particularly active substance, C, produces the reaction of A on B, because A combines with C, forming AC, and B reacts on this new compound, which has a different store of chemical energy, forming the compound AB or its products, and either setting C free again or retaining it.

It may here be remarked that all the mineral substances necessary for plants (those enumerated at the beginning of the note) are the highest saline compounds of their elements, that they enter into the plants as salts, that the lower forms of oxidation of the same elements (for instance, sulphites and phosphites) are harmful to plants (poisonous), and that strong solutions of the salts assimilated by plants not only do not enter into the plants but kill them (poison them).

Besides which, it will be understood from the preceding paragraph that the salts of potassium may become exhausted from the soil by long cultivation, and that there may therefore be cases when direct fertilisation by salts of potassium may be profitable. But manure and animal excrements, ashes, and, in general, nearly all refuse which may serve for fertilising the soil, contain a considerable quantity of potassium salts, and therefore, as regards natural salts of potassium (Stassfurt), and especially potassium sulphate, if they often improve the crops, it is in all probability due to their action on the properties of the soil. The agriculturist cannot therefore be advised to add potassium salts, without making special experiments showing the advantage of such a fertiliser on a given kind of soil and plant.

⁸ The animal body also contains potassium compounds, as would be expected, seeing that animals consume plants. For example, milk, and especially human milk, contains a considerable quantity of potassium compounds. Cow's milk, however, does not contain much potassium salt. Sodium compounds generally predominate in the bodies of animals. The excrements of animals, and especially of herbivorous animals, on the contrary, often contain a large proportion of potassium salts. Thus sheep's dung is rich in them, and in washing sheep's wool salts of potassium pass into the water.

The ash of tree stems, as the already dormant portion of the plant (Chap. VIII., note 1), contains little potash. For the extraction of potash, which was formerly carried on extensively in the east of Russia (before the discovery of the Stassfurt salt), the ash of grasses, and the green portions of potatoes, buckwheat, &c., are taken and treated with water (lixivated), the solution evaporated, and the residue ignited in order to destroy the organic matter present in the extract. The residue thus obtained is composed of raw potash. It is refined by a second dissolution in a small quantity of water. The solution thus obtained is again evaporated, and the residue ignited, and this potash is then called refined potash, or pearlash. This method of treatment cannot give

the chloride by a method similar to that by which sodium carbonate is prepared from sodium chloride. There is no difficulty in obtaining any salt of potassium—for example, the sulphate,⁹ bromide, and

chemically pure potassium carbonate. To obtain chemically **pure potassium carbonate**, some other salt of potassium is generally taken and purified by crystallisation. Potassium carbonate crystallises with difficulty, and it cannot therefore be purified by this means, whilst other salts, such as the tartrate, acid carbonate, sulphate, nitrate, &c., crystallise easily, and may thus be directly purified. The tartrate is most frequently employed, since it is prepared in large quantities (as a sediment from wine) for medicinal use under the name of cream of tartar. When ignited without access of air, it leaves a mixture of charcoal and potassium carbonate. The charcoal so obtained being in a finely divided condition, the mixture (called 'black flux') is sometimes used for reducing metals from their oxides with the aid of heat. A certain quantity of nitre is added to burn the charcoal formed by heating the cream of tartar. Potassium carbonate thus prepared is further purified by converting it into the acid salt, by passing a current of carbonic anhydride through a strong solution. KHCO_3 is then formed, which is less soluble than the normal salt (as is also the case with the corresponding sodium salt), and therefore crystals of the acid salt separate out on cooling. When ignited, they part with their water and carbonic anhydride, and pure potassium carbonate remains behind. The physical properties of potassium carbonate are sufficient to distinguish it clearly from sodium carbonate; it is obtained from solution as a powdery white mass, having an alkaline taste and reaction, and, as a rule, shows only traces of crystallisation. It also attracts the moisture of the air with great energy. The crystals do not contain water, but absorb it from the air, deliquescent into a saturated solution. It melts at a red heat (1045°), and at a still higher temperature is even converted into vapour, as has been observed at glass works where it is employed. It is very soluble, and at the ordinary temperature, water dissolves an equal weight of the salt. Crystals containing two equivalents of water separate from such a saturated solution when strongly cooled (Morel obtained $\text{K}_2\text{CO}_3 \cdot 3\text{H}_2\text{O}$ in well-formed crystals at $+10^\circ$). Its reactions are all analogous to those of sodium carbonate. When manufactured sodium carbonate was but little known, the consumption of potassium carbonate was very considerable, and even now washing soda is frequently replaced for household purposes by **ley**—i.e., an aqueous solution obtained from ashes—which acts like soda.

A mixture of potassium and sodium carbonates fuses with much greater ease than the separate salts, and a mixture of their solutions gives well-crystallised salts—for instance (Marguerite's salt), $\text{K}_2\text{CO}_3 \cdot 6\text{H}_2\text{O} \cdot 2\text{Na}_2\text{CO}_3 \cdot 6\text{H}_2\text{O}$. Crystallisation also occurs with other relative proportions of K and Na (in the above case 1 : 2, but 1 : 1 and 1 : 3 are known), and always with 6 mol. H_2O . This is evidently a combination *by similarity*, as in alloys, solutions, &c.

⁹ **Potassium sulphate**, K_2SO_4 , crystallises from its solutions in an anhydrous condition, in which respect it differs from the corresponding sodium salt, just as potassium carbonate differs from sodium carbonate. In general, it must be observed that the majority of sodium salts combine more easily with water of crystallisation than those of potassium. The solubility of potassium sulphate does not show the same peculiarities as that of sodium sulphate, because it does not combine with water of crystallisation; at the ordinary temperature 100 parts of water dissolve about 10 parts of the salt, at 0° 8.3 parts, and at 100° about 26 parts. The **acid sulphate**, KHSO_4 , readily obtainable by heating crystals of the normal salt with sulphuric acid, is frequently employed in chemical practice. On heating the mixture of acid and salt, fumes of sulphuric acid are at first given off; when they cease to be evolved, the acid salt is contained in the residue. At a higher temperature (above 600°) the acid salt parts with the acid contained in it, the normal salt being re-formed. The definite composition of this acid salt and the ease with which it decomposes render it exceedingly valuable for certain chemical transformations accomplished by means of sulphuric acid at a high temperature, because it is possible

iodide¹⁰—by the action of the corresponding acid on KCl and especially on the carbonate, whilst the hydroxide, **caustic potash**, KHO, which is in many respects analogous to caustic soda, is easily obtained by means of lime¹¹ or by the action of an electric current on a solution of KCl (about 2 kilo-watt hours are consumed per 1 kilo of KHO). Therefore, in order to complete our knowledge of the alkali metals, we will only

to take, in the form of this salt, a definite quantity of sulphuric acid, and to cause it to act on a given substance at a high temperature. In this case, the acid salt acts in the same manner as sulphuric acid itself. The acid potassium sulphate is employed, where for conversion of certain oxides, such as those of iron, aluminium, and chromium, into salts, a high temperature is required.

¹⁰ The **bromide** and **iodide of potassium** are used, like the corresponding sodium compounds, in medicine and photography. Potassium iodide is obtained by saturating a solution of hydriodic acid with caustic potash. In practice, however, it is prepared by the direct formation of hydriodic acid in solution in the presence of potassium hydroxide or carbonate. Thus iodine is thrown into a solution of pure potash, and hydrogen sulphide passed through the mixture, the iodine being thus converted into hydriodic acid. Or a solution is prepared from phosphorus, iodine, and water, containing hydriodic and phosphoric acids; lime is then added to this solution, when calcium iodide is obtained in solution, and calcium phosphate as a precipitate. The solution of calcium iodide gives, with potassium carbonate, insoluble calcium carbonate and a solution of potassium iodide. If iodine is added to a slightly heated solution of caustic potash (free from carbonate—that is, freshly prepared), so long as the solution is not coloured from the presence of an excess of iodine, there is formed a mixture of potassium iodide and iodate. On evaporating the solution thus obtained and igniting the residue, the iodate is destroyed and converted into potassium iodide. On dissolving the residue in water and then evaporating, cubical crystals (like NaCl) of the anhydrous salt are obtained, which are soluble in water and alcohol, and on fusion give an alkaline reaction, owing to the fact that when ignited a portion of the salt decomposes, forming potassium oxide. The neutral salt may be obtained by adding hydriodic acid to this alkaline salt until it gives an acid reaction. It is best to add some finely divided charcoal to the mixture of iodate and iodide before igniting it, as this facilitates the evolution of the oxygen from the iodate. Potassium iodide may also be prepared by mixing a solution of ferrous iodide (it is best if the solution contains an excess of iodine) and potassium carbonate, in which case ferrous carbonate, FeCO_3 , is precipitated (with an excess of iodine the precipitate is granular, and contains a compound of the suboxide and oxide of iron), whilst potassium iodide remains in solution. Ferrous iodide, FeI_2 , is obtained by the direct action of iodine on iron in water. Potassium iodide considerably lowers the temperature (by 24°), when it dissolves in water; 100 parts of the salt dissolve in 73.5 parts of water at 12.5° or in 70 parts at 18° , whilst the saturated solution, which boils at 120° , contains 100 parts of salt per 45 parts of water. Solutions of potassium iodide dissolve a considerable amount of iodine, strong solutions dissolving even as much or more iodine than they contain as potassium iodide (see note 3a, and Chap. XI., note 64).

¹¹ Caustic potash is also formed by igniting potassium nitrate with finely divided copper (see note 15), and also by mixing solutions of potassium sulphate (or even of alum, KAlS_2O_8) and barium hydroxide, BaH_2O_2 . It is sometimes purified by dissolving it in alcohol (the impurities, for example, potassium sulphate and carbonate, are not dissolved) and then evaporating the alcohol.

The specific gravity of potassium hydroxide is 2.04, but that of its solutions (see Chap. XII., note 18) at 15° is expressed by $S = 9.992 + 90.4p + 0.28p^2$. Strong solutions, when cooled, yield a crystallo-hydrate, $\text{KHO} \cdot 4\text{H}_2\text{O}$, which dissolves in water, producing cold (like $2\text{NaHO} \cdot 7\text{H}_2\text{O}$), whilst potassium hydroxide in solution develops a considerable amount of heat.

describe two salts of potassium which are of practical importance, and whose analogues have not been described in the preceding chapter, namely, potassium cyanide and potassium nitrate.

Potassium cyanide, which presents in its chemical and physical^{11a} relations a certain analogy with the halogen salts of potassium, is not only formed according to the equation, $\text{KHO} + \text{HCN} = \text{H}_2\text{O} + \text{KCN}$, but also whenever a nitrogenous carbon compound—for instance, animal matter—is heated in the presence of metallic potassium, or of a compound of potassium, and even when a mixture of potash and carbon is heated in a stream of nitrogen. Potassium cyanide is obtained from yellow prussiate of potash, which has been already mentioned in Chapter IX., and the preparation of which on a large scale will be described in Chapter XXII. If the yellow prussiate is ground to a powder and dried, so that it loses its water of crystallisation, it then melts at a red heat, decomposing into carbide of iron, nitrogen, and potassium cyanide, $\text{FeK}_4\text{C}_6\text{N}_6 = 4\text{KCN} + \text{FeC}_2 + \text{N}_2$. After the decomposition it is found that the yellow salt has been converted into a white mass of potassium cyanide. The carbide of iron formed collects at the bottom of the vessel. If the mass thus obtained is treated with water, the potassium cyanide is partially decomposed by the water, but if it is treated with alcohol, the cyanide is dissolved, and on cooling separates in a crystalline form.¹² If the yellow prussiate is heated with potassium, it deposits all its iron and is converted into potassium

^{11a} Thus, for instance, KCN crystallises in cubes like KCl.

¹² When the yellow prussiate is heated to redness, all the cyanogen which was in combination with the iron is decomposed into nitrogen, which is evolved as gas, and carbon, which combines with the iron. In order to avoid this, potassium carbonate is added to the yellow prussiate while it is being fused. A mixture of 8 parts of anhydrous yellow prussiate and 3 parts of pure potassium carbonate is generally taken. Double decomposition then takes place, resulting in the formation of ferrous carbonate and potassium cyanide. But by this method a pure salt is not obtained, because a portion of it is oxidised and forms potassium cyanate, KCNO. By adding one part of charcoal powder to the mixture of 8 parts of anhydrous yellow prussiate and 3 parts of potassium carbonate, a mass is obtained which is free from cyanate, but in that case it is impossible to obtain a colourless salt by simple fusion, although this may easily be done by dissolving it in alcohol. Cyanide of potassium may also be obtained from potassium thiocyanate, which is formed from ammonium thiocyanate obtained by the action of ammonia upon bisulphide of carbon (see works upon organic chemistry). Potassium and sodium cyanides are now prepared in large quantities from yellow prussiate for the extraction of gold (Chap. XXIV.) and for gilding and silver-plating. KCN and NaCN are prepared by heating powdered and dried yellow prussiate with metallic sodium: $\text{K}_4\text{Fe}(\text{CN})_6 + 2\text{Na} = 4\text{KCN} + 2\text{NaCN} + \text{Fe}$. This method (Rossler and Gesslaker) offers two advantages over the above methods: (1) the whole of the cyanide is obtained in a combined state and does not decompose with the formation of N_2 and C_2 , and (2) no cyanates are formed, as is the case when carbonate of potash is heated with the prussiate. Pure KCN is obtained by passing CNH into an alcoholic solution of KHO.

cyanide, $\text{K}_4\text{Fe}(\text{CN})_6 + 2\text{K} = 6\text{KCN} + \text{Fe}$. A solution of potassium cyanide has a powerfully alkaline reaction, a smell like that of bitter almonds, peculiar to prussic acid, and acts as a most powerful poison. Although exceedingly stable in a fused state, potassium cyanide easily changes when in solution. Prussic acid is so very feebly energetic that water gives a certain amount of KHO with potassium cyanide. A solution of the salt, even at a low temperature, quickly turns brown and decomposes, and when heated evolves ammonia and forms potassium formate; this is easily comprehensible from the representation of the cyanogen compounds which was developed in Chapter IX., $\text{KCN} + 2\text{H}_2\text{O} = \text{CHKO}_2 + \text{NH}_3$. Furthermore, as carbonic anhydride acts on potassium cyanide with evolution of prussic acid, and as potassium cyanate, which is also unstable, is formed by the action of air, it will easily be seen that solutions of potassium cyanide are very unstable. Potassium cyanide, containing as it does carbon and potassium, is a substance which can exert a very vigorous reducing action, especially when fused; it is therefore used as a powerful reducing agent at a red heat.¹³ The property of potassium cyanide of giving double salts with other cyanides is very clearly shown by the fact that many metals dissolve in a solution of potassium cyanide, with the evolution of hydrogen. For example, iron, copper, and zinc act in this manner. Thus—

Gold and silver are soluble in potassium cyanide in the presence of air, in which case the hydrogen, which would otherwise be evolved in the reaction, combines with the oxygen of the air, forming water (Eissler, MacLaurin, 1893), for example, $4\text{Au} + 4\text{KCN} + \text{O} + \text{H}_2\text{O} = 2\text{AuKC}_2\text{N}_2 + 2\text{KHO}$, which is taken advantage of for extracting gold from its ores (Chap. XXIV.).^{13a} Platinum, mercury, and tin are not dissolved in a solution of potassium cyanide, even with access of air. The sodium salt acts in the same manner.

Potassium nitrate, or common nitre or saltpetre, KNO_3 , is chiefly used as a component part of ordinary black gunpowder, in which it cannot be replaced by the sodium salt, because the latter is deliquescent.

¹³ A considerable quantity of potassium cyanide is used in the arts, more particularly for the preparation of metallic solutions employed in electro-silvering and gilding. An alkaline solution is prepared, which is moderately stable owing to the fact that in the form of certain double salts—that is, combined with other cyanides—potassium cyanide is far more stable than when alone.

^{13a} A dilute solution of KCN is taken, containing not more than 1 per cent. of KCN. MacLaurin states that such solutions dissolve more air (than strong ones), the oxygen of which is necessary for the reaction (see Chap. XXIV., note 30).

The nitre in gunpowder should therefore be perfectly pure, as even small traces of sodium, magnesium, and calcium salts, especially chlorides, render the nitre and the gunpowder capable of attracting moisture. Nitre may easily be obtained pure, owing to its great disposition to form crystals, which aids its separation from other salts. The considerable differences between the solubilities of nitre at different temperatures help this crystallisation. A solution of nitre saturated at its boiling-point (116°) contains 335 parts of nitre to 100 parts of water, whilst at the ordinary temperature—for instance, 20° —the solution is only able to retain 32 parts of the salt. Therefore, in the preparation and refining of nitre, its solution, saturated at the boiling-point, is cooled, and nearly all the nitre is obtained in the form of crystals. If the solution is quietly and slowly cooled in large quantities, large crystals are formed; but if it is rapidly cooled, so as to prevent the formation of large crystals (in the crevices of which the mother liquor, together with the impurities, would remain), the very minute crystals of nitre known as saltpetre flour are obtained, and this is the usual method adopted for crystallising nitre.

Common nitre occurs in nature, but only in small quantities in admixture with other nitrates, especially those of sodium, magnesium, and calcium. Such a mixture of salts of nitric acid is formed in those localities, where, as in **the soil**, nitrogenous organic remains are decomposed in the presence of alkalies or alkaline bases with free access of air. This method of the formation of nitrates requires moisture, besides the free access of air, and takes place principally during warm weather.¹⁴ In warm countries, and in temperate climates during the summer months, fertile soils produce a small quantity of nitre. In this respect India is especially known as affording a considerable supply of nitre extracted from the soil. The nitre-bearing soil after the rainy season sometimes becomes covered during the summer with crystals of nitre, formed by the evaporation of the water in which it was previously dissolved. This soil is collected, subjected to repeated lixiviations, and treated for nitre in the way to be presently described. In temperate climates nitrates are obtained from the **lime rubbish** of demolished buildings which have stood for many years, and especially from those portions which have been in contact with the ground.

¹⁴ Besides which, Schloëssing and Müntz, by employing similar methods to Pasteur, showed that the formation of nitre in the decomposition of nitrogenous substances is accomplished by the aid of peculiar micro-organisms (ferments), without which the simultaneous action of the other necessary conditions (alkalies, moisture, a temperature of 37° , air, and nitrogenous substances) cannot give nitre. The addition of colonies of these organisms facilitates the rapid formation of nitre. The organisms occur in the atmosphere.

The conditions there are very favourable for the formation of nitre, because the lime used as a cement in buildings contains the base necessary for the formation of nitrates, while excrements, urine, and animal refuse are sources of nitrogen. By the methodical lixiviation of this kind of rubbish a solution of nitrogenous salts is formed similar to that obtained by the lixiviation of fertile soil. A similar solution is also obtained by the lixiviation of the so-called **nitre plantations**. These are composed of manure interlaid with brushwood, and strewn over with ashes, lime, and other alkaline rubbish. These nitre plantations are set up in localities where the manure is not required for the fertilisation of the soil, as, for example, in the south-eastern 'black earth' governments of Russia. The same process of oxidation of nitrogenous matter freely exposed, during the warm season, to air and moisture in the presence of alkalies takes place in nitre plantations as occurs in fertile soil and in the walls of buildings. From all these sources there is obtained a solution containing various salts of nitric acid mixed with soluble organic matter. The simplest method of treating this impure solution of nitre is to add a solution of potassium carbonate, or to simply treat it with ashes containing this substance. The potassium carbonate enters into double decomposition with the calcium and magnesium salts, forming insoluble carbonates of these bases and leaving the nitre in solution. Thus, for instance, $K_2CO_3 + Ca(NO_3)_2 = 2KNO_3 + CaCO_3$. Both calcium and magnesium carbonates are insoluble, and therefore after treatment with potassium carbonate the solution contains only the salts of sodium and potassium together with organic matter. The latter partially separates in an insoluble form on heating, and is entirely destroyed by heating the nitre to a low red heat. The nitre thus obtained is easily purified by repeated crystallisation. The greater part of the nitre used for making ordinary gunpowder is now obtained from the sodium salt, **Chili saltpetre** or **cubic nitre**, which occurs in nature, as already mentioned. The conversion of this salt into common nitre is also carried on by adding potassium carbonate (when, on mixing the strong and hot solutions, sodium carbonate is directly obtained as a precipitate), or, as is now most frequent, potassium chloride. When a mixture of strong solutions of potassium chloride and sodium nitrate is evaporated, sodium chloride first separates, because this salt, which is formed by the double decomposition, $KCl + NaNO_3 = KNO_3 + NaCl$, is almost equally soluble in hot and cold water; on cooling, therefore, a large amount of potassium nitrate separates from the saturated solution, while the sodium chloride remains dissolved. The nitre is ultimately purified by recrystallisation and by washing with a saturated solution

of nitre, which cannot dissolve a further quantity of nitre, but only the impurities.

Nitre is a colourless salt having a peculiar cool taste. It crystallises easily in long striated six-sided rhombic prisms terminating in rhombic pyramids. Its crystals (sp. gr. 1.93) do not contain water. At a low red heat (339°) nitre melts to a colourless liquid.^{14a} Potassium nitrate at the ordinary temperature and in a solid form is inactive and stable, but **at a high temperature** it acts as a powerful **oxidising agent**, giving up a considerable amount of oxygen to substances mixed with it.¹⁵ When thrown on to incandescent charcoal it brings about its rapid combustion, and a mechanical mixture of powdered charcoal and nitre ignites when brought into contact with a red-hot substance, and continues to burn by itself. In this action, nitrogen is evolved, and the oxygen oxidises the charcoal, in consequence of which potassium carbonate and carbonic anhydride are formed: $4\text{KNO}_3 + 5\text{C} = 2\text{K}_2\text{CO}_3 + 3\text{CO}_2 + 2\text{N}_2$. This phenomenon depends on the fact that oxygen in combining with carbon evolves more heat than it does in combining with nitrogen. Hence, when once the combustion has been started at the expense of the nitre, it is able to go on without the aid of external heat. A similar oxidation or combustion at the expense of the contained oxygen takes place when nitre is heated with different combustible substances. For

^{14a} Before fusing, the crystals of potassium nitrate change their form, and take the same form as sodium nitrate—that is, they change into rhombohedra. Nitre crystallises from hot solutions, and in general under the influence of a rise of temperature, in a different form from that given at the ordinary or lower temperatures. Fused nitre solidifies to a radiated crystalline mass; but it does not exhibit this structure if metallic chlorides are present, so that this method may be taken advantage of to determine the degree of purity of nitre.

Carnelley and Thomson (1888) determined the fusing-point of mixtures of potassium and sodium nitrates. The first salt fuses at 339° and the second at 316° , and if p is the percentage amount of potassium nitrate, the results obtained are—

$p = 10$	20	30	40	50	60	70	80	90
298°	283°	268°	242°	231°	231°	242°	284°	306°
